Mental health professionals can help to protect the next generation and prepare them for the future. Clinicians need to be aware of how the climate crisis can cause emotional distress, and recognise and respond to the psychological consequences of exposure to the effects of climate change, especially in the Global South, where psychological help is scant.⁸ Supporting young people in speaking out and taking action, whether to protect their communities from the effects of climate change or to demand action by politicians and others, may be the most beneficial approach that mental health professionals can take. Such action builds beliefs in self-efficacy and collective efficacy, practical active citizenship skills, courage and hope,^{9,13} which is reinforced when young people can see that mental health professionals are also taking action. This editorial seeks to help give voice to youth and provide an example of intergenerational partnership.

However, without speedy action at a global scale to prevent catastrophic climate change, it will not be possible to protect young people's psychological well-being, or even their survival. Today's adults may be the last generation that can ensure a liveable world for future generations. They need to act as citizens to demand effective and speedy climate action, and not rely on young people to carry this burden alone. For mental health professionals who have responsibility for protecting human health and well-being, there is a particular moral imperative to use their status and expertise, individually and collectively, to speak out on behalf of the children and youth of today and tomorrow.

Ethics and consent

No ethical approval was required for this editorial. Young people provided quotes voluntarily and explicitly agreed to them being used. This paper includes quotes volunteered by young people aged 17–24 years, who were known to the second author through their joint engagement in the school strike movement. They were invited to provide responses to a series of questions for the purposes of this editorial, and gave their written consent to them being used herein.

Ann Sanson (PhD) is an Honorary Professorial Fellow at the Department of Paediatrics, University of Melbourne, Australia. **Marco Bellemo** is an organiser with School Strike For Climate in Australia.

Data availability

The quotes used in this editorial were provided specifically for this purpose. Access to them would require further consent from the participants. The corresponding author (A.S.) can be contacted for further information.

Both authors made substantial contributions to this editorial, jointly planning and co-writing it.

Declaration of interest

None.

1.2.64 Crisis care: tackling the climate and ecological emergency

Cate Bailey Norman A. Poole Adrian James

Correspondence

Cate Bailey (cate.bailey@nhs.net)

date

2021-08

Abstract

The climate crisis is a health crisis; it demands the urgent attention and action of healthcare professionals and organisations. In this issue of the *BJPsych Bulletin*, we consider what the destructive effects of the climate and ecological crisis entail for the mental health of populations, and what the response of psychiatrists, both individual and collective, must be. We also highlight the opportunities and benefits a more sustainable and preventative approach could offer individuals, communities and the planet.

pmc “‘We are perilously close to the collapse of civilization, we are all in danger, and only a mobilization of our entire economy and society can protect us’ – Margaret Klein Salamon, activist, psychologist and author.¹ ‘Undoubtedly climate change poses the most profound long-term threat to the health of the nation’ – Simon Stevens, Chief Executive, National Health Service in England.²”

Without question, human activity throughout the past century and more has led to the destruction of ecosystems on which we depend, and contributed to unprecedented levels of greenhouse gases in our environment. The results of these activities are a disrupted ecology: extreme weather, severe storms, floods, droughts and heatwaves at a frequency and intensity never before seen during the span of human existence. Changing patterns of land use, rising sea levels, destruction of habitats, biodiversity loss, deforestation, soil degradation, plastic waste and air pollution combine with climate change to create food shortages, forced migration, social upheaval and conflict, and increased vulnerability to infectious disease.³ The World Health Organization estimates that in the next 20 years, climate change alone will lead globally to 250 000 additional deaths per year.³

In this issue of the *BJPsych Bulletin*, we consider what the destructive effects of the climate and ecological crisis entail for the mental health of populations, and what the response of psychiatrists, both individual and collective, must be. We also highlight the opportunities and benefits that a more sustainable and preventative approach could offer individuals, communities and the planet.

The climate crisis is a health crisis

The climate crisis is a health crisis; it demands the urgent attention and action of healthcare professionals and organisations. We at the *BJPsych Bulletin* share this view with the authors of the *Lancet* Countdown on Health and Climate Change,⁴ editors of the *BMJ*^{5,6} and members of the UK Health Alliance on Climate Change (including the Royal Colleges of Nursing, Physicians, General Practitioners, Emergency Medicine and Surgeons; Faculty of Public Health; Royal Society of Medicine and Royal College of Psychiatrists (RCPsych)).⁷

While the RCPsych first appointed an Associate Registrar for Sustainability in 2015, supported by an active committee, it has recently prioritised its focus in this area. In a new position statement, the College declared a climate and ecological emergency that is impacting on the mental health of populations, including the amplification of existing inequalities.⁸ The position statement⁸ describes the intimate connections between health and the natural world; our species is one part of a complex inter-dependent ecosystem. Depression, anxiety and post-traumatic stress disorder are associated with floods.⁹ Suicide is linked to drought and hotter temperatures.¹⁰ People with severe mental illnesses are three times more likely to die in a heatwave.¹¹ Psychiatric medications such as antidepressants and antipsychotics affect heat-regulating functions.¹² Dehydration and sweating can contribute to lithium toxicity, which places those taking these treatments at increased risk during heatwaves.¹² Food insecurity affects childhood development.¹³ Air pollution is associated with anxiety and depression,¹⁴ and neurodevelopmental effects in children,¹⁵ and accounts for 6% of the modifiable risk for dementia.¹⁶ Climate change and ecological breakdown leads to poverty, precarity and social unrest, with associated psychological trauma.^{17,18} Extreme weather events are likely to make it increasingly difficult for us to deliver healthcare to communities. The secondary effects of the crisis include climate grief and anxiety, which are particularly noticeable in children and young people.¹⁹ Their anger, too, is understandable, as they face a future where leaders have delayed action and misinformation continues to permeate mainstream media. A burgeoning field of climate psychology aims to help us understand how we reached this state, face the losses that are already certain and deal with 'present traumas'.²⁰ In the face of such threats, denial of the crisis is a luxury we can no longer afford.

In this special issue, we will learn of the direct effects of extreme weather events and habitat loss, and the resulting social disintegration, on mental health, and the indirect effects of the climate emergency and the sense of insurmountable challenge on our mental well-being. Concepts such as eco-distress, climate grief and solastalgia²¹ (mourning for the degradation of one's home) are explored. We also consider the way forward, and the potential immediate and longer-term health and economic gains in urgent, collective action.

The climate and ecological crisis can trigger a complicated set of psychological reactions, including grief, guilt, fear, anxiety and a fluctuating awareness of our own destructiveness, resulting in varying forms of denial and disavowal.²² These responses have been extensively documented by activists and experts in the field of climate psychology. They can, in part, explain why so little action has been taken at the necessary scale and pace, despite repeated promises.^{20,23} Weintrobe describes how the neoliberal mindset of 'uncare' and narcissistic entitlement perpetuates ways of living that damage ourselves, our relationships to others and to the planet.²⁴ She argues that the more we are able to face the violence beneath our convenient lives, the better we can turn to a more moral path, but courage and kinship is required for facing these realities.²⁴

The consequences of ecological destruction fall first and worst on the most marginalised people, including those who are poor, those with severe mental illness, older people and children. Climate and environmental justice is linked to racial justice globally, as the most significant effects of the crisis are already being felt by indigenous peoples and by those in the Global South, who are disadvantaged by colonialism and exploitation. These populations are also least likely to have contributed to the root causes of the climate crisis.

Healthy solutions

Public health experts have clearly described what must be done to limit the damage. The United Nations Intergovernmental Panel on Climate Change has advised that greenhouse gas emissions need to drop drastically by 2030 to give us any chance of avoiding the most catastrophic effects of global warming.²⁵ The *Lancet* Countdown describes the pathway we are on, leading at its current trajectory to a possible 3°C warming, and the second pathway, which aims to keep warming ‘well below’ 2°C above pre-industrial levels.⁴ The reality of those targets is already being felt in all parts of the world. Facing the catastrophe of the climate emergency means putting in place a number of correctives to the way we live today.

At this point, individual action to manage emissions will not produce the rapid decarbonisation and restoration of our habitat that is needed to prevent further loss of life and livelihood. Although many of us will find solace in personal deeds, which are important, an overemphasis on individual behaviour distracts from the collective action that is necessary to face the challenge. We need governments to go beyond goal-setting and begin to deliver on ambitious targets, to take brave and bold steps. But they are unlikely to move far and fast enough without firm instruction, including from healthcare professionals and leaders.

Action to address the causes of the climate crisis improves the well-being of populations, prevents disease, reduces inequalities and is good for the economy.²⁶ By reducing use and switching to clean forms of renewable energy, and building active travel infrastructure and sustainable food networks, we create a low-carbon society with enormous health benefits.²⁷ Modelling of the potential effect of active travel in England and Wales suggests that increasing walking and cycling could reduce ischaemic heart disease, lung disease, dementia and cancer.²⁸ Preserving and increasing biodiverse, unpolluted green and blue spaces carries significant benefits for patients, families, staff and communities.

Embracing our connectedness to the natural world is not only about prevention, but also the potential for healing. Nature-based interventions show a wide range of benefits, including improved well-being and sense of coherence, and reduction of distress and anger in both clinical and non-clinical populations.²⁹ The RCPsych statement⁸ highlights the importance of services where staff and patients work together in ‘Choosing Wisley’,³⁰ which could reduce waste and replication, and improve sustainability and quality.

The role of doctors

As engaged and informed doctors have long argued, healthcare professionals need to be aware of, and able to articulate and engage in the politics of the climate and ecological crisis. We are trusted professionals, and as such have an opportunity and, furthermore, a duty to act as leaders in our own organisations and communities. We must be able to communicate the urgency of the problem and the immense benefits of action in preventing unnecessary mortality and morbidity. The National Health Service (NHS) is the single largest source of greenhouse gas emissions in the UK public sector, and 60% of the carbon footprint of the NHS relates to medication and medical equipment.²⁶ The Greener NHS report, which sets accelerated targets for a net zero NHS, makes reducing emissions a key responsibility of all NHS staff.²⁶ Drivers include professional and patient transport, energy use and consumption, use of natural resources, shifting to preventative practices and reducing unnecessary prescribing.²⁶

Increasingly, psychiatrists are raising awareness through direct and coordinated action. Whether through activist groups, such as Doctors for Extinction Rebellion and Psych Declares; through the RCPsych Sustainability Committee; internationally, through the Climate Psychiatry Alliance; or locally, through NHS Trust Green Plans, there are ways for everyone to get involved. Health professionals play an important role in drawing attention to the physical, mental, social and psychological effects of the crisis, and the opportunities offered by its solutions. Our ability to influence government decision-making and public perceptions through awareness is likely to be at least as important as action on reducing our own emissions.

The RCPsych’s response to the climate and ecological crisis has been robust and multifaceted. An important step was the February 2020 announcement of divestment from fossil fuels and signing up to the Principles of Responsible Investment supported by the United Nations.³¹ In 2020, a guide and podcast on eco-distress was produced for parents, carers and young people.¹⁹ A key aspect of these resources is the validation that climate anxiety is not in itself pathological, but an appropriate reaction to the peril we face.

Educating future generations of psychiatrists has been an important focus of the RCPsych's work, and 2020 saw the inclusion of sustainability as a core area of the new curriculum and the launch of a Continuing Professional Development module on sustainable healthcare.³²

It is, perhaps, younger psychiatrists who best understand the implications of today's climate and ecological crisis. In giving voice to future leaders, the *BJPsych Bulletin* celebrates the winner of the 2020 Praxis Editorial Award, Dr Daniel Romeu, whose entry eloquently argued the importance of action from psychiatrists. The competition received entries from medical students, foundation doctors, trainees, Specialty and Associate Specialist Doctors (SAS) responding to the question 'Is the climate a mental health crisis?' They responded with an emphatic 'yes'. We were impressed with their creativity, passion and hope for improving individual and planetary health and addressing inequalities. Congratulations also to the highly commended authors Dr Karyn Ayre, Mr James Street, Dr Fergus Brown and Dr Kris Roberts. We are grateful to our panel of judges: Anouchka Grose, Professor Alex Ford and Dr Katherine Kennet.

Conclusions

Psychiatrists are in a position to use their collective voice, medical expertise and understanding of both individual and systemic factors, to advocate for redressing inequalities and lead organisational change. The climate crisis amplifies existing health disparities, and disproportionately affects those already vulnerable owing to poverty or underlying conditions.

This special issue of the *BJPsych Bulletin* contributes to the compelling argument that the climate crisis is a mental health crisis, and that working to redress this should become core business for psychiatrists. Not only must this climate crisis issue induce alarm, but it should also generate hope, resolve and action.

Sally Weintrobe reflected in a recent paper, 'People, young and old, are at the point of beginning to find the collective courage to face the shock required to emerge from our retreat from reality'.²⁴ We trust these papers motivate and inspire you not only to face the reality of this emergency, but to engage creatively with action that improves the health of the populations you serve, and the environment in which you live and work.

We thank the editorial committee who commissioned and handled papers in this special issue: Dr Norman Poole, Dr Cate Bailey, Dr Anouchka Grose, Dr Neil Armstrong, Dr Harriet Stewart and Dr Nitin Gupta.

Dr Cate Bailey is an ST7 General Adult and Old Age Psychiatrist with the East London NHS Foundation Trust, UK; Honorary Clinical Lecturer with Barts and the London School of Medicine, UK; Trainees' Section Editor of the *BJPsych Bulletin*, on behalf of the Royal College of Psychiatrists, UK; and co-Chair of the Older Adults Section of the Association for Psychoanalytic Psychotherapy in the NHS, UK. **Dr Norman A. Poole** is Editor-in-Chief of the *BJPsych Bulletin*, on behalf of the Royal College of Psychiatrists, UK; and a Consultant Neuropsychiatrist at St George's Hospital, South West London and St George's Mental Health NHS Trust, UK. **Dr Adrian James** is President of the Royal College of Psychiatrists, UK.

C.B. devised and wrote first drafts of this article to frame a special issue of the *BJPsych Bulletin* on the Climate Crisis. N.P. and A.J. commented on these drafts and enhanced content on the potential benefits of sustainable practices for the health of communities and the action taken by the RCPsych.

1.2.65 What mental health professionals and organisations should do to address climate change

Adam Monsell Jacob Krzanowski Lisa Page Sharon Cuthbert Guy Harvey

Correspondence

Adam Monsell (Adam.monsell@nhs.net)

date

2021-08

Abstract

Aims and method

The climate change emergency is also a mental healthcare emergency. We seek to provide a framework for what mental health professionals and organisations should do to make their practice more sustainable.

Results

There are ethical, legal and organisational imperatives to make mental healthcare more sustainable. Mental healthcare must be refocused with an emphasis on prevention, building social capital and community resilience. Patients must be empowered to manage their own mental health. Efficiencies should be found within the system. Low-carbon ways to deliver care must be found, measured and improved upon. Greater adaptability needs to be built into the system to mitigate the impact of climate change. Sustainability should be integrated into training programmes, and good examples of practice shared and celebrated.

Clinical implications

Mental health organisations and individuals must act now to prevent and adapt for the climate and ecological emergency. Sustainable practice is also good practice.

- *Summary*
- *Declaration of interest*

Climate change will increase and alter the burden of poor mental health worldwide. Direct effects, such as floods and droughts, have been shown to worsen a variety of mental health disorders. Indirect effects, such as displacement of populations, are likely to compound this trend.¹ There are ethical, legal and organisational imperatives to make mental healthcare more sustainable. The climate emergency is also a health emergency, and clinicians have a duty to act as individuals and as part of organisations.² Sustainability is written into the constitution of the National Health Service (NHS),³ and the Climate Change Act of 2008 legislated for a reduction in NHS carbon emissions of 80% over 30 years.⁴ More recently, the NHS has made the formal commitment to become carbon neutral by 2040.⁵

Mental health services are estimated to emit 1.47 million tonnes of carbon dioxide annually.⁶ We must act now to reshape services, both to meet the ambitious targets set by the NHS, and to avoid runaway consequences.

The COVID-19 pandemic has required us to think differently about how we deliver mental healthcare, and provides an opportunity to enact changes now consistent with sustainable future.⁷

What should people and organisations do?

The Consensus Statement on Sustainability in Mental Health establishes four tenets of practicing mental healthcare sustainably (*Box 1*).⁸ These focus on reducing greenhouse gas emissions and enabling organisational, social and cultural factors that will help patients achieve better mental health in the future. A health service that targets its resources and empowers patients to take ownership of their health will become more efficient, resilient and less carbon-intensive. **Box 1** Tenets of sustainable mental healthcare. Prevent mental illness, build social capital and promote individual, social and community reliance and mental well-being. Empower patients, staff and carers to manage their mental health. Eliminate wasteful activity. Make use of low-carbon alternatives.

Focus on prevention, build social capital

Prevention protects resources, and hence saves carbon. Preventative healthcare is more cost-effective than a reactive approach. This is true in mental healthcare, where preventative programmes have shown to be effective in a wide range of common mental health problems such as depression, anxiety and first-episode psychosis.⁹ Prevention of conduct disorders could save £150 000 per case in lifetime costs.¹⁰ Early intervention programmes can delay or prevent transition to psychosis among participants,¹¹ and have significant cost-savings.¹² Some preventative measures are outside the purview of psychiatric services. Adverse childhood experiences increase the risk of depression by four times, and suicide attempts by 30 times,¹³ yet mental health services are not involved at the advent of these life events. Greater joint working between public service bodies would achieve better long-term mental health outcomes.

Addressing the social determinants of poor mental health can also achieve better outcomes. The Marmot Review established that ‘the lower one’s social and economic status, the poorer one’s health is likely to be’.¹⁴ Organisations should make targeted use of resources in areas such as housing, social isolation and employment, to work to improve social capital.

Housing

Homelessness and long-term mental illness are linked.¹⁵ Models such as Housing First have been shown to help individuals engage better with treatment programmes, doing this at around half the cost of traditional models.¹⁶ The Critical Time Intervention programme can also be effective in preventing homelessness on discharge from in-patient care.¹⁷

Isolation

People with mental ill-health are more likely to suffer adverse consequences of social isolation.¹⁸ Recent lockdown conditions have shown the impact of social isolation on previously well-managed mental health conditions.¹⁹ Befriending services can be effective in improving depression,²⁰ and is highly valued by patients. Social prescribing can also help address isolation, loneliness and inactivity.

Employment

Unemployment is associated with poor mental health,²¹ whereas being in employment or volunteering promotes better mental health.^{22,23} Individual Placement Support services have demonstrated successes, when used, by integrating employment specialists into community teams to support those with severe mental health problems into work.

Addressing social determinants of mental health will enable populations to become more resilient to the effects of climate change. Groups with less social capital are both more likely to experience poor mental health,¹⁴ and more vulnerable to the effects of climate change.²⁴ Conversely, a better housed, stably employed, socially connected population will require less mental healthcare as circumstances change.

Empower patients to manage their own mental health

A variety of opportunities exist to enable patients to take a leading role in the management of and recovery from their conditions (*Box 2*). *Box 2* Sustainability within a management plan. Dr Alvarez, has been reviewing John, a 57-year-old man with depression, who drinks alcohol regularly. John has been calling the ambulance service and police when intoxicated, resulting in frequent visits to his flat. Emergency services suspect that he is doing this in part because he is lonely and isolated. John has said he ‘doesn’t do much’ in the day, and his care coordinator confirms he goes to the shop twice a week but nothing else. Dr Alvarez asks what John has enjoyed before – he says he remembers helping his father in the garden but ‘of course, I don’t have a garden now’. John discussed him at the team meeting and hears from the occupational therapist about ‘Men in Sheds’, a local gardening group coordinated by peer-support workers. Dr Alvarez contacts John’s general practitioner to establish contact with a link worker from the local social prescribing initiative, who meets with John to enable him to attend. After 4 weeks of attending together, John feels ready to go himself and says it is the highlight of his week. Dr Alvarez asks John to monitor his symptoms via an online symptom tracker, and is able to demonstrate to John that he his mood has improved, and alcohol consumption reduced. He is no longer calling emergency services. Dr Alvarez and John discuss a keeping well plan, getting John to identify what has got him better. They agree to meet again in 3 months via video conferencing to review his progress.

Co-production

If done correctly, individual, jointly developed care planning forms an opportunity identify what works for patients correctly first time, and hence reduce wasted effort. This needs to be done in a non-tokenistic way that does not marginalise patients.²⁵ Co-production must also form an integral part of any service redevelopment.²⁶

Self-monitoring

Technology can empower patients to manage their own symptoms. Tracking their symptoms online or via smartphones has been shown to benefit a variety of disorders, including anxiety, stress, alcohol and sleep disorders, depression, suicidal behaviours and post-traumatic stress disorder.²⁷ Use of symptom monitoring is well developed in Improving Access to Psychological Therapies, and could be expanded to other services.

Peer support

Peer support provides excellent opportunities for patients to take ownership of their mental health. They can reduce in-patient admissions across a variety of diagnoses,²⁸ and can also link patients to a social support network.²⁹

Social prescribing

Social prescribing is a key component of personalised care,³⁰ and provides for an opportunity to tie together many aspects of sustainable healthcare practice. It has potential to lower the carbon footprint of healthcare by empowering people to pursue their own non-pharmacological solutions to their social, practical and emotional problems.

Green and blue space

Access to green and blue space can promote mental health and improve symptoms in a variety of mental and physical disorders.³¹ Green space and horticultural therapy projects should be part of any hospital build or redesign, and Trusts should identify areas where they could form part of their existing portfolios. Green walking groups³² and activities centred on blue space both have benefits.³³ Importantly, those with poor mental or physical health are least likely to have access to green and blue space,³⁴ and efforts will be needed to engage these groups.

Eliminate wasteful activity

Wasteful activity is a significant contributor to both the carbon footprint and financial cost of the NHS. A leaner, smarter service will deliver higher-value, more sustainable healthcare.

Medicine optimisation

Although the carbon impact of psychiatric prescription is currently poorly understood, some quick wins exist. Using long-acting injectable medications at the longest evidenced-based interval rarely occurs, but could reduce the cost of prescribing by £250 per patient per year, or a total of 170 000 kg carbon dioxide equivalent.³⁵ Psychiatry also has considerable influence over prescribing in primary care, and should routinely work with general practitioners to reduce pharmaceutical waste, polypharmacy and overprescribing. There should be greater use of structured medication reviews to work with patients to optimise their medications.³⁶ These form further opportunities for shared decision-making over treatment.

Concordance and treatment effectiveness

Half of all medicines dispensed are not taken as directed.³⁷ In mental healthcare, the figure is likely to be even higher. Better understanding the reasons for non-adherence, such as side-effects, personal beliefs or other barriers, may go some way to reducing waste. There may also be opportunities for patients to pursue treatment strategies that de-emphasise the role of medication, if circumstances permit. The open dialogue approach has been successful both in treating symptoms of psychosis and returning patients to work, largely in the absence of medication;³⁸ its efficacy in the UK is currently being evaluated. In some situations, it may be possible to continue to support people with severe mental illness who choose to not take medications at all; so called 'managed non-adherence'.

Reducing 'did not attend' rates

'Did not attend' rates in mental healthcare are estimated to be between 15 and 20% higher than other specialties.³⁹ Patients who miss appointments tend to be more unwell, and have a higher chance of relapse and hospital admission.⁴⁰ A reduction in missed appointments can be obtained by gaining a better understanding of their cause, and adapting to this in ways relevant to patients.⁴¹

Make use of low-carbon alternatives

Mental healthcare emissions are more evenly spread across a variety of these direct and indirect sources than in other specialities (*Fig. 1*).⁵ The lack of a quick fix reinforces the need for collective action by individuals across mental health organisational divisions. *Fig. 1* Mental healthcare carbon emissions compared with other healthcare sectors. Relative carbon emissions of healthcare sectors (kgCO₂e).

Low-carbon treatment choices

Clinicians need to be aware of the carbon impact of their treatment choices, and offer low-carbon treatment choices when possible. There is a need for a better understanding, and the NHS should work with pharmaceutical companies to make this readily available for clinicians. Meanwhile, evidence-based alternatives, such as electronic cognitive-behavioural therapy and other web-based psychology programmes, are available for disorders such as depression,⁴² anxiety⁴³ and insomnia.⁴⁴ These have as little as a fifth of the carbon emissions of face-to-face cognitive-behavioural therapy (230 kg v. 1100 kg), and a quarter of the carbon emissions of a course of antidepressant treatment with psychiatrist follow-up (900 kg).⁴⁵

Active transport and reduction in vehicle emissions

Staff and patient travel forms a significant component of mental healthcare carbon emissions. Clean and zero emissions fleet vehicles, cycling and other types of active travel are all part of the solution; mental health organisations must take steps to procure and promote these. The 2019 Royal College of Psychiatrists sustainability prize winners from Southern Health NHS Foundation Trust ran a project to reduce their transport emissions, using online meetings, cycling or walking, and car sharing, saving 22 216 kg carbon dioxide equivalent over a year.⁴⁶

Energy use

Mental health organisations should invest in smart energy systems, and to procure their energy from the greenest possible sources. By installing a piece of software that remotely shut down computers not in use overnight, NHS Oldham was expected to save over 800 000 kg carbon dioxide equivalent and £41 000 in the first year.⁴⁷ Clinicians can identify energy-saving schemes in their workplaces. The Centre for Sustainable Healthcare run the Green Ward competition, offering guidance and support for sustainable schemes, including energy use.

Waste and recycling

Although a relatively small component of the overall carbon impact of the NHS, interventions involving waste often are the most definable and easily engaged-with green programmes. The Royal Surrey Hospital's recycling programme grew from a group of nurses carrying home recyclable waste into a dedicated recycling centre for the Trust, and 60 'sustainability champions'.⁴⁸

Food and catering

Mental health organisations must work to offer their in-patients and staff members sustainable and healthy food options. North Bristol NHS Trust successfully worked with their wholesalers to source all of their ingredients within a 50-mile radius.⁴⁷ Clinical staff can do much via feedback to on-site catering options to include more sustainable options, or taking steps to change their own diet at work.

Plan, measure and improve

Transitioning toward sustainable models of care requires unprecedented coordination between and within mental health organisations and their local partners. Success depends on a structured, coordinated strategy and ways of measuring and improving changes.

Green Plans

All mental health Trusts are required to have a board-approved Green Plan, but their importance to organisations currently varies. Sustainability should be an integral part of mental health organisations' strategic approach and should have executive-level buy-in. An effective Green Plan will be led by a Board member and have wide representation. The Sustainable Development Unit and NHS England have published guidance on how to develop a Green Plan.⁴⁹

Carbon footprint

The Sustainable Development Unit has tools for NHS Trusts to measure and reduce their carbon footprint in procurement, and have forthcoming plans for other divisions. An 'ethical procurement' tool is also available. The Royal College of General Practitioners has produced a 'Green Impact for Health Toolkit', enabling general practices to audit their practice – a similar toolkit should exist for mental healthcare organisations.

Quality improvement

Quality improvement is an effective framework to achieve sustainability aims. One advantage of the quality improvement model is that it seeks to understand local systems first, making it more effective at solving local problems. It is also a 'bottom-up' approach, fostering a sense of ownership and ambition among staff. The Centre for Sustainable Healthcare have adapted the quality improvement model for sustainability, which can be used in mental healthcare settings (*Fig. 2*). *Fig. 2* Applying sustainable clinical practice principles in quality improvement. Published from the Centre for Sustainable Healthcare under creative commons licence CC BY-SA 4.0.

Adapt the system

Climate change will bring about longer-term shifts in patterns of need, mediated through changing populations, economic hardship, increased social division¹ and poorer physical health.⁵⁰ In the UK, climate change is leading to more flooding and heatwave events, which have adverse impacts on mental health.⁵¹⁻⁵³ In the global South and elsewhere, additional hazards such as wildfires, droughts, hurricanes and cyclones, are recognised drivers of poor mental health,⁵⁴ particularly for those with pre-existing difficulties.⁵⁵

Clinicians must prepare for this change and increase in mental disorder. There will need to be flexibility built into the system, as the full effects of climate change on the population are unknown.

Equipping psychiatrists to become sustainable practitioners, now and in the future

Organisations must play the central role in directing a shift in the organisation and delivery of clinical services. However, the normalisation of such practice through education, knowledge sharing via networks, and empowerment, is essential to allowing clinicians to play their part.

Training

There is broad interest among psychiatry trainees and medical students in becoming sustainable practitioners, but many do not see it as a core feature of their role as trainee doctors. Sustainability should be integrated into training and established as a central responsibility of a psychiatrist. Medical schools such as Lancaster Medical School are already embedding sustainability into their curriculum,⁵⁶ and sustainable practice should be made part of e-portfolio and annual review of competency progression commitments. There are also broader arguments to place sustainability at the heart of the General Medical Council's duty of a doctor Gold Guide.

Sharing good practice

Attendees at conferences and meetings should routinely expect to see a focus on sustainable healthcare, as has been the case at several regional conferences to date. Video conferencing opens up more opportunities to do this in a sustainable way. Networks such as PsySustnet provide an additional resource to exchange learning. Awards such as the Royal College of Psychiatrists' annual sustainability prize have successfully celebrated outstanding achievement in sustainable mental healthcare.

Empowering employees

Mental health organisations should enable their employees to engage with sustainable activities, and bring their knowledge and energy to their workplaces. The psychiatry higher training programme has integrated ‘special interest’ time, where trainees can pursue projects to the benefit of patients, Trusts and trainees alike. This could be widened to other mental health practitioners to allow all to engage in sustainability projects. A central part of empowerment should also support the growing understanding of supporting the well-being of clinicians.

Summary

Mental health organisations must act now to prevent and adapt for the climate and ecological emergency. Clinicians’ involvement is vital for developing effective and safe sustainable models of care. There is much work to be done, and there are significant changes to be made to the system to adapt to these needs. The good news is that much can be achieved through prevention of illness, choosing low-carbon treatment strategies, controlling waste and empowering patients to be more in control of their care and treatment. The best news is that sustainable practice is also good practice.

Abstract

There is scientific consensus that anthropogenic climate change is real and that it provides an existential threat to humanity and the planet. In this article, we focus on climate change conspiracy theories and the impact of such beliefs on mental health. We discuss the psychiatric disorders that

might be relevant to conspiracy belief endorsement and we present the underlying psychological mechanisms. We note that there is little to no literature to associate beliefs about climate change with serious mental health conditions. However, we anticipate that such beliefs may manifest pathologically in psychiatric presentations as climate change becomes increasingly at the forefront of the global agenda.

pmc There is a consensus among climate scientists that anthropogenic climate change is real, harmful to the environment and a threat to our futures.¹ Despite this, climate change denial and scepticism are prominent in social and political discourse, with support from influential public figures.² Conspiracy theories are bedfellows of climate denialism and scepticism and have been defined as ‘attempts to explain the ultimate causes of significant social and political events and circumstances with claims of secret plots by two or more powerful actors’.³ Climate change conspiracy theories are popular, with endorsement between 20%⁴ and 40%⁵ in the USA. In other Western countries, denial is less prevalent, though still present.⁶

Douglas & Sutton² noted climate change conspiracy theories to follow four main themes: scientists are faking climate change (a) for political reasons or (b) to secure research funding, or climate change is a hoax to (c) enable the ‘green agenda’ and (d) promote nuclear power. Notably, each theme implicates ‘scientists’ in perverse and deceptive actions. It would appear that this is required to undermine the consensus position among experts.

Why do people believe climate change conspiracy theories?

Douglas et al⁷ suggested that epistemic, existential and social motivations underpin conspiracy beliefs. Epistemic motivations relate to the extent to which individuals or groups hold knowledge of phenomena that affect their lives. Conspiracy beliefs are strengthened when events are significant and/or wide-reaching⁸ and mainstream explanations are simplistic or lacking emotional charge.⁹ Conspiracy beliefs can provide a sense of understanding in the face of contradiction and uncertainty, and may offer closure when mainstream narratives do not provide satisfactory explanations.¹⁰ Existential motivations relate to the experience of anxiety, threat or a perception of powerlessness in the face of danger. In such instances, conspiracy theories may provide safety.^{11,12} Finally, social motivations concern issues of power and hierarchy, with conspiracy theories more likely to emerge in those who have experienced oppression, victimisation or persecution.¹³ In such circumstances, groups can become insular and develop an ‘us versus them’ narrative.¹⁴ Safety is achieved through a narcissistic defence, whereby power is transferred from perceived ‘elites’ to the conspiracy belief holders.¹⁵ Of note, such groups are predominantly single and isolated ethnic-minority males with lower socioeconomic

status and educational achievement.¹⁶

Holding one conspiracy belief increases the likelihood of believing another¹⁷ and individuals predisposed to general conspiracy thinking are more likely to deny climate change.¹⁸ An underlying tendency to prioritise counter-narrative explanations and to distrust institutions may be apparent. The notion of political socialisation is important (e.g.¹³); climate change denial is part of the conservative rhetoric and conspiracy talk that is common among world leaders such as Trump¹⁹ and Bolsonaro.²⁰ Political polarisation of climate attitudes has been well-evidenced in the USA²¹ and Europe,⁶ among other regions. Climate change conspiracy theories might suggest allegiance to a particular conservative world view and be phenomenologically different from more emotionally charged beliefs such as the QAnon and COVID-19 conspiracy theories.

Conspiracy theories, overvalued beliefs and delusions: challenges with definitions

Psychiatrists work with symptoms and diagnoses that are based on criteria set out by manuals such as DSM-5 and ICD-10. When criteria are met, a diagnosis can be made and a treatment plan devised. When thinking about conspiracy theories, the psychiatric terms ‘overvalued ideas’ and ‘delusions’ are challenged. Psychiatry defines ‘overvalued ideas’ as an erroneous response to an idea – ‘an acceptable, comprehensible idea pursued by the patient beyond the bounds of reason. It is usually associated with abnormal personality’.²² The overvalued idea may be based on true evidence. The term was coined by Wernicke in 1906 and has further been explored by Jaspers and Fish, who made various suggestions of how to distinguish overvalued ideas from delusions.²³ A delusion is defined as a ‘false, unshakeable idea or belief that is out of keeping with the patient’s background; it is held with extraordinary conviction and subjective certainty’.²² Consequently, there can be a diagnostic dilemma as to which category climate change conspiracies – or any conspiracy theory beliefs – best align.

The evidence supporting climate change conspiracy theories

Conspiracy theory beliefs are widespread (e.g.^{24,25,26}). The internet is rife with ‘fake news’ and ‘misinformation’. Social media platforms, blogs and a whole range of other websites are dedicated to the mass propagation of ‘evidence-base-less’ theories that directly refute scientific findings.^{27,28} Bye Bye Blue Sky is one of many groups that promote and raise awareness of climate change conspiracy theories. For example, their mission statement describes ‘chem-trails’ and a government conspiracy to control the weather as ‘the toxic spraying of nano particulate metals which are further amplified by ionospheric heaters to steer, direct and control our weather for military purposes ... we seek to apply the wealth of our knowledge, passion and talents to end the illegal spraying of our planet’ (byebyebluesky.com/). Alarming, the internet content and group demonstrations can be very convincing. Furthermore, some theorists have mastered the ability to navigate through such forums and use them to their advantage to disseminate their views to a large population.²⁹

An interesting quality of conspiracy theories is that the counter-evidence is shunned by theorists who claim that the refutation of their ideas by powerful figures is further evidence of truth suppression. This introduces an ‘us versus them’ dynamic.¹⁴ It may also have a directly proportionate effect – the stronger the evidence against the conspiracy theory, the more vehemently the counter-narrative is held.³⁰ This is further reinforced by computer algorithms that provide a feed of confirmatory evidence and omit counter-narratives from view.³¹ Curiously, it is evident that the scientific community’s message on climate change does not have the same footing or far-reaching sustenance as the competing conspiracy theories.

Referring back to the traditional definitions of overvalued ideas and delusions, it seems that conspiracy theories about climate change could be categorised as either or neither. A diagnostic challenge is introduced when groups or ‘masses’ of believers share the same conspiracy theory and it almost has the constructs of a culture. Studies^{4,5} have found the existence of large populations that believe conspiracy theories, supporting the idea that such beliefs extend beyond the individual. This directly causes conflict with the definition of delusions. It emphasises the need for clinicians to consider the presence of additional psychopathology and/or functional impairment in order to make a diagnosis in an individual who is preoccupied with conspiracy beliefs. It could be postulated that this may divide psychiatrists. Some may consider that this group hold pathological beliefs, whereas others may frame the beliefs as in keeping with a ‘subculture’ and therefore not indicative of psychopathology.

Climate change conspiracies and mental disorders

Although there is an abundance of literature on climate change conspiracy theories in terms of their nature and spread, there appears to be very little on how such theories have had a clinical effect on mental health. In this section, the link between climate change conspiracy theories and mental disorders is discussed.

Personality disorders

Individuals with certain personality disorder diagnoses are likely to be more susceptible to preferring narratives engineered by conspiracy beliefs due to the nature of the definition in diagnostic manuals such as ICD-10. In particular, the cluster A personality disorders have the fitting profile. The description of paranoid personality disorder specifically makes reference to a 'preoccupation with unsubstantiated conspiratorial explanations of events both immediate to the patient and in the world at large'. Additional traits include recurrent suspicions without justification, general suspiciousness and a pervasive tendency to distort experience by misinterpreting neutral actions of others as hostile or malicious. Persons with a diagnosis of paranoid personality disorder may also have a rather rigid world view and an assertive sense of personal rights, which may not be proportionate to actual situations.³² It is apparent how this profile might cross over with characteristics identified in those who endorse conspiracy theories (e.g.⁷).

The ideas characteristic of paranoid personality disorder are typically persecutory and self-referential. Individuals diagnosed with this disorder are likely to be socially withdrawn and perceive that they are unduly victimised.³³ Imhoff & Lamberty³⁴ noted similar characteristics in relation to subclinical paranoia. However, instant access to widespread networks, facilitated by the internet, allows the formation of clusters of like-minded individuals who also hold similar persecutory, self-referential ideas. There is now a mechanism by which such individuals can indulge pathologically in misinformation to bolster their false beliefs together and 'connect'. Therefore, in this scenario, self-referential ideas become a collective experience.³⁵ This could further add opposition to the mainstream narrative and have an impact on individual presentation.

The criteria for schizoid personality disorder include traits such as an 'invariable preference for solitary activities', 'a lack of close friends or confiding relationships', 'poor acknowledgement of social norms and conventions' and, importantly, 'excessive preoccupation with fantasy and introspection'.³² A combination of such traits could underpin a tendency to believe conspiracy theories.

Schizotypy is also implicated in the conspiracy theory literature.³⁶ Schizotypy is captured in DSM-5 as a personality disorder and categorised with schizophrenia in ICD-10. March & Springer³⁷ explored whether the 'odd beliefs' and 'magical thinking' seen in schizotypy predicted belief in conspiracy theories and found a significant association between the two. The authors commented that the results indicated that individuals with 'unusual patterns of thinking and cognitions' and 'interpersonal and affective' deficits were more likely to hold conspiracy beliefs. There are indications that particular personality traits are risk factors for psychosis in an attenuated form.^{38,39}

Nihilistic and apocalyptic delusions in psychotic depression

Severe depressive disorders may have a psychotic component in which mood-congruent delusions are a feature. Nihilistic delusions, where the patient has abnormal conviction that they are dead, their organs are rotting or the world is dead around them, are not uncommon.⁴⁰ There is a possibility that this belief could extend to an individual believing that they are personally responsible for climate change or – in extreme cases – the destruction of the world.

Another type of delusion referred to in the literature is 'apocalyptic delusions' or 'end-of-the-world delusions'. The content of such delusions is thought to be influenced by contemporary culture and societal changes. Early content of such delusions included fears of the plague, famine and asteroids hitting the earth.⁴¹ Although these persist, the content has evolved in the present day, as would be expected, and includes despair over climate change. 'Climate apocalypse' and 'climate dystopia' are terms that encompass the idea that an apocalypse will occur as a result of climate change – severe weather changes, forest fires and a depletion of natural resources will render the earth uninhabitable and therefore bring about the inevitable impossibility of the survival of human life.⁴²

There is a single published case study to describe this phenomenon. Wolf & Salo⁴³ described a 17-year-old boy diagnosed with a depressive disorder, who developed a delusion that his consumption of water would lead to the deaths of millions of people, as water supplies would be depleted. This was associated with ‘visions’ of an apocalypse.

Overall, there is a lack of recorded clinical cases of severe depression related to climate change or climate change conspiracy theories. However, with heightened attention on and uncertainty about climate change in modern society, there may be an increase in manifestations of this in depressive disorders through the modes suggested.

Psychotic disorders

There are controversial terms such as ‘mass delusion’, ‘climate alarmists’ and ‘greenhouse sceptics’, which refer to various groups of people who hold certain beliefs about climate change.⁴⁴ There are conspiracy beliefs propagated by some ‘climate deniers’ to state that climate change is a hoax.⁴⁵ Counter-conspiracy beliefs also exist, which propose that the impact of climate change is understated, data are suppressed and governments are purposefully minimising the accelerating impact on the earth to fit with their political agendas.² In terms of psychiatric diagnosis there is no evidence to suggest that such beliefs have a delusional quality. The terms ‘mass delusion’ and ‘climate deniers’ do not have clinical connotations. Nonetheless, there is likely to be a minority with associated risk factors for psychiatric disorders within the groups who are prone to holding these beliefs with absolute conviction despite contrary scientific evidence. Such delusions may be considered part of an evolving clinical picture of a delusional disorder, or a psychotic disorder such as schizophrenia. Considering the nature of these disorders, if climate change delusions were present, they would be expected to have a bizarre quality; and it would not be unusual for extreme conspiracy theories to be the themes.

There is a small literature base – and accompanying anecdotal evidence – concerning the interplay between socio-cultural events and delusional content. For example, Cannon & Kramer⁴⁶ have noted that delusional content in the USA related to syphilis in the early 20th century, Nazis during Second World War, communists during the Cold War and technology in more recent years. The internet has become increasingly relevant to delusional content (e.g.^{47,48,49}). Curious case studies also exist. For example, Caseiro & Queiros⁵⁰ reported a case in which football was thematic, in the context of Portugal winning Euro 2016. Notably, psychosis is often triggered by real-world events and the nature of delusional content can reflect genuine concerns about the world, anxiety and existential threat.⁵¹

It is possible that concerns about climate change could exacerbate existing delusional beliefs, or extreme views could escalate above a delusional threshold. Consequently, such beliefs could become ‘diagnosable’ and meet criteria for a psychotic disorder.

A psychological adjunct

There is an association between the cognitive and affective processes that underpin conspiracy beliefs and those evidenced in delusional thinking. For example, the jumping-to-conclusions bias has been observed in psychotic-like thinking.⁵² This bias is associated with the overly rapid appraisal of stimuli to form a conclusion and has recently been evidenced in a sample of conspiracy theory believers.⁵³ Poorer analytical thinking is also implicated,⁵⁴ and cognitive distortions noted in depression could also be relevant.³⁵ Similarly, historical victimisation and a schematic view of the world as dangerous are risk factors for psychosis⁵⁵ and can provide a framework through which anomalous information is perceived. Individuals with schizotypal and paranoid personality disorder diagnoses are also likely to have experienced danger in their early lives^{56,57} and such threatening experiences are also precipitants to conspiracy beliefs.^{11,13} Distortions in human information processing are commonplace, adaptive and dimensional, with evidence to suggest that some individuals perceive ‘true’ information, whereas others omit, deny or delude as their environmental niche requires.⁵⁸ Events that elicit threat responses are particularly relevant. Additionally, the demographic profiles of those who endorse conspiracies¹⁶ are similar to those found within psychosis cohorts.⁵⁹

Many theorists and clinicians support the concept of dimensional psychosis with phenomenological continuity.^{60,61} Subclinical delusional thinking has been associated with conspiracy beliefs,⁶² as has paranoia.^{34,63} Conspiracy theorists may not be delusional or paranoid. However, it is plausible that they exhibit similar genetic, psychological and/or social characteristics to those who are vulnerable to psychosis. The proneness–persistence–impairment model⁶¹ and

extended psychosis phenotype⁶⁴ are helpful frameworks for exploring the relationship. For many, a belief in climate change conspiracies could simply concern loyalty to conservative values.¹³ However, some may have an underlying predisposition to psychosis, with a tendency towards conspiracy thinking. Potential migration towards clinical thresholds could occur in response to greater perceived threat from significant events and exposure to, and preoccupation with, conspiracies. Individuals with diagnoses of paranoid or schizotypal personality disorder may fall into this position. The notion of the extended phenotype could explain why individuals who hold one conspiracy belief are more prone to believing others (e.g.¹⁷); this has also been called ‘conspiracist ideation’.^{65,66}

Forecast

There is evidence to suggest that historical events have informed delusional content^{46,49} and there are some indications that the COVID-19 pandemic has had a recent effect.⁶⁷ Delusions can be triggered by real-world events and the content can reflect genuine concerns about the world, anxiety and existential threat.⁵¹ Notably, the conditions in respect to the above phenomena were opportune for the development of conspiracy theories. That is, these events generated real threat to individuals and communities (e.g.⁷).

It can be hypothesised that the global reluctance/opposition to impactful climate policy change is actually protective with regard to the pervasive development of conspiracy belief psychopathology. That is, conspiracy theories emerge when a way of life is threatened. At present, climate policy has not had a tangible impact on freedoms, rights or lifestyle. Nonetheless, we forecast that this will likely change in the coming decades (e.g. as governments fall in line with the Paris Agreement). To our knowledge, there is only a single case study⁴³ to describe the interplay between climate change conspiracy beliefs and severe psychopathology. It is hypothesised that climate change has not yet become a common feature of delusional beliefs.

For those who have a predisposition to psychopathology, such changes may trigger migration towards clinical disorder. It is possible that climate change and associated conspiracy beliefs may affect mental health in the following ways: (a) dramatic societal changes (e.g. energy conservation policies, restrictions on existing freedoms) might precipitate an increase in climate change conspiracy theories, and individuals predisposed to conspiracy thinking (including those with underlying paranoid, schizoid and schizotypal traits) might migrate to delusion; (b) the increasing presence of climate change discourse in public conversations could lead to such content appearing in the content of pre-existing delusional belief systems; and (c) concerns and guilt about climate change could lead to presentations of depressive psychosis with nihilistic and/or climate-related apocalyptic delusions.

Concluding remarks

As climate change becomes more present in public consciousness, conspiracy theories are likely to become increasingly prominent and to manifest in the presentation of several mental disorders. This article has hypothesised that there may be a potential commonality between pervasive conspiracy thinking and mental disorders, particularly psychosis and certain personality disorders. However, it is proposed that clinicians approach individuals who hold conspiracy beliefs with diagnostic caution, given that conspiracy beliefs are widely held within the general population. Careful assessment is needed to identify those who are psychologically vulnerable to developing mental health complications due to exposure to conspiracy beliefs.

Further research is recommended to investigate whether a proportion of climate change conspiracy theory advocates do have underlying psychological risk factors for the development of concerning psychopathology; and also how such theories have featured in mental disorders, particularly as symptoms of psychosis or personality disorder.

1.2.67 Silver linings: how mental health activists can help us navigate wicked problems

Neil Armstrong Keira Pratt-Boyden

Correspondence

Keira Pratt-Boyden (kzp2@kent.ac.uk)

date

2021-08

Abstract

This article explores how ‘wicked problems’ such as climate change might force psychiatry to rethink some of its fundamental ideas and ways of working, including clinical boundaries, understandings of psychopathology and ways of organising. We use ethnographic evidence to explore how mental health service ‘survivor’ activists are already rethinking some of these issues by therapeutically orienting themselves towards social problems and collective understandings of well-being, rejecting ‘treatment as usual’ approaches to distress. In this way we provide an example of the potential of activists to help psychiatry negotiate the climate crisis.

pmc In *Hyperobjects: Philosophy and Ecology after the End of the World*, Timothy Morton suggests that the climate emergency is a ‘wicked problem.’¹ Problems might be described as wicked in cases where their complexity, our lack of knowledge or the absence of stable, defined goals make them extremely difficult (or even impossible) to solve. Wicked

problems are often highly entangled and interdependent, such that addressing one area leads to unwanted consequences in another. When dealing with a wicked problem, the answer does not lie in a single solution. Wicked problems require broad perspectives, which examine social processes and systems and are responsive to phenomena that may be marginal or poorly understood. Morton argues that the wicked problem of the climate crisis is placing an intense and transformative pressure on our patterns of reasoning and that it demands an overhaul of some of our key ideas and values. As Boulton notes, climate change ‘renders *vulnerability* [our italics] as the tangible human experience of environmental degradation and destabilizes our sense of existence’ to the extent that it challenges ‘human-scale understandings of personhood, planetary existence, and cognition in general’.²

We suggest that psychiatry cannot be left out of any overhaul of key ideas or values, not least when they pertain to vulnerability and our understanding of the person. There are at least two aspects to this. First, we suggest that the climate crisis disrupts ideas about psychopathology that draw on notions of autonomy, independence, functioning, goal orientation and economic activity. Second, we note how the crisis unsettles critical but unexamined assumptions about how individuals and institutions should be organised by questioning the values of orderliness, preparedness and managerial rationality often found within organisations such as the UK’s National Health Service (NHS) and Department for Work and Pensions. To investigate this we draw on ethnographic fieldwork with mental health service ‘survivor’ activist networks in London, who reject ‘treatment as usual’ and challenge some of the main premises of mental illness and what it means to live healthily. We explore interlocutors’ preferences for ‘dis-organisation’ and disorder in group meetings as a therapeutic act. We also present how activists reframe their inability to work and to receive sickness benefits as a means of community engagement, collective ethics and undertaking social ‘goods’. Ethical approval for the fieldwork cited in this article was approved by the University of Kent. Verbal informed consent was obtained from all participants.

Mental health service survivor activists: the Challenge Mental Health network

Mental health service survivor activists have iatrogenic and traumatic experiences of NHS mental healthcare. As a collective, they draw their alternative understanding of what it means to be a valuable member of society away from individual ‘functions’ and towards socioenvironmental concerns. Global phenomena such as the climate emergency are used by activists to think through how mental distress is conceptualised in mental health services. They find that it no longer makes sense to work within a framework and discourse of individual responsibility when the climate emergency shows how profoundly interconnected our lives really are. In this article, we provide ethnographic material to think these issues through, suggesting not solutions but ways that psychiatry might begin to respond to the climate crisis in a more inclusive and holistic manner.

Survivor groups such as Challenge Mental Health (CMH) network meet across London to campaign for better understandings of mental distress and improvement of local and national mental health services and treatments. One of CMH’s main premises is that psychiatry underestimates the social causes and treatments of ‘mental illness’ (or what they term ‘distress’). They argue that undervaluing social processes in this way contributes to poor mental health. As a group, CMH are opposed to thinking in terms of individual vulnerabilities or pathologies. Instead, they emphasise social attitudes, collective pathologies and systemic barriers that impede recovery. They concentrate on collectively alleviating social influences of distress and support one another by telling personal stories of distress and discussing ideas around illness beliefs and causes. They also allow individuals to experience distress in the presence of the group without intervention or treatment.

The way survivor groups organise themselves reflects an ambivalent relationship with bureaucratic working; this in part involves a conscious construction of a meeting space which is entirely ‘other’ from places such as the clinic or the hospital. At first glance, these preferences might appear at odds to those with training in goal-oriented therapeutic approaches. CMH have particular ways of approaching their meetings for example. They reject orderly, rule-governed practices and behaviours which are rooted in planning and preparedness and which might remind them of NHS ‘treatment as usual’. CMH meet according to consensus in spaces all over London – responding to members’ needs at the time. Meetings can last for hours and involve complete strangers. I have often witnessed people walking in off the street, or straight from a hospital discharge for example. The meetings are informal and are conducted without set procedures or agendas. Meetings are reactive – responsive to personal stories, events or news – and topics of discussion are changeable and unpredictable. Official leadership or facilitation in meetings is rare and they are typically initiated by whoever wants to speak at the time. All are welcome, but there are rarely introductions – it is up to individuals to

introduce themselves; sometimes members sit for hours together and never find out who one another are. There are no expectations of turn-taking, as in more conventional group therapy settings.

These arrangements have their difficulties – interlocutors sometimes express frustration about the lack of structure in meetings and, when there is a disagreement, there are no procedures in place to ask members to leave. But it is telling that these arrangements cannot just be read in the negative, as absences of positive qualities. Rather, they are consciously curated and challenge many assumptions about trusting therapeutic interactions needing to occur in contexts that are safe, ‘contained’, stable, orderly, predictable and familiar. Here, it is the very lack of order that is therapeutic, felt by participants to be empowering and healing, where rational institutional working had been found to be alienating, demoralising and stigmatising. Through certain ways of being-in-place, activists resist processes and relations that might in other contexts be seen as organisational virtues that define the gold standard of conventional healthcare – such as professionalism and expertise, impersonal institutionally defined roles and processes, and the standardised relationship, even the ‘routinised intimacy’, that characterises contemporary mental healthcare.³ Activists instead rely on spontaneity, mutual attentiveness, responsiveness and informal group working.

Interlocutors speak about medical procedures associated with bureaucratic rationality, planning and accountability as countertherapeutic. During a meeting, one newcomer asked members of CMH why there were no meeting minutes, because then others could contribute remotely. One reply was, ‘If we took minutes, everything we say would be documented, get out of context and we would feel scrutinised’. Many interlocutors expressed a specific dislike of documentation (and particularly, being ‘written about’), especially those with experiences of being detained under the Mental Health Act (‘sectioned’) and/or claiming benefits (something that the majority of activists experience). Interlocutors described how it felt alienating and disempowering to not know what is written (or spoken) about them (i.e. in medical notes), particularly being unable to read or understand what the notes say when shorthand or medical terminology is used. Thus, meetings do not run according to agendas and the group do not write manifestos; rather, they operate on the principle that to have any ‘rules’ evokes those systems and modes of behaviour they specifically reject.

How does this relate to the climate crisis?

For those for whom ‘therapeutic’ places provided by service providers are often harmful and exacerbate or elicit unwellness, making spaces according to these sensitivities requires flexibility. Therein lies Morton’s ‘overhaul’; this rejection might be understood by psychiatrists and service managers in negative terms as an absence of organisation, or an inability to generate efficient ways of working. Understanding recovery collectively as activists do may even be read as a sign of dependence. Yet the climate crisis might suggest a different frame. A distaste for planning, organising and preparing reflects an awareness that these forms of organising (and the values and sensibilities that drive them) are discredited because the ecological crisis is driven by them. The production of pollutants on such a scale that they threaten life on earth demands industriousness, discipline and rational organisation on a huge scale. But as Bouton reminds us, we are all interdependent and interconnected and ‘all vulnerable’.⁴ Not acting in accordance with conventional psychotherapeutic thinking concerning relationships and ways of behaving enables mental health activists to have more control and ownership over their recovery, as does questioning the logic underpinning certain clinical ‘goals’ pertaining to health and wellness. Recovery for many survivor activists is relational, flexible and agentic and creating meeting spaces to behave in ‘disorderly’ ways is part of this process.

Boundary objects

Psychiatric categories are an example of what Bowker & Star call ‘boundary objects’ – concepts that work across different institutional settings and contexts.⁵ Star & Griesemer define boundary objects as ‘objects which are both plastic enough to adapt to local needs and the constraints of the several parties employing them, yet robust enough to maintain a common identity across sites’.⁶ Boundary objects are terms that allow cooperation and communication between individuals (say, within an organisation) even if they do not necessarily agree with the precise meaning and definition of the terms. They have different meanings for different people. An example of such a term might be ‘recovery’: it is contested but also has a generalisable meaning in mental healthcare. Clinical terms designed to guide treatment decisions, for example, also guide access to benefits and relate to legal responsibility, capacity and disability.

In this way psychopathology is tied to conformity and deviance as conceptualised in the context of the welfare state. But we can only take deviance as a sign of ill health and conformity as a marker of health if we think that society is more or less healthy. The climate crisis challenges that. Our collective inability to respond to emerging climate science looks compulsive and irrational, perhaps even delusional. It is functional people who produce and consume and thereby drive the production of greenhouse gases and undermine food security, while the economically inactive have the lightest carbon footprint.

‘Unemployment’ as mental illness or an enabler of social ‘goods’?

Survivor activists can be sceptical that good ‘health’ is so easily mapped onto capacity, function and ability to find and keep work. Many of CMH’s campaigns revolve around the idea that people on benefits for mental illness are being pushed into work as part of new benefits changes and government targets related to financial management and (post)austerity measures and that this is harmful to claimants’ sense of autonomy and agency. CMH hosts film nights as opportunities to air concerns and grievances around such topics. One evening, Lissa, one of the founding members, stood in front of the small group of CMH members, therapy students and passers-by and announced that, ‘The government is trying to persuade us that unemployment is a mental illness. This driving force telling us we should all be in and doing productive work alters the sense of *who* and *what* we are’.

The discourse around ‘getting into work’ affects those in distress. Members discussed the connections between mental health services and the welfare system anxiously. Will, for example, a young activist in his 20s, feels guilty about his inability to work. He says he has never been in the position where ‘they thought enough of me to get to work’, even though he has tried. Will has spent most of his adult life living in supported accommodation and has been in hospital under various Mental Health Act sections. He was diagnosed with Asperger syndrome in school and had other mental health difficulties. He explains that he has undergone a work capability assessment and is waiting for the results. He feels as though he has to constantly justify why he has not worked and struggles with feeling illegitimate for never having had a job. At the job centre Will asked a receptionist whether he could just get ‘normal jobseeker’s allowance’ instead of sickness or disability benefits. She was surprised and told him that he would receive more money by accepting illness benefits. Yet Will insisted on claiming jobseeker’s allowance, lamenting that he ‘just wants to be like everyone else’.

At the film night, the group reflected on how people on benefits are treated with hostility and that they have the added disadvantage of having psychiatric diagnoses. ‘I don’t want to go around being seen as the victim’, remarks one, ‘especially when we already have a self-blaming culture’. Julie raises a recent comment made by George Osborne about people on benefits lying in bed with their curtains drawn while others go out to work and that they remain closed when workers come home again.⁷ ‘We are trying to change this narrative,’ she says. Lissa adds that she cannot stand the perception that people on benefits for mental illness do not do much all day because they don’t ‘work’. Her community psychiatric nurse (CPN) asked her what she ‘actually *does* all day’. So, she presented him with a list, ‘I get up early, check on my elderly mother, take my disabled sister to her hospital appointments, do her grocery shopping, call people up as part of my mental health support group mutual aid chats. Campaign for the end of workfare, write letters and articles. Lobby MPs, attend seminars in Westminster, draft responses and initiate public inquiries ...’. Lissa’s CPN was surprised, ‘It seems like you do more than me!’.

Julie explains that receiving benefits has meant that she gets to choose what she does with her life. She volunteers in the community, is a trained co-counsellor, runs literary events for mental health service survivors, supports benefit claimants with their claims and letters, and sanctions and lobbies Parliament to increase spending in mental health services in her free time. She supports as many friends and peers in mental distress as she can. She explains that, rather than running in ‘the rat race’, she has time to take action on behalf of those who are working. Employment caused her to have breakdowns. Implicit in her understanding is the idea that not working allows you to think, reflect, act collectively and undertake altruistic social ‘goods’; it gives you the time and energy to consider things that are bigger than you, to support others and gives you purpose and meaning.

Conclusions

Wicked problems such as the climate crisis force us to rethink our understandings of what mental health is, how mental healthcare should be organised and what its goals should be. What we have learned from mental health service survivors is that, for them, it is healthy to challenge ideas about individual functioning and social responsibility. Resisting the pressure of working employment or assuming the role of a ‘productive’ member of a society by resisting workfare can be healthier for recovery than what is desired according to the psychiatric model of mental health. For activists, recovery outcomes are not connected to gaining employment. In fact, the push towards function via work/employment can exacerbate stress, feelings of stigma and of low self-worth. Therapeutic activities for activists instead involve creating environments for exploration in group settings, where the unpredictability and uncertainty of distress is given space. By interrogating the social causes of distress but refraining from seeking solutions to it, activists avoid attempting to fix or resolve problems and instead allow for ‘not knowing’. Thus, they suggest that the model of mental illness needs to be more flexible – it needs to allow for debate around what is classified as ‘healthy’ behaviour, to make room for dialogue and the open exploration of wicked problems, and to be reactive and responsive to the moment we are living in.

1.2.68 Freedom to think: the need for thorough assessment and treatment of gender dysphoric children

Marcus Evans¹

Correspondence

Marcus Evans

(marcusevans3012@outlook.com)

date

2021-10

Abstract

Referrals (particularly natal female) to gender identity clinics have increased significantly in recent years. Understanding the reasons for this increase, and how to respond, is hampered by a politically charged debate regarding gender identity. This article starts with a discussion of the so-called 'affirmative approach' to gender dysphoria and considers the implications of the Memorandum of Understanding on conversion therapy. I then say something about the relationship between gender dysphoria and the developmental problems that are characteristic of adolescence. Finally, I outline what changes to the current approach are needed to do our best to ensure these patients receive the appropriate treatment.

– Declaration of interest

pmc There has been a 3264% rise in referrals to the national gender identity service at the Tavistock and Portman NHS Trust in London over the past 10 years (from 77 in 2009–2010 to 2590 in 2018–2019).¹ The profile of referrals has also undergone a major transformation: we have seen a reversal of the gender ratio from two-thirds male:female to two-thirds female:male, with a recently described clinical phenomenon of as yet uncertain diagnostic significance making up a substantial proportion. This gender dysphoria of recent onset among adolescents (sometimes termed ‘recent-onset gender dysphoria’ or ROGD, ‘rapid-onset adolescent dysphoria’² or ‘adolescent-onset transgender history’³) lacks an agreed name or established diagnostic criteria, but its emergence has been documented by a number of gender clinics worldwide.⁴ Bernadette Wren, the then associate director of the Tavistock and Portman NHS Foundation Trust’s Gender Identity Development Service (GIDS), gave evidence to a House of Commons select committee in which she summarised the GIDS intake in the following terms: ‘many of the young people, and increasing numbers of them, have had a gender-uncontentious childhood, if you like, and it is only when they come into puberty and post-puberty that they begin to question. That now represents a substantial proportion of our group’.⁵ We have very little understanding of what underlies these changes, and indeed of the understanding of this whole area is extremely limited and it is particularly important to examine it from different perspectives. This is very difficult in the current environment, as the necessary debate and discussion is continually being closed down, either through individuals being prevented from expressing their views or being self-censoring through fear of the accusation of ‘transphobia’.

The ‘affirmative approach’

The affirmative approach to gender dysphoria appears to have been adopted by the majority of NHS and privately provided children’s services in the UK. Again, Bernadette Wren stated in the House of Commons: ‘I work in a service where a lot of the young people – and anybody who wants it – have physical intervention. We have no record of turning people down for physical intervention’.⁵ This approach endorses the child’s belief that they were born in the wrong body and practitioners are required to support the child’s self-identification. Commenting on the decision of the American Academy of Paediatrics (AAP), Cantor says ‘Although almost all clinics and professional associations in the world use what’s called the “watchful waiting approach” to helping gender diverse children, the AAP statement instead rejected that consensus, endorsing gender affirmation as the only acceptable approach’.⁶ This is despite research findings which strongly suggest that most of these cases would eventually desist if left untreated.^{7,8} The ‘affirmative approach’ risks sending children down a path towards concrete and sometimes irreversible medical interventions for what is in very many cases a psychological problem. This approach, in my view, is driven by political ideology rather than clinical need and inhibits the clinician’s curiosity and freedom to explore a child’s underlying belief systems and motivations. The ‘affirmation approach’ looks narrowly at a problem in only one area of psychological functioning, as if one part of the individual could be isolated from other areas of the personality, so ignoring the complex relationship between the overt symptomatic picture and trauma, social anxieties and even the relatively normal turbulence of adolescence.

The Memorandum of Understanding on Conversion

The Memorandum of Understanding on Conversion, which many healthcare professionals have signed, purports to protect the patient from conversion therapy. The Royal College of Psychiatrists signed the first version of the Memorandum (in 2015)⁹ as it referred to homosexuality but declined to sign the second Memorandum (2017)¹⁰ as the definition had been expanded to include transgender individuals. The Memorandum is very often interpreted as obstructing the clinician’s freedom to examine and explore the various pathways that have led to gender dysphoria, but, somewhat surprisingly, when one reads the document one discovers an acknowledgment that the therapist or healthcare professionals’ job is to help the patient discover and come to terms with who they really are: “‘For people who are unhappy about their sexual orientation *or their transgender status* [my italics], there may be grounds for exploring therapeutic options to help them live more comfortably with it, reduce their distress and reach a greater degree of self-acceptance’.¹¹”

This Memorandum implies that there is a fixed category called ‘transgender’ which, like eye colour, is simply a given that need not be thought about or understood. Children’s sexual orientation and gender identity are formed out of a

complex developmental process that involves an interaction between their body, their mind and society at large. Sexual identity and gender identity are developmental processes that evolve as the individual goes through the different life stages.

The Memorandum is, in my view, symptomatic of the way that political agendas have influenced this area of clinical practice. We do not just accept/affirm a patient with anorexia when, although she weighs 45 kg, she thinks she is overweight and needs to diet more carefully. Instead, we take it as our duty to try to understand what it is that is driving that belief while persuading her that she needs to eat.

Children with complex problems

There is a growing body of knowledge that connects the development of gender dysphoria with psychological factors.^{12–17} A group of parents whose children were treated at the Tavistock and Portman NHS Foundation Trust's Gender Identity Development Service (GIDS) in London wrote to the trust's board. In their letter they express deep concern that children with no long history of gender dysphoria, who were on the autism spectrum or suffered from social anxiety adjustment disorders were, with very insufficient investigation, diagnosed as transgender. They believed that the GIDS adopted a superficial approach that was in danger of colluding with the child's belief that all their problems will be solved if only they could change gender.

The parents wrote to *The Guardian*, which reported on Saturday 3 November 2018 that children were 'fast-tracking' young people into life-altering decisions without fully assessing their personal histories. Their letter stated that:¹⁸ "the GIDS team is being asked to engage with and assess complex and difficult cases within a highly constrained time frame."

They also believed that their children had been indoctrinated as a result of online websites that recruited the child into membership of the trans community.

Research

One needs to be very cautious about recommending medical and surgical interventions that place a lifelong burden of treatment on patients. We know little about their effectiveness (there have been no long-term follow-up studies). Carl Heneghan, Oxford University's Professor of Evidence-Based Medicine and Editor-in-Chief of the journal *BMJ Evidence-Based Medicine*, has called the puberty blocker treatment an 'unregulated live experiment on children'.¹⁹ *Research Digest*, published by the British Psychological Society, reported on an Australian review which concluded that the current medical approach is based on extremely limited evidence.²⁰ The Royal Society of General Practitioners has drawn attention to 'the significant lack of evidence for treatments and interventions which [...] is a major issue facing this area'.²⁰ Professor Robert Winston (Lord Winston) of Imperial College London has expressed concern about medically transitioning young people without having 'really defined what is really wrong: what is the cause for people seeking gender reassignment? Until we define the problem, I think we're going to have a very blunderbuss problem'. Winston also highlights how often medical transition may not meet the expectations of patients: "He said 40 per cent of people who undergo vaginal reconstruction surgery experience complications as a result, and many need further surgery, and 23 per cent of people who have their breasts removed "feel uncomfortable with what they've done". He added: "What I've been seeing in a fertility clinic are the long-term results of often very unhappy people who now feel quite badly damaged. "One has to consider when you're doing any kind of medicine where you're trying to do good not harm, and looking at the long-term effects of what you might be doing, and for me that is really a very important warning sign." He added that the long-term effects of taking hormones "are likely to affect reproductive function".²¹

Even GIDS's own senior psychologist Bernadette Wren has mused: 'Of course, you have to think that in another generation we will have done something which is not regarded as having been wise.'²² Professor Donal O'Shea, an endocrinologist, has been highly critical of the World Professional Association for Transgender Health's (WPATH's) Standards of Care, which inform NHS England's guidelines: 'Aligning with them would result in significant harm accruing to those with gender confusion'. His colleague, psychiatrist Dr Paul Moran, considers that the WPATH guidelines 'are clinically unsafe, and unsuitable for use in a public healthcare gender clinic.'²³

Patients that regret treatment

An increasing number of ‘regretters’ or ‘detransitioners’ are speaking out on social media and at conferences to argue they have been let down by mental health services that have failed to assess their psychological problems before prescribing medical treatments such as puberty blockers and cross-sex hormones, or surgery as treatment for their gender dysphoria. A number of clinicians have called for research into desistance, detransition and regret among gender dysphoric adolescents. The US National Institutes of Health (NIH) Sexual & Gender Minority Research Office (SGMRO) recently named detransition in its report outlining scientific research gap areas in the field of sexual and gender minority health.²⁴ The 8th edition of WPATH’s Standards of Care will include a section on detransitioning.²⁵

Sky News reported on Saturday 5 October 2019 that Charlie Evans, who has detransitioned, has set up a charity to help others in a similar situation and has been contacted by hundreds of people seeking advice.²⁶

During the 1980s, I led a parasuicide service in King’s College Hospital, London, and treated a number of individuals who had self-harmed or attempted suicide after gender reassignment surgery. These patients had a history of serious and enduring mental illness and/or a personality disorder. Having developed a late-onset gender dysphoria, they were often angry at the loss of their biological sexual functioning and aggrieved with psychiatric services, which they felt had failed to examine their motivations for requesting reassignment surgery and/or to adequately investigate their psychological difficulties. A common theme in their presentations was a belief that physical treatments would remove or resolve aspects of themselves that caused them psychic pain. When the medical intervention failed to remove these psychological problems, the disappointment led to an escalation of self-harm and suicidal ideation, as resentment and hatred towards themselves were acted out in relation to their bodies.

Informed consent

David Bell was approached by a large number of clinicians who had very serious ethical concerns about the service. His report was presented to the Tavistock and Portman NHS Foundation Trust board. In his report he wrote: ‘This is a highly complex and difficult area which appears at times to be treated superficially’. *The Times* (8 April 2019) quotes an anonymous clinician from the GIDS as saying: ‘It was regarded as taboo to discuss the impact of medical intervention on later sexual functioning in such a young cohort’.²⁷

In the National Health Service (NHS), clinicians are usually required by law to discuss the potential negative effects of any treatment. However, for reasons that are not clear, the treatment for gender dysphoria has evolved operating outside the usual medical/professional practice. Children are signing up for treatments that permanently modify their bodies, but they may not fully understand the life-long consequences of their decision or acknowledge the potential risks and uncertainties of treatment. Their ability to provide informed consent has been questioned, including by some clinicians working in gender clinics.^{28–30} Are children of 12 and under really aware of what it will mean to become an infertile adult, who cannot have an orgasm and has to remain a patient dependent on hormones and medical care for the rest of their lives? Do girls know what it will mean in the future to have to undergo hysterectomy to avoid vaginal atrophy? It is also important to discuss openly that, although patients may decide in the long term to transition, they cannot eradicate the biological realities of their natal sex and will have to find some way of living with the losses involved. A full assessment and psychological engagement over a prolonged period can help the individual think through the social, psychological and biological implications of the medical interventions.

Comprehensive assessment

A thorough assessment process involves two parts. First, an extended open-minded psychotherapeutic approach has the capacity to create the conditions whereby the factors, conscious and less conscious, that have led to the presentation can be understood (it needs to be borne in mind that a large number of individuals present with ‘rapid-onset gender dysphoria’, suggesting underlying triggering factors). An understanding of the family and social context will, of course, be critical. This difficult psychological work needs to be carried out by experienced mature and sensitive clinicians, as it can easily be felt to be threatening, especially where the individual presents with strongly held convictions – for example many believe that only a change in physical sexual identity can bring them the relief they need. There is considerable evidence of children and adolescents changing their minds if given enough time and space to explore things. Second,

it is clearly vital that consent be fully explored. For example it will be important to gauge how much understanding the individual has of the implications of medical and surgical treatment. If an individual has no concern at all about the prospect and outcomes, this lack of concern should be thought of as *a symptom* that needs to be investigated and understood, rather than being treated superficially as a positive indication of their motivation. Unfortunately this kind of superficial approach is not uncommon. One needs to be able to empathise deeply with the individual's confusion, distress and mental pain, yet maintain adequate separation in order to be able to resist the pressure to join the patient in their view that active medical rather than psychological intervention is the only solution that can be even considered.

We must not forget our ordinary understanding of adolescence as a time of turmoil and considerable psychic pain as individuals have to come to terms with who they are, their strengths, weaknesses and limitations. Much of this, of course, centres on coming to terms with changes in the body and the new social roles that these changes demand. Gender services very often discuss only gender, with little mention of the relation with the changing sexual body. One young woman in my clinic, who was on a path to transitioning and then changed her mind, reported that there was no discussion of any biological realities in the pro-trans groups: 'Lots of talk about gender politics and none about the physical realities involved in transitioning'. The majority of children prescribed puberty blockers go on to take cross-sex hormones.

Gender conflicts are a normal part of development

We also need to bear in mind that adolescence is a time of experimentation that inevitably stirs up all sorts of conscious and unconscious confusions, doubts and conflicts which drive individuals to manage the anxiety and psychic pain through the use of powerful psychological defences such as denial, projection and splitting. When the child or adolescent is in danger of being overwhelmed there will be a tendency to focus on a fixed solution to deal with the most pressing concern, particularly the unbearable pain of confusion. The experience of being dislocated from one's body, which is changing rapidly in many ways, is not uncommon in adolescence. (This is perhaps one element of Kafka's classic tale *Metamorphosis* (1915) of a man who wakes up as a monstrous insect.) These feelings may be dealt with by premature foreclosure: 'I am not the gender of the biology I was born with; I am the other' – a statement that any experienced and mature clinician would resist through trying to create the conditions where confusion and psychic pain can be more tolerated. One of the central developmental tasks of adolescence is to come to terms with all sorts of realities, providing the basis for an integration of body and mind.

A political, rights-based approach to the treatment of children is at risk of forcing these complex psychological needs into the background. Pro-transitioning websites encourage children to view anyone who puts a different view, including parents, as suspect/the enemy; to self-diagnose and view the taking on of a trans identity as a wide-ranging solution to all their problems; to learn a script/obtain online tutoring so that the clinician who carries out the assessment will come to the 'right' conclusion, i.e. medical referral for transitioning. The so-called 'affirmative approach' persuades schools and others to accept unquestioningly the child's claims. Clinicians work in a take out zone where question is not welcomed. These various forces combine to ensure that these children very often get an assessment that is nowhere near adequate.

This radical disconnection of gender dysphoria from its potential roots in psychological disorder is fiercely promoted by pro-trans lobbies, who brand clinicians as 'transphobic' if they insist on a thorough psychological assessment of young people seeking to transgender/transition. That is, clinicians who are trying to protect the child from embarking prematurely on irreversible treatment are rebranded as a malign influence getting in the way of what the child 'needs'.

In 2019, Dagny, a young woman who later realised her mistake and seeks to live again as her natal sex (a 'de-transitioner') published an article about her experience of transitioning. She highlights the influence of the online site Tumblr and gives a very good description of the ways in which she internalised the ideals of the website:¹¹ "One of these unhealthy beliefs I held was the belief that if you have gender dysphoria, you must transition. And anyone that appeared to stand in my way was a transphobe – an alt-right bigot."

De-transitioners often describe being ostracised by the pro-trans group when they started to express doubts or question the treatment. Dagny writes that she became a different person when she started using Tumblr: "My online experience, having been affected by that level of groupthink, that level of moral policing and the constant implicit threats of social exposure and ostracisation made me an intensely internal and anxious person. It made me paranoid about the motives

of people around me – I saw my parents as bigots because Tumblr told me to; because they held out for so long to prevent me from starting hormones.’”

Children can also get online tutoring on how to get past the assessment process. *The Times* of 16 February 2019 also quoted David Bell as saying that they ‘have learnt through online resources [or] coaching from parents or peers exactly what to say in order to get the results they want’.²⁷

Many parents have expressed concern that school counsellors and child and adolescent mental health services are adopting an unquestioning gender-affirmative approach. They describe how, once children announced that they believed they were the wrong sex, practitioners immediately endorsed this belief, often after only one meeting. Politically driven proposals proclaim the right of the child to define their own identity. But this denies the fact that identity is developed in relation to internal and external realities, both of which remain outside the individual’s control. We do not control our biological inheritance and we cannot have complete control over the way we are seen by others.

Political pressure on institutions and research

The extraordinary grip of powerful trans lobbies is having the effect of silencing clinicians who fear them. Television producers and journalists continually report that, although clinicians at GIDS are willing to speak in confidence to them about their reservations of treatment in these areas, they shy away from being named for fear of the consequences – being branded a transphobic bigot. Some fear disciplinary action being taken against them by their trust. Kenneth Zucker, a well-known researcher and clinical lead of the Child, Youth and Family Gender Identity Clinic in Toronto, was sacked from his post after being accused of conducting ‘conversion therapy’. The centre had a policy of first trying to help the individuals deepen their understanding of themselves before recommending medical interventions. The investigation subsequently completely exonerated Zucker.³¹ James Caspian, a psychotherapist with considerable experience of working with transgender patients, has described his sudden realisation of the increasing number of patients who regretted the sexual reassignment they had undertaken. In 2019, he wrote that he had been contacted by more than 50 patients in the preceding 2 years. However, his proposal to carry out a formal research project to investigate this phenomenon was rejected by his university department for fear of a backlash.³² In 2018, Lisa Littman described the insights of parents whose adolescent children had recently adopted a transgender identity – a phenomenon she provisionally labelled ‘rapid-onset gender dysphoria’.³³ Littman’s paper prompted huge controversy: *The Guardian* called her work ‘a poisonous lie used to discredit trans people’ and the result was that the paper was withdrawn, only to be subsequently republished with only very modest revisions.³⁴

It is thus clear that this politically driven culture interferes with the freedom of thought necessary to work with these very troubled children and adolescents. It ceases to be possible for them to be assessed with an open mind, as individuals with their own unique difficulties and instead they become political symbols, actors in a wider ideological conflict – prejudice – and this is causing very serious damage.

Conclusions

The fantasy that the body can be rapidly sculpted as a way of being rid of profound psychological problems needs to come under much closer scrutiny. There is a great reluctance to even consider that the difficulties can be understood, at least sometimes, through the lens of body dysmorphia, where the individual becomes obsessed with a perceived physical flaw. Plastic surgeons are very familiar with patients who seek surgery to erase a psychological difficulty and refer these individuals accordingly. Medical and surgical interventions in those with gender dysphoria very often leave the underlying problems completely unaddressed. It is, of course, not the case that surgical interventions can remove all evidence of natal sex – which remains as a source of persecution, a constant reminder of the continued existence of an unwanted aspect of the self. Individuals need help and support in coming to terms with who they are, as part of the maturational process. However, patients often put enormous pressure on family, schools and clinical services to join with them in the belief that to transition to the ‘ideal’ body, i.e. to eradicate unwanted aspects of their body, is the only solution to their problems. Perelberg makes the point that, if the family or clinical service accepts this without sufficient question, then there is a ‘confusion of registers’, i.e. the patient acts as if they are convinced that a problem of self-representation existing in the mind can be cured by concretely treating the body. The cost is that the individual

is dissociated from their own body, treating it like a mannequin rather than a part of the self with anxieties, feelings and confusions.³⁵

Whatever decisions are made regarding medical treatment, a thorough psychotherapeutic and psychiatric assessment is essential to enable us to help these vulnerable young people, their families and their clinical teams make informed decisions. It is a process of opening up a dialogue with the individual about their motives, beliefs, the issues they are struggling with – and, crucially, trying to understand the complex role of gender identity in their more global functioning. A clinician has a duty to protect and this cannot be honoured without a thorough understanding of who the child is and how they arrived at the place they are.

Recommendations

Clinicians and patients need a service that is independent and protected from intrusions by pressure groups to force a rigid ‘one size fits all’ affirmative approach to gender dysphoria. NHS gender identity services have been functioning as if acting outside the ordinary requirement of good medical and psychiatric practice. The accusation of transphobia serves to shut down thoughtful enquiry and has been remarkably successful. As a result, the very thing that is most needed to protect children from harm is lost. This rapidly expanding and poorly understood phenomenon requires a new regulator tasked with appropriate oversight of gender identity services to ensure a more clinically rigorous, balanced and ethical approach to this complex area. Perhaps the Human Fertilisation and Embryology Authority (HFEA) developed to address ethical concerns in a rapidly expanding new field can provide the right kind of model.

1.2.69 Sex, gender and gender identity: a re-evaluation of the evidence

Lucy Griffin Katie Clyde Richard Byng Susan Bewley

Correspondence

Lucy Griffin (drLucygriffin@outlook.com)

date

2021-10

Abstract

In the past decade there has been a rapid increase in gender diversity, particularly in children and young people, with referrals to specialist gender clinics rising. In this article, the evolving terminology around transgender health is considered and the role of psychiatry is explored now that this

condition is no longer classified as a mental illness. The concept of conversion therapy with reference to alternative gender identities is examined critically and with reference to psychiatry's historical relationship with conversion therapy for homosexuality. The authors consider the uncertainties that clinicians face when dealing with something that is no longer a disorder nor a mental condition and yet for which medical interventions are frequently sought and in which mental health comorbidities are common.

pmc In 2018 the Royal College of Psychiatrists (RCPsych) issued a position statement to promote good care when dealing with transgender and gender-diverse people that relates to 'conversion therapy'.¹ In this article we reappraise the phenomenology of gender identity, contrast 'treatments' for homosexuality with those for gender non-conformity, analyse the relationship between gender dysphoria and mental disorders with particular reference to the younger cohort of transgender patients, and ask how psychiatrists can address distress related to gender while upholding the central tenet of 'first do no harm'.

Homosexuality and conversion therapy

Male homosexuality was outlawed in the UK in 1865 until the Sexual Offences Act 1967 decriminalised sexual acts between men. During that time, homosexuality was shameful, stigmatised and conceptualised as a mental disorder. Psychiatry was instrumental in its treatment, which continued even after the legal change.²

Attempts to 'cure' same-sex desire included psychotherapy, hormone treatment and various behavioural interventions. These interventions are now considered 'conversion' or 'reparative' therapy.³ One high-profile failure for such 'treatments' was Alan Turing. After being found guilty of gross indecency in 1951, he was prescribed oestrogen, which rendered him impotent and caused gynaecomastia. He died by suicide in 1954.⁴

Conversion therapies lost popularity as evidence emerged of their ineffectiveness,⁵ coupled with more tolerant social attitudes. Homosexuality was removed from the World Health Organization (WHO) ICD-10 classification in 1992. In 2014, the RCPsych published a position statement explicitly rejecting conversion therapy and supporting a ban.⁶ Same-sex orientation is regarded as a normal, acceptable variation of human sexuality.

Enshrined in the Equality Act 2010, lesbians and gay men in the UK now enjoy the same civil rights as heterosexuals in terms of healthcare, marriage and raising of children, and equal employment. Although they enjoy equal status and

increased visibility in most Western societies, there remain countries and cultures where same-sex practice is taboo or criminal, and where people still seek treatment.

Beyond sexual orientation

In recent years, increasing links have been forged between lesbian and gay communities and those representing other gender identities. Stonewall describes ‘any person whose gender expression does not conform to conventional ideas of male or female’ as falling under the umbrella term ‘trans’.⁷

Definitions have evolved beyond those included in the 1992 ICD-10 under ‘gender identity disorders’, with which psychiatrists might be familiar.⁸ Transsexualism was widely understood to mean ‘a desire to live and be accepted as a member of the opposite sex, and an accompanied discomfort of one’s anatomic sex’.⁸ Underlying mechanisms are poorly understood, although there are similarities and overlaps with both body dysmorphia and body integrity identity disorder.^{9,10} Sufferers might embark on social and medical intervention to help them ‘pass’ as the opposite sex. Historically, a diagnosis of gender dysphoria would have been required for doctors to intervene in this group.¹¹

Transgender, however, has become a much broader category (*Fig. 1*). New terminology reflects a conceptual shift from clinical disorder to personal identity.¹² Crucially, gender dysphoria is no longer integral to the condition. The World Health Organization has renamed ‘gender identity disorder’ as ‘gender incongruence’ and reclassified it as a ‘condition related to sexual health’ rather than retaining it in the chapter pertaining to ‘mental and behavioural disorders’,¹³ a somewhat discrepant placement, reflecting a political rather than scientific decision-making process. *Fig. 1A* page from *The Gender Book*¹² (reproduced with permission of www.thegenderbook.com).

By contrast, DSM-5 has removed ‘gender identity disorder’, renaming it ‘gender dysphoria’. It is possible to meet the criteria for a diagnosis of gender dysphoria within DSM-5 without experiencing body dysphoria relating to primary or secondary sexual characteristics,¹⁴ and the American Psychiatric Association emphasises that ‘not all transgender people suffer from gender dysphoria’.¹⁵

The following is from the 2018 ICD-11:¹⁶ “‘Gender incongruence of childhood is characterized by a marked incongruence between an individual’s experienced/expressed gender and the assigned sex in prepubertal children. It includes a strong desire to be a different gender than the assigned sex; a strong dislike on the child’s part of his or her sexual anatomy or anticipated secondary sex characteristics and/or a strong desire for the primary and/or anticipated secondary sex characteristics that match the experienced gender; and make-believe or fantasy play, toys, games or activities and playmates that are typical of the experienced gender rather than the assigned sex.’”

Definitions are inadequate in explaining how anyone experiences the gender of the opposite sex. Without further explanation of ‘toys, games or activities’ that are typical of each sex, this is left to parents, teachers and doctors to determine. The inference might be that gender-congruent behaviours have some objective existence and not fulfilling them might indicate a ‘trans’ identity. Children who do not conform to social norms and expectations come to dislike their sexual characteristics: that embodiment of their gender dissonance.

There is a lack of consensus demonstrated as to the exact nature of the condition. Questions remain for psychiatrists regarding whether gender dysphoria is a normal variation of gender expression, a social construct, a medical disease or a mental illness. If merely a natural variation, it becomes difficult to identify the purpose of or justification for medical intervention.

Conversion therapy relating to gender

The RCPsych gives a description within the position statement of ‘treatments for transgender people that aim to suppress or divert their gender identity – i.e. to make them exclusively identify with the sex assigned to them at birth’.¹ Conversion therapy is described as ‘any approach that aims to persuade trans people to accept their sex assigned at birth’. It goes on to include ‘placing barriers [to] medical transition’. Unfortunately, the statement does not define ‘approach’ beyond alluding to psychoanalytic or behavioural talking therapies. Thus, conversion therapy for transgender people appears conflated with that for homosexuality. Furthermore, there is little evidence that it is taking place in the UK.¹⁷ Historically, a diagnosis of gender dysphoria was required before medical intervention;¹⁰ this is a part of standard gatekeeping that is now being criticised as a ‘barrier’ instead of regular safe medical practice.² Now, a self-declaration of being ‘trans’ appears to be indication enough for a patient to expect their doctor provide a range of complex medical treatments, with no evidence of dysphoria being required.¹⁸

The position statement¹ could also be read as suggesting that full medical transition is an ultimate goal in gender-diverse patients, rather than considering a range of possible goals, which might include limited interventions or reconciliation with one’s own (sexed) body. With regard to conversion therapy in children, the statement does not refer to desistance; evidence suggests that the majority of children left alone reconcile their identity with their biological sex; the feelings of 60–80% of children with a formal diagnosis of gender dysphoria remit during adolescence.^{19–21}

Definitions of sex, gender and gender identity

Gender theorists propose that all people must have a gender identity; it is not waivable. For those people whose internal identity aligns with their sex, the word cisgender and ‘cis’ terminology are used. Those whose identity is wholly that of the opposite sex are described as transgender or ‘trans’. However, there are other identities for those whose internal sense lies somewhere between or outside a neat fit into either gender-binary category. Fluidity and fluctuation in gender identity is also recognised, with categories such as ‘non-binary’, ‘gender-fluid’, ‘genderqueer’, ‘pangender’ and ‘genderfuck’ all recorded by clinicians at the UK’s Gender Identity Development Service (GIDS) for under-18-year-olds.²² The social networking site Tumblr presently describes over 100 different genders.²³ Without a strong male or female identification, ‘agender’ becomes itself another gender identity.

Some consider gender identity to be fixed and absolute, with some neuroscientists asserting that it develops *in utero* in the second-trimester brain.^{24,25} However, there is little to no convincing evidence to support fundamental differences between the brains of females and males.²⁶ If one’s ‘internal sense of being a man or a woman’ no longer refers to a ‘man’ or ‘woman’ as defined by biological sex²⁷ then the definition of gender identity risks becoming circular.

Within current debates, if gender identity becomes uncoupled from both biological sex and gendered socialisation (*Box 1*), it develops an intangible soul-like quality or ‘essence’. As a pure subjective experience, it may be overwhelming and powerful but is also unverifiable and unfalsifiable. If this identity is held to be a person’s innermost core concept of self, then questioning the very existence of gender identity becomes equated with questioning that person’s entire sense of being, and consequently risks being considered a threat to the right to exist, or even as a threat to kill. Behaviours such as ‘misgendering’ or ‘dead-naming’ are understood by proponents of gender theory to be destructive, debasing and dehumanising.²⁸ This might explain why the prevailing discourse has become as sensitive and at times inflammatory as it has.

Box 1 Sex, gender and gender identity

Sex Humans are sexually dimorphic: there are only two viable gametes and two sexes, whose primary and secondary sexual characteristics determine what role they play in human reproduction. Sex is determined at fertilisation and revealed at birth or, increasingly, *in utero*. The existence of rare and well-described ‘disorders (differences) of sexual differentiation’ does not negate the fact that sex is binary. The term ‘assigned at birth’ suggests a possibly arbitrary allocation by a health professional, rather than the observed product of sexual reproduction.

Gender Gender describes a social system that varies over time and location and involves shaping of a set of behaviours deemed appropriate for one’s sex. It operates at an unconscious level via strong social norms, yet is also rigidly enforced by coercive controls and sometimes violence.¹⁸ The ‘rules’ exist regardless of how individuals feel about them. Gender can thus be perceived as oppressive and potentially painful to all people of both sexes within patriarchal societies, the dominant form of social structure across most, although not all, of the globe. Feminist theory holds that gender operates as a hierarchy, with men occupying the superior position and women the subordinate. As long as this hierarchy exists, all women are harmed to some extent, whether or not they conform to their sex stereotypes.¹⁹

Gender identity If sex refers to biology, and gender to socialisation and role, then gender identity may

be viewed as the psychological aspect. The American Psychological Association defines it as ‘someone’s internal sense of being a man or a woman’.²⁰ Gender identity is thus distinguished from biological sex and gendered socialisations.²¹

Nonetheless, notions of gender identity are still contested and raise some ethical questions for professionals working at the interface of physical and mental disorder. Most psychiatrists reject Cartesian dualism, whereby the mind is something imprisoned inside the body, or the ‘ghost in the machine’.²⁹ How should doctors consider the body? We are born as, and die as, a body; we *are* our bodies. How can someone be born in the wrong body? Many patients bring a ‘wrong’ or ‘wronged’ body to their doctor; these may be traumatised, wounded, diseased or disliked bodies. How should doctors react when someone informs them that, although they inhabit the body of a man, they are in all other respects female? We must deal with all our patients with compassion but also make safe medical decisions when demonstrable material reality is at odds with a patient’s subjectivity.

Children and adolescents

The Gender Identity Development Service (GIDS), Britain’s only specialised gender service for children and adolescents and based at the Tavistock Centre, London, has recorded a 25-fold rise in referrals since 2009, most marked in biological girls (‘assigned female at birth’), who make up the majority of referrals presently (*Fig. 2*).³⁰ *Fig. 2* Referral rates to the Gender Identity Development Service at the Tavistock Centre (Tavistock and Portman NHS Trust) in London between 2009 and 2019.³⁰

Despite gender dysphoria no longer falling within the remit of mental illness in ICD-11, there is a substantial body of evidence of increased levels of mental illness among adults, usually attributed to societal responses to gender non-conformity or ‘minority stress’.³¹ De Vries et al measured psychiatric comorbidity among those referred to a child and adolescent gender clinic in The Netherlands and also found increased rates of depression, anxiety and suicidal ideation in this younger group.³² However, a potentially worrying picture regarding causes and consequences emerges from more recent research in this young, increasingly natal-female population.

Kaltiala-Heino et al examined referrals to an adolescent gender identity clinic in Finland over a 2-year period, finding high rates of mental health problems, social isolation and bullying (*Fig. 3*).³³ Most bullying pre-dated the onset of gender dysphoria and was unrelated to gender incongruence. *Fig. 3* Referrals to an adolescent gender identity clinic in Finland over a 2-year period (from 2011–2013).³³

Similarly, in the UK, Holt et al³⁴ found that associated difficulties were common in children and adolescents referred to the GIDS in London (*Fig. 4*). Same-sex attraction was particularly common among natal females, with only 8.5% of those referred to the GIDS describing themselves as primarily attracted to boys. This raises important questions about current societal acceptance of young lesbians even within youth LGBTQ+ culture. It is possible that at least some gender-non-conforming girls come to believe themselves boys or ‘trans masculine non-binary’ as more acceptable or comfortable explanations for same-sex sexual attraction,³⁵ a kind of ‘internalised homophobia’. Autism spectrum disorders are consistently overrepresented in referred children and adolescents.³⁶ *Fig. 4* Referrals to the Gender Identity Development Service at the Tavistock Centre (Tavistock and Portman NHS Trust) in London between 1 January 2012 and 31 December 2012.³⁴ ASD, autism spectrum disorder.

The RCPsych’s position statement acknowledges these elevated rates of mental illness within the transgender population,¹ but appears to attribute them primarily to hostile external responses to those not adhering to gender norms (or sex-specific stereotypes).^{37,38} A deeper analysis of mental illness and alternative gender identities is not undertaken, and common causal factors and confounders are not explored. This is worrying, as attempts to explore, formulate and treat coexisting mental illness, including that relating to childhood trauma, might then be considered tantamount to ‘conversion therapy’. Although mental illness is overrepresented in the trans population it is important to note that gender non-conformity itself is not a mental illness or disorder. As there is evidence that many psychiatric disorders persist despite positive affirmation and medical transition, it is puzzling why transition would come to be seen as a key goal rather than other outcomes, such as improved quality of life and reduced morbidity. When the phenomena related to identity disorders and the evidence base are uncertain, it might be wiser for the profession to admit the uncertainties. Taking a supportive, exploratory approach with gender-questioning patients should not be considered conversion therapy.

Suicide, self-harm and current controversies

Transgender support groups have emphasised the risk of suicide. After controlling for coexisting mental health problems, studies show an increased risk of suicidal behaviour and self-harm in the transgender population, although underlying causality has not been convincingly demonstrated.³⁹ Then, expressed in the maxim ‘better a live daughter than a dead son’, parents, teachers and doctors are encouraged to affirm unquestioningly the alternative gender for fear of the implied consequences. There is a danger that poor-quality data are being used to support gender affirmation and transition without the strength of evidence that would normally determine pathways of care. One 20-year Swedish longitudinal cohort study showed persisting high levels of psychiatric morbidity, suicidal acts and completed suicide many years after medical transition.⁴⁰ These results are not reassuring and might suggest that more complex intrapsychic conflicts remain, unresolved by living as the opposite sex.

Established risk factors for self-harm and suicidal behaviour appear to be age related (younger trans patients are at higher risk) and include comorbid mental health problems, particularly depression, and a history of sexual abuse.³⁹ Thus, all new patients of any age warrant thorough assessment and formulation using a biopsychosocial model; the best evidence-informed interventions should be provided. If this is followed by an individual desisting it should not be considered conversion therapy. That term should perhaps be reserved for coercive treatments.

Best psychiatric practice avoids oversimplification of the causes and treatment of suicidal behaviour and self-harm. Preliminary data from a small ‘before and after’ pilot study of the use of puberty blockers at the Tavistock Centre in selected children found a reduction in body image problems in adolescents following a year of puberty suppression. However, positive effects were offset by increases in self-harm and suicidal thoughts.⁴¹ Surprisingly, this unpublished study was deemed a success such that prescribing of puberty blockers was introduced as standard practice and commissioned with scaling up of services. There was no development of alternative psychological approaches, nor were randomised controlled comparisons made.

Evidence suggests that almost 100% of children commencing puberty blockade go on to receive cross-sex hormones.⁴² This requires further interrogation to ascertain whether the high figures are due to robust, effective selection and gate-keeping or to a less palatable interpretation that preventing physical and sexual maturation crystallises gender dysphoria as a first step on a cascade of interventions.⁴³ The GIDS remains under intense scrutiny regarding research criticisms.⁴⁴ Although in the early 2000s it was criticised for being too conservative and not offering puberty blockers, there appears to have been a volte-face made in response to external pressure,⁴⁵ without the publishing of robust data showing that this intervention is effective and safe.

Puberty blockers are known to affect bone and, possibly, brain development. They put users at risk of developing osteoporosis⁴⁶ and are associated with reductions in expected IQ.⁴⁷ They are described as ‘buying time’ for adolescents to make up their mind about whether to proceed with transition. Long-term effects are not known, but infertility appears inevitable when cross-sex hormones are introduced shortly after puberty blockers.⁴⁸ Loss of sexual maturation will also be associated with lack of adult sexual function, although it is unlikely that a pre-pubertal child can truly understand this side-effect at the time of consent.

Those seeking transition are a vulnerable population who suffer from high levels of suicidality, psychiatric morbidity and associated difficulties. Medical and surgical transition is sought to relieve these psychiatric symptoms. Plausibly, there is an initial reduction in distress following transition, although no controlled trials exist. Therefore, the long-term outcome of medical and surgical transition in terms of mortality and quality of life remains unknown. No long-term comparative studies exist that satisfactorily demonstrate that hormonal and surgical interventions are superior to a biopsychosocial formulation with evidence-based therapy in reducing psychological distress, body dysphoria and underlying mental illness.

Clinical implications

It is unclear what the role of psychiatry is in the assessment and treatment of gender dysphoria, now that it is no longer considered a diagnosable mental illness, and whether there is still a place for a routine psychosocial assessment. It could be argued that patients should be deterred from gender intervention pathways while comorbid mental illness is treated (*Fig. 5*). Without long-term follow-up data, it is not possible to identify those who might reconcile with their sex and those who might come to deeply regret their medical and/or surgical transition. Moreover, it is not transparent where ultimate and legal responsibility for decision-making lies – with the patient, parents (if the patient is a child), psychologist, endocrinologist, surgeon or psychiatrist. *Fig. 5* Are these scenarios examples of good clinical practice or conversion therapy?

Psychiatrists understand that human development is necessary, but not always comfortable. Puberty, although a normal physiological process, is associated with particularly high levels of psychological and bodily discomfort. Psychiatrists' role is to journey with patients as change is navigated and to provide support through sharing uncertainty and difficult decision-making. But in the current climate, psychiatrists may be unsure whether addressing psychological and social antecedents will lead to accusations of conversion therapy. Attempts to reconcile a sufferer's discomfort with their actual body would be good practice in other conditions involving body image disturbance, such as anorexia nervosa.

The magnitude of any benefits of medical and surgical transition is not clear. Follow-up studies are sparse, and with the new cohort of adolescents, clinicians step even further into the unknown.⁴⁹ These young people are not comparable to adult, mainly male-to-female, research participants on whom existing empirical clinical guidelines were based. Doctors are now questioning the wisdom of gender-affirmation treatment of children and young people, citing poor diagnostic certainty and low-quality evidence.⁵⁰ A recent review of evidence for the use of gender-affirming hormones for children and adolescents states that these drugs 'can cause substantial harms, including death' and concludes 'the current evidence base does not support informed decision making and safe practice'.⁵¹

Among a plethora of online videos by teenagers proudly displaying their mastectomy scars a worrying increase in detransitioner testimonies can now be found⁵² (*Fig. 6*). These are mainly young women who have rejected their trans identities and are reconciling with their birth sex. *Fig. 6* Reasons given for detransitioning in a female detransition and re-identification survey run between 16 and 30 August 2016 and shared through online social networking sites.⁵²

Feminist concerns

In theory, universal human rights should not pit disadvantaged groups against one another, but in practice, disputes occur. Women's rights activists point to persistent global inequalities, sex discrimination and violence against women and girls. They are concerned that ignoring sex as a reality risks no longer being able to name, measure and ameliorate sex-based harms. Endorsing old sex and gender stereotypes in an attempt to validate young patients may inadvertently shore up outdated notions of how men and women should look and behave. There is no reason to believe that women have an innate love of pink and wearing high heels and find map-reading difficult, any more than men have a natural leaning towards blue and playing football and make excellent leaders.

Inherent in the notion of 'gender identity' is that there already exists a specific subjective experience of being a man or a woman. However, there cannot be a significant intrinsic experiential difference between male and female human beings when we cannot know what those differences are. One cannot possibly know how it feels to be anything other than oneself. Medicine may be in danger of reinforcing social norms and reifying a concept that is impossible to define over and above material biological reality. At present, many health, social, educational and legal policies are being adapted to give gender primacy over sex.^{53–57}

Conclusions

Language that confuses or conflates sex and gender identity, while appearing inclusive, might have the unintended consequence of closing down the means to understand complexity and respond appropriately to patients' emotional and material reality. The medical profession must be compassionate, accept differences and fight for those who are marginalised and discriminated against.

However, viewing transgender as a fixed or stable entity, rather than a state of mind with multiple causative factors, closes down opportunities for doctors and patients to explore the meaning of any discomfort. Being gender non-conforming, or wishing to opt out of gender altogether, is not only *not* indicative of mental disorder – it is, in many ways, an entirely rational response to present capitalist reliance on rigid gender norms and roles. However, when multiple medical interventions are required on an otherwise healthy body or doctors are expected to deny the concept of sex or the sexed body, the situation becomes less coherent. The notion of conversion therapy for those seeing themselves as transgender relies on another binary – that of 'cisgender' and 'transgender' – being set, closed, biologically anchored categories without overlap, rather than a more plausible hypothesis that one's gender identity is flexible, informed by one's culture, personality, personal preferences and social milieu.

The push for early bodily modification and hormones by some transgender patients is a cause for concern. New services, modelled on commissioning guidance from NHS England for adults of 17 years and above, will allow for self-referral, preclude psychological formulation or therapeutic intervention as standard practice, and recommend hormonal intervention after two appointments.⁵⁸ This will further scale up hormonal and surgical interventions in young patients, who will miss out on pubertal development and necessary mental health treatment in their quest for interventions that may harm and that they may later regret.

In the rapidly moving and politicised debate, psychiatrists look to the RCPsych for guidance. Those providing and interpreting the scanty evidence from published research need to be independent and impartial, using best-quality measures rather than ideology. It is confusing to liken open-minded working with young patients as they figure out who they are to conversion therapy. Holding an empathic neutral middle ground, which might or might not include medical transition, should not be equated with this. Psychiatrists need to feel empowered to explore the meaning of identity with their patients, treat coexisting mental illness and employ a trauma-informed model of care when appropriate.

The General Medical Council's Good Medical Practice demands of clinicians compassion, shared decision-making and safeguarding of young people's open futures.⁵⁹ The counterargument to unquestioning gender affirmation is that the process of medical transition may itself prove to be another form of conversion therapy, creating a new cohort of life-long patients dependent on medical services and turning at least some lesbian and gay young people into simulacra of straight members of the opposite sex. Psychiatry sits on this knife-edge: running the risk of being accused of transphobia or, alternatively, remaining silent throughout this uncontrolled experiment. Respectful debate, careful research and measurement of outcomes are always required.

We consulted a trans woman and a detransitioner for this article. We thank them for their input.

1.2.70 Response to Dr de Silva's letter

Gethin Morgan

2021-12

Contents

- *Response to Dr de Silva's letter*

pmc 02 December 2020

Dr de Silva's wide-ranging review of suicide prediction strategies is very welcome: it includes a number of useful new ideas on how our predictive efforts can be taken forwards. I do not wish to take issue with any of them. My own paper, however, focuses more narrowly on two specific issues. The first highlights the way in which ongoing variation in severity of intent, usually due to the random and unpredictable occurrence of stress-related events, can confound our predictive efforts, and I suggest how we might circumvent this. The second aims to show that, in spite of attempts to dismiss its value, the assessment of suicidal ideation can have a useful role in the prediction process, provided it is applied correctly and used appropriately. My approach is in the nature of risk assessment, which has been criticised by some as being too dependent on negative issues. I hope I have shown that by helping to identify future hazards and so anticipate ways of dealing with them, this is not just a negative process. A capable clinician should surely be able to ensure that such assessment does not compromise the establishment of a good trusting relationship with the patient. My overall hope for the future of suicide prevention is that polarised views, in which different approaches are seen as either good or flawed, will not prevail. Good points from each and every approach can then be incorporated into an overall synthesis of preventive strategy that can be used in clinical practice.

Abstract

Although the research base on mental health in intellectual disabilities is advancing, there are long-standing barriers that hinder successful completion of funded studies. A variety of stakeholders hold the key to mitigating the challenges and arriving at sustainable solutions that involve researchers, experts by experience, clinicians and many others in the research pathway. Lessons learned during the COVID-19 pandemic can also contribute to improvements in the conduct of research in the medium to long term. People with an intellectual disability and mental health conditions deserve high standards of evidence-based care.

pmc Research evidence is essential in supporting professional decision-making for the benefit of patients across health and social care. The benefits of participation in research include better outcomes and more efficient use of resources, with harmful or unhelpful treatments being phased out.

A major driver for funded applied health and social care research is the increase in research capacity and the completion of high-quality studies on priority topics that have been identified by stakeholders, including scientists and the public. In the UK, the substantial annual investment of more than £1 billion by the National Institute for Health Research (NIHR) supports both projects spanning the range of methodologies and the infrastructure to underpin the endeavour.

Recognising the challenges of investing and supporting research in health and social care organisations, NHS England and the NIHR published a joint report¹ that included 12 actions that would help to relieve the bottleneck many chief investigators encounter at the setting-up and recruitment phases. Two major stumbling blocks at the time were setting excess treatment costs with regard to treatment delivery, and research governance; the latter ranges from ethical approval to assessment of local capacity and capability in agreeing recruitment targets.

Although progress has been made, these issues, which are common in research activity across many different health and social care domains, have not completely resolved 3 years on. In this editorial we address a variety of both barriers to research and facilitators of research, with a specific focus on research in intellectual disability services. We argue that such problems may be relevant in research in other hard-to-reach populations who may or may not have cognitive impairment.

Since the launch of the NIHR in the UK in 2006, there has been an increase in the number of funded studies investigating a variety of research questions in intellectual disabilities, including developing, adapting and testing interventions in randomised controlled trials (RCTs). The majority of these are trials of psychosocial interventions. However, the portfolio of studies remains small compared with other fields of medicine, estimated at 1.4% of all NIHR-funded studies.²

People with intellectual disabilities (global developmental delay evident in childhood that affects adaptive functioning) account for approximately 2% of the population in the UK and are more likely to suffer health-related multimorbidity, higher and earlier mortality and face significant inequalities.³ Many lack capacity and therefore decisions about their participation in research depend on families' and paid carers' understanding and attitudes towards research projects and research processes. This is because they may be called on to act as consultees to enable participation of those most vulnerable. It is therefore essential that people lacking capacity should also be able to take part in and benefit from research specific to people with intellectual disabilities, with appropriate safeguards as mandated in the Mental Capacity Act 2005 or equivalent permissions internationally.

Barriers

Despite the amount of research conducted over time, many challenges that have been reported previously still remain and have an impact on the completion of studies. Lennox et al⁴ described identification of substantial numbers of participants, frequent need for substituted decision-making, occasional limited literacy of both person and carer, and organisational gate-keeping practices as significant barriers to recruitment in an RCT of health checks in Australia. More recently, a systematic review of 53 papers reporting RCTs in people with intellectual disabilities published between 2000 and 2017⁵ identified similar barriers in recruiting to target, participant treatment preferences, engaging with stakeholders, obtaining consent and staff turn-over. Optimistically the authors concluded, 'conducting RCTs with people with cognitive disabilities can be challenging, however, with reasonable adjustments, many of these barriers can be overcome'.

People with intellectual disabilities are excluded from research that may be relevant to their health vulnerabilities,² as well as being sceptical about the impact of it on their lives. This is illustrated by the Research Voices project,⁶ which revealed a number of serious concerns that parents of people with profound and multiple disabilities harbour about research, such as mistrust of health professionals seeking participants for studies, the emotional and time burden of research assessments, frustration with not knowing the findings or findings not translating to real improvements in practice.

Research infrastructure brings its own multifaceted challenges. The role of clinical research practitioners (CRPs) (who are National Health Service (NHS) based and able to recruit from services directly) is not fully understood by intellectual disability services and there is significant variation among the operations of clinical research networks across the different UK countries. Therefore, professionals in the services may be asked to undertake recruitment in addition to an already busy clinical role. Further, data guarantors are frequently local authorities, who are providers of social care services not directly connected to the NHS in England. Finally, intellectual disability services that are located outside NHS structures have fewer opportunities to be informed of ever-evolving research processes, thus remaining unable to utilise available resources to assist them in incorporating and supporting research in their day-to-day practice.

Clinician factors are also important in maintaining non-engagement in research activities, including older age, being male and working in the private sector.⁷ Oliver-Africano et al⁸ identified beliefs about drug efficacy, potential ethical conflicts in medication trials and multidisciplinary team processes as having adversely affected recruitment to a clinical trial of antipsychotics in adults with intellectual disabilities. Delays associated with any of these factors inevitably matter in completing studies that depend on time-sensitive research contracts and are likely to hamper the validity of the research findings if there is underrecruiting.

Finally, clinicians and scientists in general may not make sufficient effort to include participants from underrepresented groups in their studies, thus perpetuating the limited access of people with intellectual disabilities in research. This is particularly important for diseases where it has been demonstrated that there is excess morbidity and/or mortality in this population.⁹

Facilitators

Prioritisation of research is likely to confer benefits to both health and care organisations, as shown by views reported in a review of engagement in research:¹⁰ “The wider review demonstrated [...] how collaborative and action research can encourage some progress along the pathway from research engagement towards improved health-care performance. There is also evidence that organisations in which the research function is fully integrated into the organisational structure, out-perform other organisations that pay less formal heed to research and its outputs.” These lessons, although not specific to intellectual disabilities, are relevant in this context as presenting a justification for embracing research by the multitude of service configurations delivering care to this population.

In other changes to research governance, the new Health Research Authority has halved the time needed to obtain regulatory approvals,¹¹ although other milestones along the research pathway remain areas of concern.

Although the funding for research in intellectual disabilities may be lower than what is essential for investigating the increased morbidity, mortality and the health inequalities seen in this population group, there is an emerging cohort of completed high-quality studies. There are also many committed researchers, healthcare service professionals and other staff whose enthusiasm and problem-solving capacity signal their willingness to engage with the process. These may further promote interest in research by influencing national clinical practice and through targeted dissemination, including to people with intellectual disabilities and their carers. Clinician familiarity with academic work, peer support and support from management are also likely to increase positive attitudes towards research. Research that is seen as arising out of patient concerns and that could lead to tangible benefits in interventions and care improvements is also likely to be supported.⁶

Recently the NIHR Dissemination Centre published a themed review on intellectual disability research.¹² More than showcasing the funded projects, it highlighted the meaning of the findings for the care that people with intellectual disabilities and their family carers receive. In addition, the collection of studies included in the review demonstrate that funded research can be conducted successfully in the field of intellectual disabilities but that all the studies have had significant involvement of people with intellectual disabilities and their family carers throughout. These studies are examples of good practice that can be shared between researchers, people with intellectual disabilities, their carers and charities supporting them.

Solutions

A primary area for mitigation lies in health and social care professionals’ and people with intellectual disabilities’ conviction of the importance of research and its wider contribution to lives and well-being. A recent course¹³ devised to train people with intellectual disabilities in research methods suggests that learning about conducting research and driving the research process is feasible. Such courses could increase the number of suitably trained people with intellectual disabilities who could be recruited to work as researchers in various projects.

Incentives for encouraging donation of time to research activities by family and paid carers may improve uptake and retention, alongside other strategies. Increasingly, experts by experience are being asked to interpret and comment on research findings and this is a way of increasing familiarity with research processes, as well as consumer feedback.

The well-intended efforts of paid carers to protect vulnerable adults if they lack capacity, including the personal data protection regulations, often stifle participant recruitment. In England and Wales, this could be addressed by a revision of the Mental Capacity Act 2005. Heywood et al¹⁴ outlined how the Act is predominantly focuses on treatment and decision-making within a ‘best interests’ framework, rather than on research where decisions are not made using that framework. The sections of the Act governing research do not effectively balance protection and empowerment, and researchers may be reluctant to include participants who lack capacity in research projects.

The research community may also need to take some responsibility in providing solutions to the present challenges. Being clear about what the findings mean to the wider group of people with intellectual disabilities, proactive dissemination strategies and other activities in engaging the public with research are paramount in moving forward. Research aims to shape service delivery and to translate advances in science into measurable benefits for the population at large. It is questionable whether consumers consider research findings relevant to their health and whether those who commission services apply research findings to enhance clinical effectiveness and value for money.

An example of fostering closer links between clinicians, academics and people with lived experience of intellectual disability is the newly formed RADiANT consortium, a platform that works to increase health and social care staff's awareness of research and develop research skills and capacity. The consortium is focused on mental health and behavioural problems in intellectual disabilities, autism and other neurodevelopmental conditions (see radiant.nhs.uk for more information). So far it has produced guidance on how to manage the COVID-19 pandemic in different mental health settings and has delivered several educational activities. Its wider impact remains to be established.

Professional bodies across all professions must also promote research-related objectives in training curricula and on public-facing forums such as websites and newsletters.

Strengthening health and social care links is an area for further development, especially as social care is identified by NIHR as a domain for research investment. This means extension of the research infrastructure to reach the neglected care sector, which is central to accessing individuals to take part in research activities as proxy informants.

The coronavirus pandemic has shown that, while continuing to endorse ethically conducted research, it is possible to do so at pace.¹⁵ It will be important to remember those lessons as we are coming out of the pandemic and in the event of future public health emergencies. In particular, they can inform how to carry out remote research assessments and interviews with participants with intellectual disabilities and ensure that the voice of experts by experience remains central to research activity. During the pandemic, people with intellectual disabilities have been disproportionately affected in both their health and social care needs and require high standards of support in both. We must be able to reassure them and their families that being partners in research pays off in achieving those standards.

Correspondence

Dr Anne Aboaja (anne.aboaja@york.ac.uk)

date

2021-12

Abstract

Aims and method

Patient and public involvement (PPI) is a priority for health research. PPI improves the relevance and quality of research. The study aimed to involve service users in identifying research priorities for the service. A two-phase adapted Delphi technique was used to generate a list of research topics from service users in secure in-patient mental health settings and on specialist mental health prison wings. Topic content analysis was undertaken. Service users were further consulted, and research themes were ranked in order of priority.

Results

Of the eight research themes identified, the three given the highest priority by service users were, in descending order, physical health, future plans and moving on, and causes of illness and crime.

Clinical implications

Service users are willing to be involved in setting research priorities for mental health services. Through non-tokenistic PPI, service users can uniquely shape the research agenda of mental health services.

pmc Patient and public involvement (PPI) is a strategic priority for the National Institute of Health Research,¹ enabling stakeholders to have roles other than as research participants throughout the research process.² Despite the barriers,³ challenges of time and methodological conflict, PPI can bring benefits to research.⁴ It improves the relevance and quality of research,¹ and increases recruitment success.⁵ Researchers in this field have evidenced the value that the PPI perspective can bring to research,⁶ but caution using tokenistic approaches. Utilising a devolved model of working with user-led organisations or groups can support effective involvement,⁷ as long as all parties clearly understand the underpinning philosophy. A related approach of using a reference group specifically established to guide and assist with the conduct of a research project is also recognised as valuable.⁸

The Tees Esk & Wear Valleys NHS Foundation Trust's forensic directorate aims to significantly increase research activity. Although forensic mental health priorities have been previously proposed, they have arisen from studies that did not include service users,^{9,10} focused on specialist areas outside of in-patient¹¹ or prison settings,¹² and sought consensus between service users and professionals.¹¹ This paper describes how non-tokenistic PPI through adapted Delphi methodology can be applied in a forensic service, to identify service user priorities for research.

Method

Setting

The forensic service has 18 in-patient clinical areas, offering 224 medium-secure, low-secure and locked rehabilitation beds to adult males and females with a range of mental disorders, intellectual disabilities (also known as learning disabilities in UK health services) and autism spectrum disorders. The service also provides mental healthcare to 11 prisons in the north of England and to patients in the community. Within the prison system, there are 29 beds across two specialist mental health wings (clinical areas). Each of the 20 clinical areas holds a regular service user-led community meeting with staff support. The meeting is used to share information, elicit views that may be passed on to service managers and discuss items of interest to the in-patient experience. Attendance and participation at these meetings is voluntary. There is also a community service that does not have equivalent service user community meetings.

Ethical approval and service user involvement

No identifiable participant data were collated, and all data were collected through existing service user meetings. Ethical approval was not required for this study, which was accountable throughout to the Forensic Speciality Development Group in Tees, Esk and Wear Valleys NHS Foundation Trust. The project proposal was approved by the hospital-wide service user group, whose suggestions shaped study design.

Design

The Delphi technique is an established methodology that has been used widely in psychiatry to consult with and build consensus among experts in the field.¹³ A two-phase modified Delphi exercise was undertaken in which service users were consulted as experts by experience of the forensic service. An iterative process was followed to obtain consensus on the most important research themes.

Participants

All users of services who were available and willing to attend an established community meeting in one of the clinical areas were eligible to participate in the exercise. Service users in prison who were not on a specialist mental health wing and users of forensic community mental health services were therefore not eligible to participate.

Delphi process: phase 1 – obtaining the initial views of service users

A consultation form was developed for use in community meetings. The form comprised three sections. In the first section, a succinct definition of research and examples of health research questions unrelated to mental health were given; for example, ‘what causes heart attacks?’, ‘what is the cure for cancer?’ and ‘which shampoo will make your hair grow faster?’ The second section provided information about the purpose of the exercise, rationale for consulting service users, the constitution of the project team, anonymisation of responses given and the extent to which the findings would be shared. In the final section, three prompt questions were listed to elicit relevant responses about research priorities: What questions should researchers in this service try to answer? What discovery would you most like researchers to make? What do you think we need to know more about in forensic services?

The consultation form was emailed to a senior nurse in each clinical area, with a cover letter explaining the background to the project and how to use the form to elicit and anonymously record service user views. Instructions were given to record the numbers of patients on the ward, at the meeting and contributing to the process. The importance of service user voluntariness in participating in the exercise was highlighted. The senior nurse was asked to present the form during a community meeting and invite service users to answer the three questions. Answers were written down on the form, which was returned to the project administrator.

Delphi process: phase 1 – analysing the initial views of service users

Two consultant psychiatrists and an in-patient nurse from the project team jointly undertook content analysis¹⁴ of all responses, by hand. Disagreements were resolved through consensus. An inductive–deductive approach was used to move from a large number of specific research questions and objectives provided by participants to a smaller number of general research topics.¹⁴ Each individual response was read and grouped into one category with similar responses. Each category was given a title that summarised the content of the associated responses. Then, responses in each category were reviewed in turn, to consider whether it would be more appropriate to place each response in an alternative category. This step ensured that each category accurately reflected the content of the respective responses. Next, categories that were considered similar were combined. Category titles were broadened to incorporate very small groups and single responses that could not be grouped elsewhere. Principles for the iterative analysis were to avoid single-response groups, to accurately represent service users’ responses and to identify between approximately five and

ten themes. This target number of themes was chosen to ensure the service user voice was not lost through excessive combining of responses, resulting in a small number of themes. Similarly, the aim was to avoid a very long list of themes, which would be less useful in identifying the specific areas of research that should be prioritised. The final categories represented an unranked list of research priorities.

Delphi process: phase 2 – obtaining prioritised views of service users

The results of the analysis were listed as themes on a follow-up consultation form, which defined research, explained the purpose of the project, described the first phase of the Delphi process and highlighted the voluntariness of participation. To avoid responder bias associated with the ordering of the themes, the themes were displayed in a circle on the follow-up consultation form. The form and a cover letter were sent to a qualified member of staff in each clinical area who had responsibility for disseminating research information (the Research Champion). The cover letter provided instructions on how to obtain anonymised responses from service users during the community meeting. Research Champions offered copies of the form to willing service users present at the community meeting, who were invited to circle their top three priority areas for research. The Research Champion returned completed forms to the project administrator.

Delphi process: phase 2 – analysing the prioritised views of service users

Two consultant psychiatrists, a ward-based staff nurse and a senior nurse working in the prison service met to analyse the completed follow-up consultation forms from phase 2. The themes identified in phase 1 were listed on a whiteboard. Each response form was considered in turn by the analysts, jointly. A mark was added alongside each theme on the whiteboard every time that theme was circled as a priority theme on a response form. After reviewing all responses, frequency counts were calculated for each theme. The themes were then ranked according to the number of service users who had considered each theme to be one of their top three research priorities. The overall top three research priorities were highlighted.

Results

Participation in the Delphi process

Service users from 20 clinical areas (18 wards and two prison wings) were eligible to participate in each phase of the Delphi process. Some clinical areas did not provide details of the number of service users who attended the community meeting or proposed priority research areas in phase 1. Therefore, the overall response rate in phase 1 was calculated with the number of participating clinical areas rather than individual service users.

Of the 20 clinical areas invited to participate in phase 1, responses were received from six clinical areas (five wards and one prison wing) (*Table 1*). In phase 2, five clinical areas, including one prison wing, returned completed follow-up consultation forms from 27 service users (*Table 1*). Based on the number of beds in the service ($n = 253$), this is equivalent to 10.7% of the total number of eligible service users. *Table 1* Participation of service user clinical areas in phases of the Delphi process

Participation in phase 1	Participation in phase 2	Participation in both phases	Participation in at least one phase	
Number of clinical areas responding	6 (30%)	5 (25%)	1 (5%)	10 (50%)
Number of clinical areas not responding	14 (70%)	15 (75%)	19 (95%)	10 (50%)
Number of clinical areas invited to participate	20 (100%)	20 (100%)	20 (100%)	20 (100%)

There was overlap of clinical areas participating in the two phases of the Delphi process, with service users from one (5%) of the 20 clinical areas participating in both consultation phases. Although most services users were not involved in both phases, service users from half ($n = 10$, 50%) of all clinical areas, including both prison wings, participated in at least one of phases of the Delphi process (*Table 1*).

Profile of service users participating in the Delphi process

Male and female service users from both prison and in-patients clinical areas participated in the study (*Table 2*). Input during at least one of the Delphi process phases was received from service users within hospital-based clinical areas of all three levels of security provided by the forensic service. However, females in the locked rehabilitation clinical area were not involved in the study. Services users with a mental disorder, as well as those with an intellectual disability or autism, participated in the Delphi process. *Table 2* Description of the clinical areas in which participating service users resided Clinical areas involved in the Delphi process of identifying research priorities Male Female Prison Yes Yes In-patient Medium security Yes Yes Low security Yes Yes Locked rehabilitation Yes No Mental disorders Yes Yes Intellectual disabilities and autism Yes Yes

Identification of research themes that are important to service users

Service users offered 63 suggestions for research in the first phase of the Delphi process (*Table 3*). The suggestions were written in a combination of questions and statements. Eight research themes were identified through thematic analysis (*Table 3*). The second phase of the Delphi process revealed how 10.7% of all service users across the forensic service prioritise these themes. The top three priorities for research are, in descending order, physical health, future plans and moving on, and causes of crime and illness. Other themes of importance are treatment and cures, length of stay, trust and attitudes, purpose of life and dealing with change. *Table 3* Research priorities as ranked by service users Examples of responses received in Phase 1 Themes identified in phase 2 Ranking in descending order of priority Best way to lose weight? Physical health! The correlation between medication and physical health well-being My metabolism has slowed, how do I get it going again? Best way to lose weight off the stomach? How does being in a forensic service affect your chances of getting a job? Future plans and moving on 2 Anxiety about leaving [prison mental health service] Will I always need medication? What causes offenders to reoffend? Causes of crime and illness 3 We need to know more about autism Information on eating disorders Is there a cure [for] self-harm? Treatment and cures 4 We should make treatment shorter (DBT [dialectical behaviour therapy] is too long) Could we cure LD [intellectual disability]? To have a tablet that cures everything We should try to make people's stay in hospital shorter, not waiting for treatment Length of stay 5 Discover the length of time you are going to be in hospital Attitudes of staff in prison Trust and attitudes 6 Trust issues with officers Attitudes of healthcare staff... they make me nervous More about what you want from life Purpose of life 7 What is the purpose of life? Why are you born to die? Changes in staff is destabilising Dealing with change 8 How to cope with change The impact of staff leaving [prison mental health service]... it's difficult to have staff change so frequently

Discussion

Research that is to have a meaningful impact on the care, experience and recovery of those who use forensic mental health services must involve service users from the start of the research cycle, at the point of setting research priorities. First, this study showed that PPI research methodology was effective in involving some, but not all, male and female service users in both prison and hospital settings who have a mental disorder, intellectual disability or autism. Second, through this adapted Delphi approach, services users identified eight research priorities for forensic mental health and intellectual disabilities.

It is notable that service users place a high value on health research with a holistic conceptualisation of health, including physical, mental and spiritual (existential/‘purpose of life’) domains. The list indicates that service users with a history of mental disorder and offending are interested not only in obvious aspects of forensic mental health, such as mental illness, crime and treatment, but also in staff relationships (‘trust and attitudes’) and the aetiology of their difficulties.

Contextualisation of findings

In the present study, physical health was ranked as the top priority, with a focus on weight loss. Surprisingly, this theme did not feature in the lists generated from earlier exercises to establish the research priorities in forensic mental health.^{9,11,12} The explanation for this notable difference may lie in the recent incentivised drive by commissioners of secure mental healthcare in England for providers to take demonstrable steps to improve physical health, particularly through achieving a healthy weight.^{15,16}

There was overlap with the findings of a previous study showing that service users, as well as professionals, prioritise epidemiological research into factors associated with crime and recidivism, and research oriented toward recovery topics such as the future use of mental health services and employment.¹¹ Further consistency was found in the high priority given by both clinicians and service users to research about effective treatments and interventions.¹⁰⁻¹²

This finding of common interest is not surprising, given the partnership nature of many treatments involving the professional, who delivers, prescribes or administers the treatment, and the service user, who accepts or refuses the treatment that may cause harm, benefit or no effect. However, although previous studies mentioned treatment as a research priority, service users in the present study clearly linked treatment to cure. Current understanding among mental health clinicians and academics about the nature of disorder, disease, disability and concepts of recovery, diversity, social inclusion, person-centred care and stigma may partly explain why research questions such as ‘could we cure LD [intellectual disability]?’ which are important to some service users, are less likely to be posed by professionals in a research priority-setting exercise.¹⁷

The advancement of risk assessment in forensic mental health is consistently reported as a research priority in studies based on literature review, professionals-only groups or mixed professional and service user groups.⁹⁻¹¹ Although it is not clear why risk assessment did not feature as an important research area in the present study, which involved only service users, it is proposed that this topic might be of lesser importance to service users and greater interest to professionals, whose roles involve assessing and managing risk.

It is also notable that in contrast to a larger international study of research priorities for mental health and justice, the present study of service users lawfully detained in either a prison or secure hospital under the Mental Health Act 1983 did not recommend research into legislation and policy.¹¹ Length of stay in hospital emerged as one of the new research priority areas in the present study. Although it may appear surprising that this was not a theme, given priority in previous studies, it may be that addressing other themes widely reported, such as treatment, may ultimately have an effect on overall length of stay.¹⁸

Strengths and limitations

It might appear that the responses of service users point to areas that have been extensively researched. For example, much is already known about effective weight loss interventions in the general population. Although such responses may reflect limitations of the phrasing of questions used to elicit the initial views of service users, they may also reveal a lack of evidence of context-specific effectiveness and acceptability of interventions in forensic services.¹⁵ This is evident by the aforementioned current emphasis on finding effective ways to achieve weight loss among service users in secure mental health settings.

The use of existing consultation structures is recommended for ascertaining the research priorities of service users within forensic mental health services.¹⁹ The community meeting was, therefore, an appropriate forum in which to obtain the research opinions, because service users were already accustomed to voluntarily making suggestions to improve the service in this group setting. In contrast, a formal panel meeting may have been less accessible to some in-patients and prisoners.¹⁹ Although the presence of staff and other service users might have influenced responses provided, the wide range of individual answers given, including criticism of staff attitudes, suggests that group bias was not significant.²⁰

There is little evidence to guide sampling approaches in PPI, although convenience sampling is most commonly used.²¹ The modest response during both phases of the study is a significant limitation, and may reveal lack of interest in or apathy toward research among the service user group. It is possible that such explanations may relate to psychopathology experienced by potential participants; for example, anhedonia in a depressive episode, or apathy as a negative symptom

of schizophrenia. Alternatively, some service users may have limited understanding of research and the value of service user involvement in research. Unknown factors relating to the level of research interest among staff responsible for presenting the study to service users at community meetings may have contributed to the low response rate. Although the final list of priorities generated from the views of a small proportion of service users is valuable, it may not reflect the views of those service users who did not respond.

A strength of the study is effectively reaching a wide range of service users, with differing risk and health needs. The methodology of involvement was successful in increasing research involvement access to service users who, (because of reasons relating to health or risk) may not have had the opportunity to leave the ward or wing to attend a formal group meeting of service user volunteers, without limiting involvement to a select sample of existing service user representatives.²¹

Consideration was given from the outset to the evidence-based approaches to avoid tokenism and collaborate with user-led groups in a way that clearly explained the philosophy of the project. However, a formal reference research group of service users did not exist at the time of the study, although the generic (non-research) service user group was already established. Consultation with this service user group helped to shape the study design; ongoing consultation with the group may have been valuable in finding ways to increase the response,⁵ and to reduce sample bias.²⁰ Although the involvement of professionals from in-patient and prison settings, as well as nursing and medical disciplines, ensured a healthy range of perspectives during the thematic analysis, service user involvement at this stage for collaborative data analysis would have further strengthened the study.²²

Implications and future directions

To our knowledge, this is the first study to use PPI principles and the Delphi technique to establish research priorities from the exclusive perspective of service users within a forensic service for mental health, intellectual disabilities and autism. The methods showed how a mental health service can overcome barriers³ and involve its users to identify priority areas of research. By contributing to research priority-setting exercises, service users demonstrated that they wish to express their views on the greatest research needs for forensic mental health services. It also revealed a willingness to be involved at the earliest stage of the research process, and a desire to influence the work of researchers in the field. Comparisons with similar studies highlighted the importance of understanding the service user perspective separately from that of professionals.

The eight research priorities were adopted immediately by the forensic service, serving as a checklist against which all proposed research is considered before service-level approval. Additional weight is given to proposed research in an area falling within one of the top three themes. Rarely should research be undertaken within the service that does not link directly or indirectly to this list. Embedding the service user perspective to this degree avoids tokenistic involvement,⁶ and allows service users, as experts by experience, to directly shape research strategy and influence future research. Findings have been shared with service users, senior managers and staff working across the forensic service. Although the scope of this study was limited to the service user perspective, further study is required to explore the extent to which the research priorities of clinicians working in this forensic service are aligned with those proposed by service users, and to understand any differences.

There is a lack of evidence to guide the best method of achieving engagement.²¹ There is benefit in exploring the enablers and barriers to PPI in research that involves service users in a forensic service. Early conversations should commence with representatives from community service users and carers/friends/families of service users, to develop appropriate methodologies for obtaining the views on research priorities from these two groups. The development of a carer research reference group may be an effective approach to carer involvement with this process.⁸

Further consultation with service users is required to develop a strategy to support ongoing involvement, ensuring that future research questions, methods and outcomes are acceptable and relevant to service users. The exercise of setting research priorities from the service user perspective could be repeated at 5-year intervals, to ensure that the service continues to prioritise research that is relevant to those who would benefit from the service. Given the expected benefits of PPI, the challenge is to evaluate the impact of this early service user involvement in setting research priorities, on subsequent phases of the research process and future service user involvement in, and engagement with, research.^{23,24}

1.2.73 Patients in mental healthcare should be referred to as patients and not service users

Stefan Priebe

Correspondence

Stefan Priebe (s.priebe@qmul.ac.uk)

date

2021-12

Abstract

Over the past few years the term ‘service users’ has been increasingly used to describe patients in mental healthcare. This paper argues that the term ‘service user’ in this context should be avoided and outlines four reasons: the term is discriminating, cynical, patronising and detrimental. Of course, none of these effects is intentional, but that does not change them. The term ‘patient’, however, describes appropriately a temporary role in healthcare, provides parity of esteem with patients in physical healthcare and reflects the reasons why large parts of society are willing to fund healthcare, in solidarity with those who are sick.

Contents

- *Patients in mental healthcare should be referred to as patients and not service users*
 - *Discriminating*
 - *Cynical*
 - *Patronising*
 - *Detrimental*
 - *Conclusions*
 - *Declaration of interest*

pmc The terms with which we name similar objects and roles can change over time. One reason may be that a term is seen as devaluing or linked with connotations that one would like to change. Psychiatry has a long history of examples of this. Terms such as ‘madness’ have been replaced by more medical terms such as ‘mental disorders’ to emphasise that one is dealing with a health problem. Another example is seen in the former asylums, which tended to change their names to avoid the negative connotations associated with a previous name that had been built up in the population over time. For example, the Karl-Bonhoeffer-Nervenlinik (last of the changed names) in Berlin changed its name four times within a period of only 100 years.¹

Recently, there has been a shift in the National Health Service (NHS) towards calling patients in mental healthcare ‘service users’ instead of patients. The term is used in guidelines published by the National Institute for Health and Care Excellence (NICE),² in publications of voluntary organisations³ and in prestigious scientific journals.⁴ Of course, every individual should be entitled to be addressed in any way they like, but the question is whether the term service user should be generally used when referring to patients.

I will argue that the term service user should be avoided, for four reasons: because it is discriminating, cynical, patronising and detrimental. Of course, these effects are not intentional, but that does not prevent their ultimate harm.

Discriminating

The term patient describes a temporary and context-dependent role. When I see my general practitioner (GP) in their clinic, I am a patient. When I see the same person in a different context, we have different roles. I may be a neighbour, a fellow passenger on the same bus, a father of a child that goes to school with their child, or the GP may even be a patient in my clinic. There are endless possibilities. However, the term patient is a precise description of a temporary role in a professional health service, without any negative connotation. Health services have patients, whereas lawyers, insurance companies and restaurants have clients or customers or consumers, but never patients. The term patient applies to all types of health service and has only rarely been challenged outside mental health. If mental health services now diverge from other health services and decide to call their patients by another term, they turn their patients into something different. Parity of esteem – defined as ‘valuing mental health equally with physical health’⁵ – is undermined when mental health services use terms that distinguish their patients from patients in other services and, thus, discriminate against their own patients.

Cynical

Service user, as a term, suggests that the people in question either ‘use’ the services actively or that the service has been of ‘use’ to them. Neither of these assumptions necessarily applies. In England alone, more than 50 000 times a year patients are treated involuntarily, i.e. against their wishes and involving specific legislation that allows such coercion.⁶ One can hardly claim that those people ‘use’ the service, just as prisoners are not ‘prison users’. Also, although mental healthcare is hopefully beneficial to many patients, it would be grandiose of professionals and others to believe that mental healthcare helps everybody. Thus, it is not universally of ‘use’ and there is no question that in some cases – despite the best intentions of all people involved – it might even be harmful. Thus, both suggestions of the meaning of ‘use’ that are inherent in the term service user may be regarded as cynical.

Patronising

A number of surveys have asked patients in mental health services which term they prefer to be used. The results of these surveys are consistent. The majority of patients prefer the term patient, and this applies across studies that have been conducted at different times and in different settings.^{7–9} Insisting on a term that most of the patients explicitly do not want may be seen as patronising.

Detrimental

This may be the most complicated of the four points. Healthcare – at least in most European countries – is paid for through the solidarity of the population, either by sharing contributions and benefits through health insurances or in tax-funded healthcare systems. With respect to the NHS in the UK, most people in the population have little problem with paying their taxes so that people who suffer from illnesses can receive proper healthcare when they need it. This may be motivated by the expectation that each taxpayer will also receive tax-funded care when they need it, but is also based on cultural values (e.g. of Christianity and Enlightenment) and the compassion for those who suffer. As a society we accept that some people are sick and need professional – and potentially expensive – treatment for as long as they are sick. This is reflected in the term patient (originating from the Greek ‘pathos’ and Latin *patiens*, which denote suffering). When mental healthcare providers expect the population to fund their work, then the term service user is not helpful. It rather evokes the idea of a ‘service’ that someone decides to use or not to use, instead of the professional care that some people receive because they are so seriously distressed that they need that care.

Conclusions

I would therefore argue that the term patient should be re-established in mental healthcare in the NHS. In this brief paper, the argument focused on the alternative term service user. Similar arguments could be made about other terms, such as ‘client’ and ‘consumer’. Those arguments would overlap in parts with the ones put forward here (see ref.⁹).

I have personally experienced the strong views and feelings of present and former patients in NHS mental health services who prefer the term service user. As noted at the beginning, such views should be respected, as long as the requested terminology applies to those people themselves and not to everybody else. However, the general terminology that is used in mental health services should not be determined by the specific views of a minority of patients and/or professionals. Mental healthcare is based on shared values and scientific evidence. Both require precise thinking, and precise thinking requires an exact and consistent terminology.

Stefan Priebe, Dipl Psych, Dr. med. habil., is Professor of Social and Community Psychiatry in the Unit for Social and Community Psychiatry at Queen Mary University of London. 1.2.74 PsychStart: a novel mentoring scheme for supporting and valuing medical students interested in psychiatry

Thomas Hewson Nikki Thomas Kate Lovett Helen Bruce Derek K. Tracy

Correspondence

Dr Thomas Hewson

(tomhewson@doctors.org.uk)

date

2021-12

Abstract

We describe the establishment and evaluation of a career-based mentoring scheme (PsychStart) for medical students interested in psychiatry. Medical students reported multiple benefits of mentoring, including enhanced personal and professional development, increased career and clinical knowledge, and broadened exposure to psychiatry. The mentoring scheme was also found to promote and sustain interest in the specialty. Further evaluation is required to determine the long-term effects of mentoring and how this may compare with other undergraduate enrichment activities. We conclude that mentoring in psychiatry could offer innovative solutions for improving recruitment and retention, and for supporting and valuing medical students who demonstrate an early interest in the specialty.

pmc Increasing the number of doctors choosing to enter and remain in psychiatry has been a key health policy priority in the UK over the past 3 years.^{1,2}

The proportion of graduates from each medical school entering immediately into psychiatry post-foundation training varies widely, from 0.1 to 0.4%.³ Overall, approximately 5% of foundation year 2 (F2) doctors who enter directly into specialty training are appointed to core psychiatry training each year.^{3,4} However, increasingly large numbers of junior doctors are delaying their progression into specialty training, for multiple complex reasons.^{3,4} Although recruitment to core training has improved more recently, almost 10% of core and consultant posts still remained unfilled in 2019.^{5,6}

Recruiting and retaining sufficient doctors to fill these gaps requires multifaceted, long-term approaches. As well as increasing the number of doctors entering medical school, policy has recently focused on improving the exposure and experience of psychiatry training at undergraduate level.⁷ Prior research has demonstrated that regular early undergraduate exposure to psychiatry (through the Psychiatry Early Experience Programme, PEEP) can sustain positive attitudes towards psychiatry and challenge preconceptions about the specialty.⁸ However, little is known about the value of mentorship for medical students interested in psychiatry, despite this demonstrating clear value for students and doctors in other specialties and the broader literature.^{9–12}

This paper describes and evaluates the establishment of an undergraduate enrichment programme that combines opportunities for mentorship with additional clinical exposure to psychiatry. To our knowledge, this is the first paper to explore the potential role of undergraduate mentorship in improving recruitment to the profession. We also evaluate the potential utility of mentoring for supporting, and promoting the development of, the future psychiatric workforce.

Method

PsychStart, a career-based mentoring scheme for medical students interested in psychiatry, was co-founded by two of the authors (T.H. and N.T.) at the University of Nottingham in January 2018.

Medical students from all year groups were recruited to the scheme via communication through the student-led psychiatry society Mind Matters, social media advertising (Facebook and Twitter) and signposting during lectures and psychiatry teaching.

There are approximately 280 students in undergraduate years 1 and 2 of the Nottingham medical course, and 100 students in graduate-entry years 1 and 2. The undergraduate and graduate students merge during year 3, with approximately 380 students in years 3–5 of the medical programme. The psychiatry module is taught in year 4, and approximately 45 students complete this module at any one time.

Mentors were recruited from three local healthcare trusts that provide clinical psychiatry placements, as well as from the University of Nottingham and the university's Institute of Mental Health, facilitating the involvement of both academic and clinical psychiatrists. Mentor recruitment was limited to registrars (specialty trainee year 4 and above, ST4+) and consultant psychiatrists across a wide range of psychiatric subspecialties.

Places on the scheme were allocated on a first-come-first-served basis when appropriate mentors became available. Medical students were matched 1:1 or 2:1 to registrar or consultant psychiatrist mentors according to three main criteria: subspecialty interests, geographical location of mentors' workplaces and students' placements locations, and other career interests (e.g. in research, management or education).

All mentors and mentees were invited to attend a 2 h training session, with scheduled time incorporated for the initial 'meet and greet' between mentors and mentees. The mentor training was led by a consultant psychiatrist with experience of medical education and the Nottingham psychiatry module (N.T.), with input from the Director of Student Wellbeing. Mentor training topics covered the role of a mentor, theories of mentoring, characteristics of positive and negative mentorship, the structure and scope of the PsychStart scheme, the context of psychiatry at Nottingham medical school, and student welfare and support. Mentee training was coordinated by a junior doctor (T.H.) and/or the President of the student-led PsychStart committee, with oversight from a consultant psychiatrist (N.T.). Mentee training topics included the role of a mentee, characteristics of positive and negative mentoring interactions, the structure and scope of the PsychStart scheme, and career pathways and opportunities in psychiatry.

No minimum or maximum restrictions were placed on the frequency of mentor–mentee contact, but monthly email contact was recommended initially to promote engagement.

A generic email account was created for general communication and administrative queries. A separate email account monitored by a consultant psychiatrist (N.T.) was used for communication of any mentoring difficulties or issues requiring senior input.

Regular surveys were distributed to mentees to evaluate the different mentoring relationships and identify any requiring extra support. Any failing or inactive mentoring relationships, as identified by survey data and communication with the scheme's co-founders, were discussed with the concerned mentors and mentees. Where appropriate, some mentoring relationships were subject to reallocation.

To celebrate successes on the scheme and support the network, annual awards evenings were established where mentoring achievements were formally recognised. Awards were selected using information from regular feedback surveys, and mentors and mentees were also given the opportunity to submit nominations.

The data presented in this paper are from the 12- and 18-month evaluation surveys in January and June 2019 (Appendix 1 in the supplementary material, available at <https://doi.org/10.1192/bjb.2020.107>) and other feedback, including nominations for the annual scheme awards. All participants gave informed consent for their anonymised data to be included in future research and promotional materials. As this was a service evaluation to help improve a novel mentoring scheme, ethical approval was not required.

Results

In mid-2020, there are currently 66 active mentoring relationships participating in the PsychStart scheme at Nottingham University. Of these, 36 are 1:1; the remaining 30 students are matched 2:1 to mentors. There are also 20 medical students on the reserve list awaiting mentor allocation.

Mentee demographics

Of the current mentees, in mid-2020, 50 (75.8%) are women and 16 (24.2%) are men. Just under half (29; 43.9%) are in the pre-clinical phase of the medical course, with the rest in years 3 and above (37; 56.1%) (*Table 1*). The scheme is most popular among fourth year students (14; 21.2%) (*Table 1*). *Table 1* Year groups of medical students on the PsychStart scheme across the East Midlands in mid-2020

Year group	n (%)
Undergraduate year 15	7 (7.6%)
Graduate-entry year 19	13 (13.6%)
Undergraduate year 28	12 (12.1%)
Graduate-entry year 27	10 (10.6%)
Year 3a12	18 (18.2%)
Year 414	21 (21.2%)
Year 510	15 (15.2%)
Foundation years1	1 (1.5%) ¹

1

The graduate-entry medicine (GEM) students merge with the undergraduate students from year 3 onwards.

Psychiatric subspecialties

In mid-2020, there are 51 registrar and consultant psychiatrists participating in the PsychStart scheme across the East Midlands. The mentors span a range of specialties, from forensic to perinatal psychiatry, with most mentors in general adult and child and adolescent mental health services (*Fig. 1*). *Fig. 1* Specialty distribution of mentors on the PsychStart scheme across the East Midlands in mid-2020.

Survey responses

We received responses from 31 out of 44 mentees (70.5%) in the 18-month survey and 47 out of 68 (69.1%) in the 1-year survey, creating a cumulative total of 78 responses from 68 mentees; 18 students completed both surveys.

Most students had participated in the PsychStart scheme for over a year at the time of survey completion (46; 59.0%); 14 students (17.9%) had participated in the scheme for 6–12 months; and 18 (23.1%) for less than 6 months.

Subjective ratings of scheme experiences and mentoring relationships

Including all 78 survey responses, over 90% of students described their overall scheme experience as ‘good’ or ‘excellent’ (*Table 2*). The organisation of, and support available on, the PsychStart scheme were also rated as ‘good’ or ‘excellent’ by 93.6 and 89.8% of mentees respectively, with no student rating these as ‘poor’ or ‘very poor’ (*Table 2*). *Table 2* Subjective mentee ratings of their experiences on the PsychStart scheme

Rating category	Proportion of mentees selecting each rating, %
Excellent	38.5
Good	52.6
Average	7.1
Poor	1.3
Very poor	0.3
Overall PsychStart experience	38.5
Organisation of PsychStart	56.4
Support available through PsychStart	46.2
Quality of individual mentoring relationship	34.6

Over 80% of students subjectively rated the quality of their mentoring relationships as ‘good’ or ‘excellent’ (*Table 2*). Only 6.1% of students reported poor mentoring relationships (*Table 2*).

Over 80% of mentees ‘agreed’ (48.2%) or ‘strongly agreed’ (35.7%) that they had been well-matched to their mentors; 14.3% of responses were neutral and 1.8% disagreed.

Frequency of mentee–mentor contact

Two-thirds of survey responses indicated a frequency of mentee–mentor contact of every 3 months or more often (52; 66.7%), of which just under a quarter (18; 23.1%) reported monthly contact with mentors (*Fig. 2*). Over 80% (66; 84.6%) were in contact with their mentors every 6 months or more often (*Fig. 2*). *Fig. 2* Frequency of mentor contact reported by mentees on the PsychStart scheme.

The Authors own the copyrights to the individual articles.

Mentoring activities

Students reported a range of mentoring activities on the PsychStart scheme. The most popular activities were receiving careers or medical school advice, engaging in clinical shadowing, discussing psychiatry topics with mentors and being signposted to opportunities in the specialty (*Fig. 3*). Some students reported attending events, such as conferences, with their mentors, arranging clinical psychiatry electives, and engaging in audit or quality improvement projects and research (*Fig. 3*). *Fig. 3* Frequency of mentoring activities reported by mentees on the PsychStart scheme.

Effects of mentoring and the PsychStart scheme

A majority of mentees reported improved personal (71.4%) and professional (75%) development, clinical knowledge about psychiatry (60%) and knowledge about careers in the specialty (83.6%) (*Table 3*). *Table 3* Reported effects of the PsychStart mentoring scheme

Statement	Proportion of mentees selecting each response, %
Strongly agree	23.2
Agree	48.2
Neutral	28.6
Disagree	0.0
Strongly disagree	0.0

‘My mentor has supported my personal development’ 28.6
 ‘My mentor has supported my professional development’ 41.8
 ‘PsychStart has increased my clinical knowledge about psychiatry’ 29.1
 ‘PsychStart has created positive publicity for psychiatry within the medical school’ 52.7

Over 80% of mentees felt that PsychStart had created positive publicity for psychiatry within the medical school, with over half of students strongly agreeing with this statement (*Table 3*).

Potential links to recruitment

Approximately one-third of mentee responses (21; 32.3%) reported that PsychStart had increased their interest in psychiatry as a career. All but one of the remaining responses (43; 66.2%) reported that PsychStart had maintained their interest in a career in the specialty.

The one mentee who reported that PsychStart had decreased their interest in psychiatry as a career rated their overall scheme experience as excellent. On further clarification, this mentee had been deciding between careers in general practice and psychiatry, and through further experiences of both specialties had decided to pursue primary care. They claimed that PsychStart had helped them to make an ‘informed decision’ and that they were hoping to complete a foundation post in psychiatry.

Qualitative feedback

In total, 57 participants provided comments on their favourite aspects of the PsychStart scheme, from which 10 key themes were identified (*Table 4*). Most commonly, respondents cited their individual mentoring interactions and relationships as their favourite scheme component. *Table 4* Major themes identified from qualitative analysis of mentees’ reported favourite aspects of the PsychStart scheme

Theme	Example quote
Positive mentoring interactions	(My mentor is) ‘easy to contact and replies thoroughly and fast to my questions about psychiatry and medical school in general’
Self-development	‘I feel the personalised aspect of having a one to one mentor is very useful for self-directed learning and attaining personal outcomes’
Feeling supported	‘Feeling it’s a safe space to ask absolutely anything without being judged’
Early/enhanced clinical exposure	(I like) ‘how the scheme gives medics an early exposure to psychiatry’
Career planning	‘It has helped me feel like my decision to do psychiatry is well informed’
Extra-curricular opportunities	‘Gives me the opportunity to see areas I would not be able to see during my studies’
Scheme flexibility	‘I like the independence in choosing what I want to gain from the scheme’
Networking	‘A great way to make links with people within psychiatry’
Scheme organisation	‘The consistent follow-up from the committee to see how the relationship between mentors and mentees is going. I think that’s really important’
Annual awards evening	‘I loved the awards ceremony and hearing about what everyone was doing’

Six key themes were identified from the answers of 39 respondents who offered suggestions for scheme improvement (*Table 5*). The most popular suggestions included greater provision of locally available mentors, more scheme

publicity/advertisement and more communication prompts to mentors/mentees. Table 5 Major themes identified from qualitative analysis of mentees' suggested areas of improvement for the PsychStart scheme

Theme	Example quote	Distance
Distance from mentors	'My mentor is quite far away. I understand that not all mentors can be close but if I didn't have a car it would be hard to meet'	
Difficulty contacting mentors	'I haven't had much contact with my mentor due to my exams/my mentor not being contactable'	
More publicity	'More advertisement of research and conference opportunities'	
Regular communication prompts	'It might be useful to have a regular email prompt to give advice or ideas for activities and prompt mentees/mentors to reflect on what they have discussed/done together'	
More events	'There could be more events that are open to everyone on the scheme to aid networking opportunities'	
Structured activities	'More structured things for mentors and mentees to do together'	

Leaving the scheme

In total, 40 mentees have left the scheme since it began, most commonly because they graduated medical school or moved location (22; 55%). Other reasons have included other commitments 3 (7.5%), wanting to explore other specialties (2; 5%) and taking a year out of medical school (1; 2.5%); 7 mentees (17.5%) left the scheme without any specific reason and 5 (12.5%) left because of poor engagement.

Of the mentors, 9 have left the scheme since its inception for various reasons: moving geographical location (3; 33.3%), other commitments (3; 33.3%), difficulty meeting their mentees owing to travel distance (2; 22.2%) and retirement (1; 11.1%).

Discussion

The General Medical Council (GMC) mandates that all medical students must have access to educational and pastoral support and career guidance.¹³ Medical schools provide extensive educational networks for students to support academic progress, career development and well-being.

In the medical literature, the most frequently cited definition of mentoring is that provided by the Standing Committee on Postgraduate Medical and Dental Education (SCOPME), who describe it as: 'A process whereby an experienced, highly regarded, empathetic person (the mentor) guides another (usually younger) individual (the mentee) in the development and re-examination of their own ideas, learning, and personal and professional development'.¹⁴ The role of a mentor is sometimes confused, and occasionally overlaps, with that of several others, including a tutor, supervisor, counsellor, advisor and role model.¹⁵⁻¹⁷ The main distinctions are the highly personal and active nature of the mentoring interaction and the focus on the individual mentee's personal and career goals, instead of professional skills.¹⁵⁻¹⁸

Over 90% of medical students perceive mentoring to be important and are keen to engage in mentoring relationships.^{19,20} Despite this, only one-third of medical students report having a mentor.^{19,20} Furthermore, there is a lack of mentoring schemes in most countries' medical schools, including the UK.^{21,22} This lack is surprising given the evidenced widespread benefits,^{15,21} although it could be argued that there has been uneven support and guidance for potential mentors to enable them to adopt such roles.²³

Mentors provide strong role modelling for careers and can have a significant impact on specialty choice.^{21,24} In a study including over 9000 medical students, mentors and role models were identified as the most or second-most influential factor in determining specialty selection; for 'controllable lifestyle' specialties, of which psychiatry was included, their influence was exceeded only by 'lifestyle factors'.²⁵

Potential student gains from PsychStart

Our project has demonstrated that a mentoring scheme for medical students interested in psychiatry can be delivered alongside the standard curriculum and is popular among students at a large UK medical school. Participants reported several benefits from mentoring, including enhanced personal and professional development, improved careers and clinical knowledge, and feeling well supported. These benefits could apply to all students and to mentoring in other specialties, with the broader literature demonstrating similar benefits from other mentoring schemes.²¹

It is interesting that many of the qualitative comments by students highlighted generic aspects of the mentoring relationship, such as receiving personalised support, careers advice and assistance in their personal and professional development, as their favourite components of the PsychStart scheme. All students already have a personal tutor throughout the medical course, and clinical supervisors for each placement, who are also able to deliver these functions. It may be that students particularly enjoy receiving such support in the context of their desired specialty or accessing this from somebody to whom they have been closely matched on the basis of shared interests.

Many of the observed mentoring activities fulfil several selection criteria for core psychiatry training applications.³² For example, involvement in audit and quality improvement, completion of research, and demonstration of commitment to the specialty through arranging further clinical exposure and clinical electives with mentors. Hence, mentoring opportunities may increase employability and help students to maximise their chances of successful future training applications. This is likely to be an important attraction to the scheme as recruitment to core training becomes more competitive.

Potential specialty gains from PsychStart

Mentoring may also facilitate increased and broadened clinical exposure to a specialty, with many students arranging shadowing opportunities with their mentors and accessing subspecialties that are less established within the standard curriculum. This is particularly useful within psychiatry, where many subspecialties, such as forensic and perinatal psychiatry, are optional or seldom taught in medical school. The Psychiatry Early Experience Programme (PEEP) has previously demonstrated the benefits of increased psychiatry exposure for young medical students, including sustained positive attitudes towards the specialty.⁸ It is unclear whether such positive attitudes extend beyond those students who engage in psychiatry enrichment programmes, but over 80% of mentees felt that PsychStart had created positive publicity for the specialty within the wider medical school, suggesting that these may permeate throughout the student body. Ajaz et al previously reported that medical students often experience ‘badmouthing’ or ‘bashing’ of psychiatry,²⁶ which can deter them from entering the specialty; this highlights the importance of fostering positive attitudes and prompted the Ban the Bash campaign by the RCPsych, which aimed to identify and discourage disparaging comments about psychiatry.²⁷ More recently, the College has focused on emphasising positive ‘pull factors’ that promote selection of psychiatric careers.

The most common year for students to sign up to PsychStart is year 4, which coincides with the clinical psychiatry module; hence, clinical exposure to a specialty may prompt involvement in extra-curricular opportunities. The mentoring scheme was much more popular among women students, with 75.8% of mentees being women. This is considerably larger than the approximately 55% women on the Nottingham medical course (This information was obtained by T.H. through contact with Dr Pamela Hagan at the University of Nottingham Medical School. Permission was granted from the University of Nottingham Dean of Medical Education Professor Gill Doody). It is not clear why this discrepancy exists. Prior research has associated female gender with preferential selection of psychiatry at undergraduate level;²⁸ however, women have historically been less likely to receive mentorship, and to become mentors, in medical fields.^{29,30}

Our scheme data provide further evidence to support the utility of mentoring in improving specialty recruitment, with over one-third of students reporting an increased interest in psychiatric careers. Our data also suggest that mentoring may help to retain, as well as promote, students’ interests in particular specialties, with just under two-thirds of students reporting a sustained interest in psychiatry on the PsychStart scheme. This is particularly important given that 22% of medical students who exhibit an early interest in psychiatry lose this interest throughout their studies.²⁸ There is evidence that these benefits also exist outside of psychiatry; for example, Dorrance et al reported that a mentoring and research initiative showcasing a career as an internist in primary care settings resulted in a higher proportion of graduates opting for internal medicine training.³¹ Furthermore, mentoring has been found to increase interest in

academic careers.^{10,21} Holt et al reported no significant difference in specialty choice at baseline and at their 3-year follow-up for students participating in the Psychiatry Early Experience Programme;⁸ this may suggest that, although clinical shadowing may be useful, other opportunities provided by mentorship may have a greater influence on career selection. However, further follow-up and evaluation is required to determine the long-term effects of mentoring and early clinical exposure on decisions to pursue psychiatry.

Strengths and limitations

Our scheme data have several strengths. First, to our knowledge, this is the first published report to evaluate a formal mentoring scheme for UK medical students interested in psychiatry. Second, the high response rates to the two surveys (69.1 and 70.5%) assures us that we have gained a representative sample of students on the PsychStart programme. Third, the broad range of survey responses covering all year groups at Nottingham medical school gives strength to the generalisability of our findings.

However, we recognise that these data have the following limitations. First, they are subjective, based on students' written reports and ratings of their mentoring relationships. The nature of the design of the evaluation did not allow for further probing about the students' perceptions and experiences of the scheme. Furthermore, students' stated interests may not necessarily predict future actions and result in core psychiatry training applications. Second, our data were derived from a self-selecting sample of students participating in the PsychStart scheme. We were therefore unable to draw any comparisons between students who do and do not receive mentoring in psychiatry and determine whether the scheme 'adds value' for those already interested in a career in the specialty. Finally, the maximum duration of mentoring relationships at the time of survey completion was just over 18 months; hence, we are unable to comment on the long-term effects of mentoring for this cohort.

Research recommendations

We recommend that future research should examine the long-term effects of mentoring and its impact on the quantity and quality of applications to core psychiatry training. Given prior research associating mentoring with improved medical school performance and training outcomes,^{21,33} it would additionally be useful to examine the effects of mentoring in psychiatry on exam performance in the specialty. Delineating what motivates students who do and do not sign up to such mentoring schemes, and potential logistical barriers to taking part, could provide useful insights into factors both promoting and hindering engagement with psychiatry and mentoring. Further attention should be given to the experience of mentors, especially given that the concept of 'reverse-mentoring' is becoming increasingly recognised in the medical literature; this describes a process whereby junior medical professionals can mentor their senior colleagues, providing benefits such as enhanced understanding of digital technologies and online platforms, and improved workplace culture.³⁴ Critically, it is important to understand whether receiving mentoring from a psychiatrist rather than other doctors positively influences later career choice. Comparison of the impact of mentoring with other medical student enrichment activities, such as shadowing⁸ or participating in Balint groups³⁵ or medical student psychotherapy schemes,³⁶ needs further evaluation.

We thank the following organisations and groups for their support in establishing the PsychStart mentoring scheme: University of Nottingham School of Medicine, University of Nottingham Students As Change Agents Programme, Nottinghamshire Healthcare NHS Foundation Trust, University of Nottingham Institute of Mental Health, Lincolnshire Partnership NHS Foundation Trust, Mind Matters Society, and the PsychStart student committee.

1.2.75 Analysing *Joker*: an attempt to establish diagnosis for a film icon

Valentin Yurievich Skryabin

Correspondence

date

2021-12

Abstract

Todd Phillips's film *Joker*, a 2019 psychological thriller, has stirred up strong reactions to the portrayal of the lead character's mental disorder, which is never specified. I used DSM-5 criteria to study whether Joker/Arthur Fleck showed signs of a real mental disorder. The psychopathology Arthur exhibits is unclear, preventing diagnosis of psychotic disorder or schizophrenia; the unusual combination of symptoms suggests a complex mix of features of certain personality traits, namely psychopathy and narcissism (he meets DSM-5 criteria for narcissistic personality disorder). He also shows the symptoms of pseudobulbar affect due to traumatic brain injury. This apparent co-occurrence of both mental disorder and a neurological condition may be confusing for audiences trying to understand mental illness.

pmc The Joker is considered one of the most recognisable and iconic fictional characters in popular culture and one of the best comic villains.¹ Since his debut, the Joker has appeared in countless comics, TV shows and films. Like most enduringly popular fictional creations, the Joker has repeatedly morphed his mannerisms, appearance and *raison d'être* to meet the styles and trends of the time.¹ He has been adapted to serve as Batman's antagonist in various incarnations, including the 1960s television series *Batman* and 1966 film of the same name, in which he was played by Cesar Romero, and in subsequent films played by Jack Nicholson (*Batman*, 1989), Heath Ledger (*The Dark Knight*, 2008), Jared Leto (*Suicide Squad*, 2016) and Joaquin Phoenix (*Joker*, 2019). Over his 80 years of existence, the Joker's character has gone through numerous significant changes in interpretation, taking a ride between the forces of goofy and evil.

Cesar Romero's slapstick Joker is far from his modern incarnation as an intimidating mass murderer, but Joaquin Phoenix's version has almost the same aesthetic, clearly a deliberate homage to Romero.² Jack Nicholson's Joker shares a similar backstory to Phoenix's, both being normal men with real names (Jack Napier and Arthur Fleck respectively), who, after a formative traumatic incident, come to inhabit the twisted clown persona. Nicholson's Joker was a criminal who was physically and mentally altered after falling into a vat of hazardous chemicals. Heath Ledger's iconic take reinvented the character for a new age, permanently imbuing the clown with angst. Ledger described his character as a 'psychopathic, mass-murdering, schizophrenic clown with zero empathy', and Paul Levitz, president of DC Comics in 2002–2009, said, 'I keep coming back to the way he physically incarnates madness'.³ Ledger's incarnation seems to inspire Phoenix's Joker, who is also a social outcast, building on that concept to see the Joker inspire some kind of protest movement.² Jared Leto's take marks the first time that the Joker was almost universally derided, but despite controversial aesthetic choices this incarnation embodies a quintessential component of the Joker's psychology: his 'super-sanity' (as stated by Grant Morrison, it refers to the particular state of mind amalgamating elements of Carl Jung's archetypal trickster figure from mythology, and the corrupting hyper-intellectualism of the dark feminine figures in tragedies (*Lady Macbeth*, etc.), into Joker's possession of a higher realm of brain function which we perceive as irrationality; sometimes Joker is even aware that he is a fictional character). Anyway, the differences between different actors and performances should not be overemphasised. In all of his incarnations, the Joker has been a trickster figure who thrives on thwarting expectations and hovering in the uncomfortable, yet mesmerising zone beyond what description can encapsulate.¹

Todd Phillips's *Joker*

Todd Phillips's *Joker*, a 2019 psychological thriller film starring Joaquin Phoenix, is a far cry from the previous incarnations, which is stirring up a fierce debate about the portrayal of the character's mental disorder.^{4–6} The director turned a comic icon into a neuropsychological study drama that reflects on how society views and treats the mental health problems of certain individuals. According to some critics, *Joker* runs the risk of being perceived as a glorification of what one angry and disturbed loner is able to accomplish and raises debate over whether the film turns an archetype of a violent man into a heroic figure (intentionally or not).⁷ Andrew A. Nierenberg concluded that 'Sadly, the movie will increase stigma for those with psychiatric disorders and make people afraid. It will take great efforts to combat this setback in the battle against stigma'.⁸ Furthermore, doctors Annabel Driscoll and Mina Husain wrote in an opinion piece for *The Guardian* soon after the film's release, 'Severe mental health conditions, such as psychotic illnesses, remain shrouded in stigma and are consistently misrepresented and misunderstood [...] Portrayals of mental illness in film can perpetuate unfounded stereotypes and spread misinformation'.⁹ Meanwhile, British neurocriminologist Adrian Raine was impressed by how accurate the film's depiction of the psychology of a murderer was. In an interview with *Vanity Fair*, he described it as 'a great educational tool' and stated that he planned to present film clips during his classes.¹⁰

In general, *Joker* is closer to an art-house film than a typical comic book film, since it shows less explosive action but more social commentary. Unlike other interpretations, we discover a lonely, timid and uncharismatic man. The plot of the film centres on Arthur Fleck, a socially inept party clown and aspiring stand-up comedian living with his ailing mother Penny in Gotham City. Gotham is struggling with crime, unemployment and poverty. Arthur is a middle-aged, underweight and pale-faced man suffering from a medical disorder that causes him to laugh uncontrollably at inappropriate times and he depends on social services for medication. His communication skills are generally poor; he stares at people for too long, uses abnormal facial expressions and misses important interpersonal cues, making others feel discomfort. In the evenings Arthur and his mother watch a TV show with host Murray Franklin, and Fleck imagines himself being on the show and getting everyone's attention. Arthur experiences a romantic feeling towards

his neighbour Sophie, but later the film reveals that he was actually imagining all of their dates. During the film, a series of events in close succession ultimately tips him over the edge: Arthur guns down three men on the subway train ride home after he was mocked; his therapy sessions are terminated, he stops taking his medications and later he reveals that Penny adopted him after he was found abandoned. Penny had a mental disorder and her case history records at the mental health clinic mention Arthur having a head injury after she abused him, tied him to a radiator and beat him alongside her abusive boyfriend. Then the dream of the character comes true: he becomes a guest on Murray Franklin's show and asks the host to introduce him as Joker. While it initially seems that Arthur intends to kill himself live on air, he shoots Franklin instead. In the end, we find Joker in a therapy session at the mental health clinic. He is then seen running, dancing and leaving bloodied footprints in the hospital's corridors, implying the psychiatrist's death.

Diagnosing Joker's mental conditions

Although Arthur's disease remains unspecified throughout the film, we can make some conclusions if we take a look at Joker's symptoms and mental condition throughout the film. During the therapy sessions, Arthur describes his complaints as loneliness, isolation and 'constant negative thoughts'. An entry in his notebook states that 'the worst part of having a mental illness is that people expect you to behave as if you don't'. We know that the character attends therapy sessions for a long time and that he is prescribed several psychotropic medications. He even had sufficient insight to say, 'I need my medication to be increased'. Unfortunately, we have very little information on his family history since he was abandoned as a child. His foster mother has delusional disorder and probably a personality disorder and she underwent in-patient therapy. Arthur was brought up by a foster mother and did not have a father figure. The foster mother herself describes him growing up as a fun and kind boy, but later he was abused and beaten by his adoptive parents and even had a severe head injury. Thus, we can find a number of risk factors for mental disorders in our fictional patient's case history.

Pseudobulbar affect

In addition, we can assume that Arthur suffers from pseudobulbar affect, or emotional incontinence, which is a disorder of regulation of emotional expression, caused by neurological disease or injury affecting the brain.¹¹ Pseudobulbar affect is characterised by sudden, uncontrollable episodes of crying, laughing or both. These episodes are excessive, inconsistent with or disproportionate to circumstances or the patient's underlying mood at the time.¹² In Joker's case, pseudobulbar affect probably occurred secondary to severe traumatic brain injury (TBI). A number of studies have established that TBI increases the risk of mood disorders, personality changes and substance use disorders.¹³⁻¹⁵ A study by Tateno et al revealed that the prevalence of pathological laughing and crying (PLC) during the first year after TBI was 10.9%, and that compared with patients without PLC, patients with PLC had significantly more depressive, anxious and aggressive behaviours and had poorer social functioning.¹⁶ This conclusion is consistent with a recently published article that considers neurological aspects of Joker's disease and assumes that he suffers from neuropsychiatric sequelae related to childhood TBI involving the frontotemporal regions and, in particular, the lateral aspect of the left frontal lobe.¹⁷

Personality disorders

In general, Arthur appears to have a complex mix of features of certain personality traits, namely narcissism (since he craves attention by any means) and psychopathy (since he demonstrates no empathy for his victims). He also displays some traits of depression, but at the same time, he demonstrates excellent self-control. We can see no evident symptoms of thought disorder; Arthur is a highly motivated lucid thinker, he never tells his therapist about any hallucinations or delusions regarding the neighbour who is the subject of his affections, so their romantic relations and dates may be just his conscious imagination. Such diagnostic vagueness does not allow a diagnosis of psychotic disorder or schizophrenia, although to the viewer's untrained eye Joker may appear a hysterically laughing supervillain who is stereotypically 'insane'. We also have no evidence to establish a diagnosis of major depressive disorder or bipolar disorder.

Narcissistic personality disorder

DSM-5 describes 301.81 Narcissistic Personality Disorder as ‘a pervasive pattern of grandiosity (in fantasy or behavior), need for admiration, and lack of empathy, beginning by early adulthood and present in a variety of contexts’ characterised by at least five of nine criteria.¹⁸

According to criterion 1, such patients routinely overestimate their abilities and inflate their accomplishments, often appearing boastful and pretentious. They may blithely assume that others attribute the same value to their efforts and may be surprised when the praise they expect and feel they deserve is not forthcoming. Really, Arthur Fleck’s life is dominated by his aspiring stand-up career, he craves public attention and likes to imagine himself being on the TV show. Individuals with narcissistic personality disorder are often preoccupied with fantasies of unlimited success, power, brilliance, beauty or ideal love (criterion 2). Throughout the film, Arthur is infatuated with his neighbour, single mother Sophie, and later we recognise that all of their dates were just his fantasies. Individuals with this disorder generally require excessive admiration (criterion 4). Their self-esteem is almost invariably very fragile. They may be preoccupied with how well they are doing and how favourably they are regarded by others. This often takes the form of a need for constant attention and admiration. As we can see throughout the film, Arthur meets this criterion. A sense of entitlement is evident in such individuals’ unreasonable expectation of especially favourable treatment (criterion 5). They expect to be catered to and are puzzled or furious when this does not happen. In his fantasies, Arthur charms the audience of the TV show, but when he becomes a guest on the show, he awkwardly tells Murray a joke that he finds funny for its dark humour though nobody else does. After being confronted about this, Arthur grows angrier, resulting in a murder. Finally, our character meets criterion 7, which states that individuals with narcissistic personality disorder generally have a lack of empathy and have difficulty recognising the desires, subjective experiences and feelings of others. Really, Arthur feels no empathy towards his victims. Thus, as we can see, Arthur meets five of the nine criteria, which is enough to establish a diagnosis of 301.81 Narcissistic Personality Disorder.

Antisocial personality disorder

At the same time, as I have stated, Arthur has the symptoms of psychopathy. Although psychopathy is not among the ten official personality disorders listed in DSM-5, it is well recognised as a variant of antisocial personality disorder (301.7, according to DSM-5). Indeed, Joker meets a few of the criterion A group of symptoms: he fails to conform to social norms with respect to lawful behaviour, as indicated by repeatedly performing acts that are grounds for arrest; he demonstrates irritability, aggressiveness and disregard for the safety of others, as well as lack of remorse. For this diagnosis to be given, the individual must be at least age 18 years (criterion B) and must have had a history of some symptoms of conduct disorder before age 15 years (criterion C). Arthur is definitely over 18 years of age, but he has no history of symptoms before the age of 15 (or we do not have information about that). For this reason, we cannot establish a diagnosis of 301.7 Antisocial Personality Disorder, according to DSM-5.

From flawed man to cartoon supervillain

Although the film provides the audience with identifiable components of real mental disorders, in general, the psychopathology that Arthur exhibits is foggy and the combination of his symptoms is unusual. Such diagnostic vagueness helps to create a more relatable character who reflects the burden of any mental disorder; but for the mental health professional it can be confusing and leave the impression that different neurological and mental disorders have been mixed. Actually, the plot moves from a portrait of an individual who is struggling with mental disorder and striving to make a life for himself into pure supervillain caricature. Joker as a character makes it incumbent on the film to drop its pretence at serious character development to enter the comic book mode. Arthur Fleck ceases to be a human being for whom we might feel empathy and descends into a one-dimensional stereotype. The film uses Arthur’s childhood trauma as well as his struggle with mental disorder as a means to earn sympathy from the audience, rather than disgust at his actions. It is an age-old cinema psychology cliché: the character hasn’t had enough love. Thus, as a character, Arthur appeals deeply to the human tendency towards self-pity. From this point of view, the character’s mental illness just happened to be one of the stressors that are the true cause of Arthur becoming the Joker. His mental illness was

only important to the overall plot as a way of connecting all the other stressors together. Therefore, to reduce all of Arthur's actions down to his mental health problems is extremely simplistic.

In conclusion, it would be worthwhile to recall an episode from the film. When Arthur's diatribe is booted on the Murray Franklin Show, he tells the audience that 'humour is subjective'. Likewise, any considered response to divergent interpretations of Arthur Fleck's diagnosis forces specialists to acknowledge their own subjectivity.

1.2.76 Fluctuation of suicide intent and other matters in psychosocial assessment post self-harm

Prasanna de Silva

date

2021-12

Contents

- *Fluctuation of suicide intent and other matters in psychosocial assessment post self-harm*

pmc Professor Morgan's article rightly focuses on the fluctuations in suicidal intent among mentally ill people undergoing the various crises and vicissitudes of life. He emphasises the importance of repeated assessments, rather than relying on the initial one, to accommodate these fluctuations in intent.

He appears to have given up on prospects of predicting longer-term suicide risk but has not commented on the emerging body of evidence suggesting the effectiveness of combining an app-based questionnaire with inflammatory biomarkers such as interleukin subtypes, SAT1 and Toll-like receptor subtypes.¹ These biomarkers probably reflect the degree of underlying stress which Professor Morgan describes, with some quantitative features provided in addition. These types of hybrid assessments should cover both the short- and longer-term risks but will not predict when (or under what circumstances) the lethal behaviour could take place. Consequently, mitigation needs simple strategies such as Dr

Cole-King's suicide safety plan, a brief document co-produced with the patient, held by the patient and carer, describing what to do and who to contact if suicidal intent reaches a climax.²

Brief hybrid assessments might also be less intrusive and distressing to patients compared with the standard 'psychosocial assessment' carried out in emergency room settings, typically by junior psychiatric liaison staff and often under time pressure (including the 4 h wait and expectations of prompt bed clearance and discharge as the person is deemed 'medically fit'). Often both the assessor and patient are aware that this is likely to be the only contact between them, further reducing the likelihood of frank disclosure of trauma and abuse; this is strongly associated with invalid assessments and completed suicide in the future.³

Patients also find repeated disclosures of personal details to multiple mental health staff frustrating and traumatic,⁴ along the lines of 'why don't you look up the notes before speaking to me?'. Similar to the experience of repeated police interviews under implied caution ('anything you say might be used for a future Mental Health Act assessment'), patients are (perhaps rightly) suspicious that the assessors are looking for discrepancies in the history to undermine the reliability of the person's account leading to suicidal thinking and/or self-harming behaviour, thereby making it easier to discharge (or dismiss) the patient seeking help.

Professor Morgan touches on in-patient ('never event') suicides,^{5,6} mainly involving patients who have either absconded or been given planned home leave, as major improvements to ward design (including shaving off door edges and securing windows, door handles and toilet equipment) have now taken place. He does not, however, suggest practical changes in ward policy, for example, the potential benefit of a face-to-face review within 24 h of being placed on home leave in order to check on basic needs (elegantly summarised by Maslow), as well as potential toxic relationships with close family members, who might be either over-controlling or otherwise pessimistic on the prospects of the patient moving from being a burden (a variation on therapeutic nihilism and malignant alienation, not often discussed in the literature).

Finally, the issue that I, as a clinician, struggle most with when debriefing assessors or looking at longer-term suicide mitigation is that suicide risk assessment is used primarily as a defensive tool by the assessor, possibly aided by the patient, who does not wish to upset the assessor or get him/her into trouble in the future. So, the 'protective factors' often highlighted in the assessment are documented without due diligence on how stable or permanent these are.

On occasion, a suicidal person will 'blurt out' a suicide plan he/she has been considering. Often, this communication is with a staff member of low rank, for example, a ward domestic or student nurse, simply based on their compassionate nature and their not being part of the 'assessment brigade'. Typically, these patients will subsequently deny that they will carry out this plan, and at times they will deny ever having disclosed such a plan, but, given the circumstance or opportunity, they may use the plan. Alternatively, a person who has failed with a plan will deny wanting to repeat the action (for example, an overdose) but could use this as a learning experience to organise a variation or plan more violent methods such as jumping or hanging.

As Professor Morgan rightly states, an assessor needs to compassionately (and non-judgementally) ask whether alternative means have been considered following a failed suicide attempt. This is genuinely hard work and especially emotionally draining. Therefore, it is essential for staff assessing suicidal patients to be debriefed supportively and given sufficient time off (at least undertaking other duties) to regain their emotional composure.

1.2.77 Managing suicide risk in primary care

Ann Maria Albert Hannah Gallen Misha Gaur

date

2021-12

Contents

- *Managing suicide risk in primary care*

pmc 05 June 2021

We read with interest Professor Morgan's special article on predicting short-term suicide risk.¹ We are grateful for the mention of the extensive body of evidence suggesting the futility of suicide risk assessments and alleged risk factors including suicidal thoughts and behaviours in predicting suicide risk. We appreciate the statements 'To base assessment of ongoing risk on the individual's mental state during a single interview is clearly likely to be highly unreliable' and 'An important trigger for relapse is stress, particularly stress that has previously been present and has not been resolved'. It is important that the above facts are conveyed to the patient's general practitioner (GP) via the suggested correspondence. However, we wonder about the purpose of the proposed 123-word paragraph ending with the sentence 'Overall, however, the predicted level of suicide risk must still be regarded as significant, requiring vigilance until I next see him/her'. What action is required of the GP when they receive similar letters about almost every patient seen by the mental health services? If the patient requires vigilance for their mental health, would this not best be provided by secondary care mental health services with their array of highly specialist teams and army of experts? What aspects of suicide prevention are the GPs better equipped for than the secondary care mental health services? It is important to acknowledge that it is not possible to reliably predict suicide risk from single consultations. However, it appears the suggested correspondence is unrealistically asking an already overstretched primary care service to pick up responsibility in a specialist area. Furthermore, we would be grateful for any guidance on how to better assess and manage suicide risk during a 10 min GP consultation than during the 30–60 min assessment by specialists.

1.2.78 Peggy Seriès: Bayesian on a bike

Claire McKenna¹

date

2021-12

Contents

- *Peggy Seriès: Bayesian on a bike*

pmc Born near Bordeaux in 1974, Dr Peggy Seriès is a senior lecturer and principal investigator in the computational psychiatry laboratory at the Institute for Adaptive and Neural Computation (ANC), University of Edinburgh. Her career to date has included spells in prestigious computational neuroscience labs in France, New York and University College London.

Her move into computational psychiatry was motivated, she says, partly by her own experience of anxiety, but also by witnessing the suffering due to mental illness of her students and the death by suicide of two of them.

Essentially, the Bayesian brain hypothesis suggests that brains use probability calculations to make *predictions* about what we experience, based on sensory inputs and our prior experiences. Seriès's research work focuses on using mathematical and computer models to understand how our expectations and prior beliefs about the world modulate our perception. In particular she is interested in differences in prior beliefs and learning in disorders such as schizophrenia, autism, depression and anxiety.

Seriès edited and contributed to the first accessible textbook on the emerging field of computational psychiatry.¹ For any clinicians feeling jaded, read it for an overview of computational approaches in your psychiatric field of interest and to get excited about psychiatry all over again.

Seriès only started cycling competitively at the age of 39. Since then she has won multiple track cycling championships nationally and internationally, completed three half ironmans and is in training for a full ironman. In 2013 she cycled the full route of the Tour de France, considered one of the most gruelling endurance competitions in the world.

This interview took place via Zoom in June 2021 and has been edited for length and clarity.

I want to hear more about your cycling achievements! Is there a connection between your love of cycling and your interest in maths and neuroscience?

Thanks for asking! I'm actually very proud of my cycling achievements, mostly because I started competing so late in life and it was never something I thought I could do. Racing bikes has been such a blast!

I'm not sure there is a clear connection, though maybe the pleasure I get from both is the pleasure of feeling like an explorer, which is what I wanted to be when I grew up. On the bike, what I like best is putting my panniers on, carrying a tent and going for an adventure.

You diverged from an undergraduate degree in maths and physics into computational neuroscience – was that always your plan?

¹

Claire McKenna talks to Peggy Seriès, editor of the first primer on computational psychiatry, about a field that sometimes seems wilfully inscrutable. Seriès also speaks about her alter ego as an elite cyclist and ironwoman and is frank on the barriers faced by women in academia.

No, it's been a tortuous path, via electronic engineering and artificial intelligence, but I'm very happy about where I landed.

I think the deciding factor was that my father suffered an encephalitis when I was 19. For a while he had short-term memory loss, olfactory hallucinations and prosopagnosia. For me, it was a shocking awareness of how delicate and complex the brain is and how a lot of our self-identity is related to our memories: who are we if/when we lose our memories? Initially, memory was what I wanted to study.

Did anyone else inspire you?

My mother was a neurologist but has always been fascinated by psychiatry, so she'd have to be on the list. Otherwise, in the people I've worked with, I'd have to say Peter Dayan for his pioneering and very inspiring work in computational psychiatry and Eero Simoncelli, who has been a role model as a researcher and mentor.

What gets you out of bed in the morning?

Mostly porridge! After breakfast though, I think I am fascinated by understanding how one's experience of life is shaped. How free are we about how we feel, how happy we are? This is something I am working on in my private life, having more control over my own experience, and I see it related to my work as well, both my work on Bayesian perception and on mental illness: how much are we shaped by our previous beliefs? Where do those beliefs come from? How can we change them?

What keeps you awake at night?

That the causes of mental illness may lie more in how our society pressures us and lets the vulnerable down than in how our brain might become 'chemically unbalanced'. That all the neuroscience understanding in the world can't compensate for a society that makes people feel stressed and miserable.

What do you love most about what you do?

I'd have to say interacting with students, seeing my PhD students develop. In my teaching, having an honest discussion about mental illness, when they are at an age when it starts to be relevant – an age at which I certainly would have liked to be more informed about it.

Computational neuroscience still seems to be a field dominated by men – have you had any difficulties as a woman in this field?

This year a woman has been recruited [to the ANC] but until now I have been the only woman in my Institute out of 20 people. I think it's at the current stage of my career that I see how male-dominated things are in academia and when I feel that progression is harder. Or maybe I was more naive before. There's a perception that women don't put themselves forward as much as men do, and I think this was definitely true of me, and it came at a cost.

I also think it is undeniable that it is hard for women to succeed in academia while at the same time managing to settle down in one place and with one person to build a family.

You asked me about the connection between my work in neuroscience and my passion for cycling. I think the cycling gave me a lot of confidence. I am more confident now in this world of men knowing that on a bike I can actually beat them! It's as if I got on their kind of field and I am actually competitive.

Do you think things are any different now for young female academics than they were for you?

Yes, I think things are different now. Women were very clearly treated differently from men when I was young. It was so ingrained in our society that we (women) were not even aware of it.

A very long time ago during my studies, I was supposed to be supervised for a small research project by a supervisor who, in the first meeting with me, invited me for a drink and asked if I had a boyfriend. On our second meeting, he was sitting topless in his office, feet on the table and when I came through the door, commented that I was short. I never went back but also never thought to tell anyone about this – I just did my project alone.

It is now covert and more subtle and probably takes different forms – I'd like to think that behaviours like this don't happen anymore, but as in the rest of society, I think in academia women still feel they are playing a game where the rules have been written mostly by, and for, men.

Thank you for sharing that. I was reminded of the BalanceTonPorc movement in France, the equivalent of the MeToo movement. Did you ever consider denouncing your aggressor?

No. You know back then I just felt happy that I could work by myself and I didn't realise what it was. But now I think about it as a supervisor myself. If I imagine behaving like this with a student of mine, it's very difficult to understand.

You've clearly done a lot to recruit, do research with and nurture PhD students. You've also written about the importance of 'scientific humility' and making science more accessible. Perhaps this humility doesn't serve women well in a field dominated by men. You have though used your skills of collaboration to pull together international leaders in the field of computational psychiatry for your new book. Why did you think there was a need for a primer?

The field has been growing steadily in the past few years, but it is not often taught formally yet. I wanted to offer a book that could be accessible to a broad audience. I had my students in mind but it is hopefully also accessible to students coming from psychology or medicine. The book is not perfect, but I think it's a start and hopefully it will help to consolidate the field and lead to better things.

I came from a background where people often like to explain things in a very complicated way with very complicated vocabulary. I have been inspired by researchers like Eero Simoncelli, who instead would say 'it needs to be clear to your grandmother'. That was the contrary of arrogance in how you present your work – the need to aim for accessibility. For me, it was very inspiring.

Why did you use that Einstein quotation at the start of the chapter you wrote:1 'One thing I have learned in a long life is that all our science, measured against reality is primitive and childlike – and yet it is the most precious thing we have'?

What I meant is that the models we have at the moment are most certainly oversimplified and naive, but we have to start somewhere and from there we can grow and improve.

I want you to give me a bit of an 'idiot's guide' to computational psychiatry! How are computational theories of the mind linked to computers – is it anything to do with computer (hardware/software) metaphors of the mind?

In some sense – the computational theory of mind views the mind as an information processing system, and perception and cognition as a form of computation that is realised by neural activity in the brain. The software would be cognition and the hardware, the neurons.

The work we do operates at both levels: how can we describe cognitive processes and how are those cognitive processes realised by the neural substrate?

Language is a limited and imprecise way to describe how our brain and mind works. Is computation a tool to extend our own mental capacity and escape the imprecision of words?

Yes, verbal theories can only make general and somewhat vague predictions. Mathematical descriptions offer a way to formalise theories precisely and quantitatively so they can be tested, compared with data and extended.

Computational psychiatry has been called a 'Rosetta stone' linking levels of explanation in mental illness – do you agree?

I don't think it will lead to an overnight understanding of mental illness. But I think computational neuroscience tools are very good at exploring and providing links between different levels of description, for example linking the description of individual neurons and the dynamics of networks of neurons, then linking networks of neurons and behaviour etc. In that sense they can provide links between neurobiological elements and descriptions related to symptoms.

Why is Bayes' rule important in understanding the mind?

Bayes' theorem tells us how to optimally calculate the probability of an event based on new information that is, or may be, related to that event, as well as prior information.

It is important in understanding how the mind works because the mind has to do something like that: figure out at each moment in time what is in the environment and what is the best action to take. It has to combine uncertain bits of information and try to make sense of that information in view of previous knowledge. Bayesian inference can thus

offer a benchmark of how the brain (I notice you say the mind and I say the brain!) should do that if it were functioning optimally. It is often found that this benchmark comes close to what the brain does in practice.

What is the difference between Bayesian inference and predictive processing?

Predictive processing, or predictive coding, is a theory of brain function in which the brain is constantly generating and updating an internal model of the environment. The model is used to generate predictions of sensory input that are compared with actual sensory input. This comparison results in prediction errors that are then used to update and revise the mental model.

Bayesian inference is a method of statistical inference in which Bayes' theorem is used to update the probability for a hypothesis as more evidence or information becomes available.

Although the neuroscience literature often confuses the two, as both theories are related to building an internal model of the environment to generate predictions, they are distinct. Predictive processing can implement Bayesian inference, but it does not necessarily do so, nor would it be the only way to implement Bayesian inference.

What is machine learning and how is this used in computational psychiatry?

Machine learning is a branch of artificial intelligence based on the idea that systems can learn from data, identify patterns in the data and make decisions with minimal human intervention.

We distinguish two types of computational psychiatry: theory-driven and data-driven.

The first kind uses mostly models coming from computational neuroscience, that formalise psychological or neural hypotheses about how the brain learns or makes decisions and produces behaviour (such as reinforcement learning models and Bayesian models). This is the type I am mostly involved in.

The second kind uses machine learning to try to 'blindly' detect patterns in psychiatric data or do prediction or classification (without making assumptions about the underlying mechanisms).

Both types of work are complementary and can also be combined.

What translational benefit has computational psychiatry had?

There are already indications that machine learning can help predict trajectories of mental illness or predict response to treatment. There is for example a seminal study by Chekroud et al,² showing that it is possible to predict (somewhat significantly above chance) response to treatment (citalopram) for people suffering from depression. But overall, the field is really in its infancy.

You pointed out that you tend to talk about 'the brain' and I tend to say 'the mind'. Is computational psychiatry more concerned with the computational representation of cognition, as opposed to the qualia of consciousness?

Yes, we computational neuroscientists commonly like to avoid talking about qualia or even consciousness, we often feel uncomfortable around those concepts and like to leave those to philosophers of the mind! I think it's a shame that it's not a literature we often read and we are not enough exposed to it. Philosophers of mind read us, but we don't really read them.

I think, though, it will be very important to address the notion of suffering and mental pain. At the end of the day it is not really the content of the experience that makes a person feel 'ill' – some people have hallucinations they are perfectly comfortable with – but that feeling of suffering, that something is 'very wrong' or overwhelming, that is perhaps difficult to measure or model quantitatively.

What projects are you currently working on?

One of my main projects is about clarifying the differences between Bayesian theories in relation to autism and schizophrenia: the theories are quite similar at the moment for the two disorders, while the symptoms are very different.

As far as I understand it, the similarities are related to the idea that in both autism and schizophrenia there are 'weak priors', so that the influence of prior expectations on perception is weaker?

Yes, exactly. The ideas are very similar, that you'd have a weak influence of perceptual priors in both autism and schizophrenia, but perhaps at a more cognitive level you would have stronger (possibly maladaptive and overwhelming) priors in schizophrenia. But in reality the pathologies have very rarely been compared using computational methods.

I'm really interested in actually testing these theories. And what's interesting is that in our work we found differences [between autism, schizophrenia and controls], but they are very subtle. And I find that quite fascinating as well.

In reality, even between schizophrenia, autism, depression and anxiety, it's very hard to find behavioural tasks that lead to very robust differences that we can actually quantify and model. So at the moment, there is some indication that these theories are somewhat promising, but there's also data coming in that are against those theories. It's quite hard to know how much progress we have really made, I think, with these Bayesian theories and part of my work tries to assess that.

The Bayesian framework for understanding the mind seems intuitively appealing, and can be retrofitted to lots of psychological theories. However, it is often applied very liberally, in a speculative kind of way that seems unfalsifiable. The more I read about predictive processing, the more I can apply it to just about anything! Is there a risk of the Bayesian bandwagon running away with us?

As a framework, the Bayesian approach is indeed unfalsifiable; there will always be a Bayesian model that can fit the data. However, individual models are falsifiable. I think the trick is not to use Bayesian or predictive ideas in the vague sense, but to formalise these ideas as much as possible in the form of mathematical models and simulations and compare a family of different individual Bayesian models and other types of model. Only then can we test quantitatively our hypotheses, confront the data and really evaluate whether/which Bayesian descriptions really correspond to the data.

We may be able to understand the neural mechanisms behind the distress related to psychiatric disorders, but do computational approaches to understanding mental illness tell us at what level we should intervene to relieve this distress? It may still be best to intervene at the level of people's socioeconomic circumstances or preventing their trauma or challenging their negative thought patterns.

I agree, but I don't think these levels of explanation are incompatible. A computational approach (such as machine learning) can be informative in identifying what environmental factors are critical in triggering mental illness, for example.

Work looking at reinforcement learning and Bayesian inference can also hopefully ultimately inform learning-based psychotherapies, as researchers like Michael Moutoussis³ have shown.

If computational psychiatry were the Tour de France, which stage are we currently at? What would represent the Champs-Élysées in computational psychiatry for you?

We're probably at the Prologue [the time trial which starts the Tour] even if it feels like the Alps! The Champs-Élysées, for me, would be to better understand the root causes of mental illness, either at a biological or environmental level, and inform new therapies, in particular psychotherapies.

pmc 17 June

I am grateful to Drs Albert, Gallen and Gaur for their interest in my paper. Unfortunately they appear to have misunderstood some major points which I make. I certainly do not suggest that the assessment of suicidal thoughts is futile

in short-term prediction of suicide. I argue exactly the opposite, presenting evidence that provided this is carried out correctly and appropriately, it should have significant predictive value.

What is more, I do not in any way suggest that ongoing care of suicidal patients should be handed back to the general practitioner (GP), certainly not before their problems have been resolved. My suggested letters are meant as clinical summaries which should be sent routinely to GPs by any psychiatric team as part of good ongoing clinical care. They do not mean, in any way, that the secondary service thereby should relinquish ongoing clinical care of their patients before treatment is complete.

How to maintain good ongoing supportive care of patients who have experienced a suicidal crisis is an important clinical challenge. My paper considers how the psychiatrist might attempt to achieve this, by emphasising concern to provide the form of help which would be most acceptable to the patient, and to which he/she would readily turn should the crisis recur.

Abstract

For a person with mental illness, travelling abroad can be challenging but it can be easier when the traveller and healthcare practitioner have a clear understanding of the likely impact of travel on the illness and of the illness on the travel experience. Travel may also precipitate first presentations of mental illness or unmask previously undiagnosed mental disorders. We propose that mental health problems should receive greater recognition in travel medicine and that psychiatrists should collaborate more closely with travel medicine clinicians to ensure that their patients benefit from the opportunities afforded by international travel.

pmc “‘To move, to breathe, to fly, to float, to gain all while you give, to roam the roads of lands remote, to travel is to live.’ Hans Christian Anderson, *The Fairy Tale of My Life: An Autobiography* (1847)”

The psychological benefits of international travel, especially for tourism purposes, have been largely ignored until relatively recently in the travel medicine literature, whose focus to date has been on the mitigation of travel health risks through vaccination and pre-travel physical health counselling. The unique challenges faced by travellers with diagnosed mental illness are rarely addressed in the pre-travel medical consultation. Furthermore, travel may precipitate first clinical episodes of mental illness in an unfamiliar environment. Travel medicine physicians without basic knowledge of psychiatry are often poorly prepared to anticipate the likelihood of decompensation of mental illness in this cohort of travellers. We propose travel psychiatry as an emerging area of both research and clinical interest. This article draws on the sparse available literature and over 40 years of combined clinical experience in psychiatry (B.H.) and travel medicine (G.F.) to describe the effects of international travel, both positive and negative, on people with mental illness, with the aim of advocating for an integrated approach to supporting individuals with mental illness when travelling abroad.

Mental health challenges of international travel

Travel, even with a recreational motivation, is inherently stressful and the perceived stressful impact is likely a product of the travel itinerary, destination, activities and individual traveller susceptibility. Felkai & Kurimay reported that 11.3% of travellers experience some symptoms of mental illness during travel, with 0.3% of travellers experiencing an acute psychotic episode.¹

Indeed, incidence data reveal that acute psychotic episodes account for one-fifth of travel-related mental illnesses. Travellers who are deemed medically fit to travel and who have no history of mental disorder may develop acute *de novo* psychosis during their trip. The cumulative effects of travel-induced stress, culture shock, inappropriate alcohol intake and/or recreational substance use, circadian rhythm disruption, underlying brain pathology and physical illness have been implicated as contributing factors in the development of first-time psychosis during travel.¹⁻³ Another subgroup of travel-related psychosis occurs during travel to destinations with high religious, cultural and aesthetic value, so-called high-valence venues.³ However, many of these episodes occur against a background of a pre-existing psychotic illness. Airault & Valk describe a number of specific destination syndromes, including Jerusalem syndrome, Stendhal syndrome and Paris syndrome.³ In addition, travel to high-altitude destinations is increasingly regarded as an additional risk factor for the development of acute psychotic episodes and an increased risk of both suicidal ideation and completed suicide.⁴

Misuse of alcohol and/or psychoactive substances among international travellers may be associated with an exacerbation of existing mental illness and could precipitate an acute psychotic episode.^{1,5} Physicians should consequently be mindful about their patients travelling abroad for the purpose of seeking therapeutic or recreational drugs. Drug tourism, whereby tourists cross international borders for the purpose of obtaining or using psychoactive substances, is associated with significant adverse health effects, including drug-induced psychosis, unintentional physical injury, risky sexual behaviour and criminal acts.⁵ In addition to drugs of misuse, medications used in travel medicine (such as mefloquine for malaria chemoprophylaxis) can potentially trigger acute psychotic episodes in people with a previous or undiagnosed mental illness.^{1,5}

Anxiety symptoms are common in individuals engaging in travel. The sense of uncontrollability and inherent unpredictability presented by travel may cause travellers to develop anxiety symptoms or worsen an existing anxiety disorder. Culture shock is a travel phenomenon that exposes travellers to the risk of anxiety symptoms, in addition to confusion, a sense of isolation, rejection and deprivation due to cultural differences experienced while abroad. Patients may feel overwhelmed when immersed in an unfamiliar destination and struggle to make the necessary adaptations to acclimatise to local customs and cultural norms. Moreover, travelling abroad inevitably leads to a lack of daily structural routine, separation from social supports in some cases and a lack of support, which can precipitate poor adherence to prescribed psychotropic medications. Furthermore, there is evidence that jet lag can exert a debilitating effect on travellers with mental illness, with sleep loss being demonstrated to increase the risk of episodes of (hypo)mania in

individuals diagnosed with bipolar disorder.² This may be significant in international travel if the patient encounters circadian rhythm disruption and other stressors that result in sleep disturbance.

Where an individual develops an acute episode of mental illness, receiving appropriate intervention in a timely fashion can be challenging for a number of reasons, including problems communicating health difficulties to clinicians, cultural differences, poorly established diagnoses and lack of clarity in relation to the psychiatric history of the traveller. Furthermore, difficulties may arise if there is delay in the diagnosis of physical illness, such as hypoglycaemia, epileptic aura or hypothyroidism, which may initially present with alterations in mental health. Repatriation to the home country where patients can receive specialised treatment from their multidisciplinary mental health team in a familiar environment may be the most appropriate intervention.¹ However, repatriation for psychiatric reasons can be a particularly complex undertaking requiring, in many cases, medical escort by a suitably trained mental health professional(s) and stabilisation of the person's mental health before costly aeromedical evacuation that may not be covered by travel health insurance.⁶

Is travel advisable for people with mental illness?

Although it is reasonable to postulate that leisure activities abroad may be beneficial for people with mental illness, research is lacking in this area. One qualitative study from The Netherlands explored how engaging in travel contributes positively to the mental rehabilitation of psychiatric patients.⁷ Material was collected from participant observation involving eleven travellers with severe and enduring chronic mental illness who were accompanied by four psychiatric nurses during two trips. Many positive experiences were reported, including maintenance of social contact; the opportunity to develop foreign language skills; enrichment of life resulting from enjoyment and cherishable memories; positive influence on self-esteem; and a departure from the monotonies of daily routine life.⁷ The research also provided a learning environment outside of psychiatric institutions for the nurses involved. Some travellers required the nurses' support in managing psychotropic medications and some activities of daily living. We have recently reported similar positive findings from semi-structured interviews conducted with a series of patients with chronic psychotic illnesses who engaged in travel independently, on their own or with friends.⁸ The putative mental health benefits of 'prescribed travel' should be balanced against the risks in less-supported, lone travellers of developing suicidal ideation or experiencing exacerbation of mental illness. This may potentially arise from unexpected travel-related stressors, including, for example, confrontations at airport security stations.

Travel mental health recommendations

Travel psychiatry has a promising future as an integrated subspecialty of both psychiatry and travel medicine. Novel research will help to establish a stronger evidence base for clinical recommendations aimed at promoting mental health during travel.⁹ We recommend that clinicians be aware of the psychological stress and exacerbating factors that patients encounter during foreign travel and encourage patients to attend a pre-travel medical consultation in order to agree on preventive strategies (*Box 1*). **Box 1** Preventive strategies in travel psychiatry: mental health recommendations for patients and clinicians

Pre-travel

- Attend a pre-travel medical consultation, where stressful events that might be encountered during travel can be considered
- Identify significant risk factors (e.g. psychiatric history, purpose of travel, destination of travel, prescribed medications)
- Obtain comprehensive travel health insurance
- Carry a brief letter from healthcare provider about psychiatric history
- Research the destination and health facilities available locally
- Schedule a pre-travel psychiatric assessment
- Reconsider daily dosages of existing psychotropic medications

During travel

- Educate traveller about jet lag effects
- Ideally, travel with family or friends
- Prescribe a psychotropic drug with anxiolytic properties during the flight, e.g. a low-dose antipsychotic or hypnotic, but avoid benzodiazepines
- Remain in contact with medical practitioner through email or web call
- Encourage treatment adherence with support from travelling companion

Have a regular, well-planned schedule

- Avoid 'triggers' of mental illness
- Avoid psychoactive substance use and caution with use of alcohol
- Seek medical help if a deterioration in mental health occurs

Post-travel

- Follow up with healthcare professional
- Post-travel psychiatric assessment

Suicide tourism, be it planned or unplanned suicide, is one of the leading causes of mortality among international travellers.¹⁰ Research, including psychological autopsies, should focus on investigating risk factors for suicidal ideation during international travel in an effort to increase the detection of such motivations in intending travellers, who may not consult a travel clinic or psychiatrist in advance of travel.

Post-travel psychiatric assessment may be indicated for certain vulnerable traveller groups, such as volunteers and humanitarian aid workers exposed to hostile and psychologically challenging environments, to counter the effects of post-traumatic stress disorder.¹¹ Consideration should also be given to the possibility of reverse culture shock, where travellers experience depressive symptoms and disorientation on returning to their home country.

Routine coverage of psychiatric disorders in travel insurance policies should be ensured in order to provide financial security to people with mental illness travelling abroad. Unfortunately, travellers with pre-existing mental illness often find themselves excluded from such policies and this greatly complicates efforts at their repatriation.

Conclusions

The lack of research and clinical attention given to travel-related mental health benefits and risks merits the development of an integrated subspecialty of travel psychiatry. This would advance our understanding of the interaction of travel and mental illness in a variety of traveller groups and travel settings. Travel psychiatry should involve close cooperation between mental health professionals and travel medicine practitioners, with ample scope for collaborative patient-centred research. Travel medicine practitioners should receive enhanced training on the psychiatric aspects of travel: travel-related psychological stressors, the impact of travel on pre-existing disorders and the potential for first-time episodes of mental illness during travel, as well as the importance of timely consultation with a travel psychiatrist.

Abstract

Aims and method

This study explored the root causes of deaths by suicide among patients under the care of a mental health trust. Thematic analysis was carried out to identify themes from the serious incident reports for patients between 1 January 2017 and 31 July 2018.

Results

In total, 48 cases were reviewed. Three main themes emerged from this study: patient-, professional- and organisation-related factors. The majority of the deaths were caused by patient-related factors, particularly exacerbation of the patient's mental health condition.

Clinical implications

This study provides insight into perceived causes of death by suicide among mental health patients. It is hoped that this will, in turn, influence the manner in which decisions, policies and resource allocation are carried out to further prevent and reduce the incidence of suicide, particularly among mental health patients.

pmc Suicide is a global health problem. It is estimated that every year about 800 000 people die by suicide worldwide.¹ Previously, the UK has reported a significant reduction in the rate of suicide. However, a report in 2018 indicated a marked increase.² Furthermore, 28% of people who died by suicide in the UK were under the care of a mental health service 12 months prior to their death.³ This implies that more than one-quarter of patients who die by suicide have an underlying mental illness and were known to services prior to their death. Perhaps, if timely intervention had been in place, the risk of suicide might have been reduced.

Serious incident reports represent a record of events deemed to have had untoward consequences for patients, families and/or carers, and the organisation.⁴ The reports are produced to identify areas for improvement in order to avoid a recurrence of such events, and not to apportion blame.⁴ Any case of unexplained death is classed as a serious incident and is referred to the coroner for inquest. Following an inquest, the coroner will make a verdict of accident, natural causes, suicide, industrial disease, narrative or open.^{5,6} A suicide verdict is only given by the coroner following evidence from the suicide report indicating that ‘on the balance of probabilities’ the deceased performed and intended an act of suicide that would result in the end of life.⁷ This new standard for the coroner’s ruling has been in place since May 2019.⁷

Predictors of suicide

In most cases, identifying why patients die by suicide is challenging. In fact, the Samaritans⁸ supported this notion, making it clear that the causes of suicide are not straightforward but sometimes could be preventable. In the clinical setting, the SAD PERSONS scale is the risk assessment tool used to predict the possibility of suicide among patients.⁹ However, there remains insufficient evidence of its ability to predict suicide, because it fails to provide a comprehensive understanding of the underlying causes of suicide; however, it continues to be used globally.^{10,11} Thus, an understanding of possible underlying causes of suicide is imperative.

The root cause analysis within a serious incident report provides details about possible or perceived causes of suicide. The root cause is based on systematic investigation of what led to the serious incident. Root causes of suicide can be multifactorial but are generally classed as: individual, quality and safety process, organisational, situational and care-related factors.^{12,13} However, in the light of the complexities associated with suicides, understanding the root causes of suicide may be a step in the right direction to prevent suicide globally.

This study aims to explore common themes emerging from root cause analysis of serious incident reports for mental health patients who died by suicide under the care of a mental health trust. The research question is: what are the root causes of suicide among mental health patients? It is hoped that study will give an indication of the perceived underlying causes of suicides among mental health patients and therefore help service providers, researchers and policy makers to implement policies and strategies to further prevent and reduce the incidence of suicide, particularly among mental health patients.

Method

This study took place in a National Health Service trust in the UK’s Midlands. Data were collected as part of a service evaluation within the trust. The process of reporting a serious incident within the trust is detailed in *Fig. 1*. In the trust, serious incident reports are based on evidence gathered independently. Serious incident reports for patients who died by suicide provide details about the individual, the intent, and the event leading up to the suicide, with the hope of learning about the cause(s) of suicide. *Fig. 1* Serious incident report process.⁴

Serious incident reports are written by a senior clinician within the trust who was not involved in the care of the patient. The serious incident investigations are done soon after the incident to avoid issues about recollection of events. However, the report is not published until the coroner’s verdict has been established. The aim is for a serious incident report to be instigated and completed within 3 months of the event, although the coroner’s verdict may take longer

to be established. The serious incident report is based on semi-structured interviews with the clinicians, the patient's relatives and loved ones, and examination of the case notes.

The root cause is established by the serious incident review team group, following the investigation by the senior clinician. A typical root cause may be about a paragraph consisting of a few sentences and is very specific about the definitive cause of suicide. The root cause section is not based on a predefined category, and details reported vary among patients. Furthermore, in some cases, a root cause may not be identified, whereas other reports contain more than one root cause. The root causes and other findings such as shortfalls in service and delivery within the serious incident report are later disseminated in team meetings. Actions are then taken based on the recommendations suggested for the learning process and service changes.

In this study, serious incident reports for patients who died by suicide while under the care of the trust between 1 January 2017 and 31 July 2018 were reviewed. There were 71 deaths during this period, of which 36 were ruled as suicide by the coroner. It should be noted that the coroner's rulings of suicide in the serious incident reports reviewed in this study were based on the old standard of 'beyond all reasonable doubt'. A further 16 serious incident reports with a narrative verdict were considered by the service evaluation team as possible suicides and were therefore included to increase the scope of learning. This review was therefore based on 48 cases.

Thematic analysis was carried out inductively by the authors to identify themes emerging only from the root causes of the serious incident reports.¹⁴ Thematic analysis was selected owing to its ability to generate trustworthy and insightful rich data about the root causes of suicide among mental health patients.¹⁴ Moreover, the use of an inductive approach helped to create themes directed by the content and not by preconceived ideas or theory. Braun and Clarke's¹⁴ six-step procedure was used to identify themes. Familiarisation, coding, theme development, revision, naming and writing up were carried out by the main researcher and agreed by two other authors. Any disagreements were resolved by discussion.

Trustworthiness and rigour were established using Lincoln and Guba's¹⁵ criteria: credibility, transferability, dependability and confirmability. Credibility was ensured by member checking and triangulation. Member checking was carried out by the review team, who validated the findings of the serious incident reports. Triangulation was ensured by the main researcher discussing the findings with two other authors. If there were disagreements, they were resolved by discussions. Transferability was achieved by providing a detailed description of the research by all authors such that it could be easily applied in other contexts. Dependability was attained by clearly documenting the research process. Confirmability was achieved by ensuring that the interpretations and findings were derived from the data, with themes and subthemes supported by quotes.

Ethical considerations

This study was scrutinised and approved by the Research and Innovation Department of the trust. Information from serious incident reports was only disclosed to the review team. Data were protected by storing electronic data on an encrypted USB drive and password-locked computers, and paper files were stored in a locked cabinet. All materials relating to this service evaluation will be stored for at least 3 years from the end of the study in accordance with the trust's research policy.

Results

There were nearly twice as many deaths in males ($n = 31$) as in females ($n = 17$). The age range was 15–86 years. The most common method of suicide was hanging. Two-thirds of the death took place at home ($n = 32$), and only one death occurred in the hospital on an in-patient ward. It should be noted that one-sixth ($n = 6$) of the reports had no identified root cause. Three main themes emerged, each of which had a number of subthemes. Quotes only from the root cause sections of the serious incident reports were used to support the subthemes and themes emerging in this study. Quotes from each serious incident report were assigned a code. The serious incident reports were labelled in chronological order (1–48). The three main themes emerging from this study were: patient-, professional- and organisation-related factors.

Patient-related factors

The thematic analysis identified three main patient-related factors that contributed to deaths by suicide: exacerbated mental health conditions, lack of engagement with services and non-adherence to medications. An exacerbated mental health crisis was the most common patient-related factor and also the most frequently recurring subtheme emerging from the serious incident reports. The exacerbated mental health condition was often secondary to physical health problems, social and relationship difficulties, an underlying criminal offence, alcohol and substance misuse, or sexual offences, especially child pornography.

Furthermore, in some cases where lack of engagement and non-adherence to medication were identified as root causes, patients also had an exacerbated mental health condition. This is because these factors could have a bi-directional effect. For instance, lack of engagement and non-adherence to medication could result in exacerbated mental illness and *vice versa*. *“Patient had a history of being reluctant to come into hospital. Deterioration in mental health was triggered in response to an argument with his family; the patient had an argument with a family member, several days prior to his death” – Report 24* *The patient suffered from paranoid schizophrenia, discontinued depot medication and thereafter appears to have complied poorly with oral medication. There was a two month period during which no medication were taken’ – Report 16”*

Professional-related factors

These are factors related to the manner in which care and services are delivered by mental health professionals (usually doctors and nurses). Five main factors emerged: issues around risk assessment and management, inadequate clinical enquiries, non-adherence or poor adherence to policies and procedures, no interprofessional communication and collaboration, and lack of consultation of carers by clinicians.

Among these five factors, issues around patient assessment and management were the most common and represented the second most frequently recurring subtheme in this study. This was an interesting finding, as most mental health professionals are trained and are aware of the protocols and practices within the trust. Further exploration revealed that poor practice, especially improper documentation, was a major cause. This was noticed more in cases where the patient frequently presented and the health professional did not update the risk assessment and management documentation. *“Early warning signs were not documented, so it is unclear whether these were identified, known and shared. Clinical documentation provided wrong information (details were not updated) about patient current state. It was anticipated that patient would make a full recovery having presented frequently previously’ – Report 21”*

Further exploration into cases where professionals did not carry out enough detailed clinical enquiries shows that clinicians had misperceptions regarding the seriousness of the patient’s presentation. This clinical enquiry includes patient history and collateral information from carers and other professionals managing the patient. *“The patient superficially appeared to be making some progress and was fully compliant with care plan and activity schedule and was engaging well with staff and patients. There was no indication that progress would not continue. It was anticipated that the patient would make a full recovery’ – Report 15”*

Consulting carers may help clinicians to corroborate or contradict patients’ claims about their mental health. Carers may be family, friends or any loved ones that look after patients in a non-professional capacity. In this study, one report indicated that the root cause was the clinician not carrying out detailed clinical enquiries and not consulting the patient’s carer. *“Patient concealed information and gave assurance of not being suicidal. This was taken on face values, despite family expressing concerns and partners assertion that patient was concealing information’ – Report 43”*

Clinicians mostly did not adhere to the trust’s follow-up review standards. Follow-up is very important as it ensures that a patient receives continued support whether they are in crisis or not. *“Patient was discharged from mental health treatment with no follow-up or aftercare arrangements despite agreement to liaise with Hospital X, and despite further episode of self-harm and having been pending transfer from hospital Y to a mental health bed’ – Report 11”*

Likewise, a lack of interprofessional communication and collaboration may result in the patient not having the necessary support. This is particularly important for patients who have comorbid physical and mental health problems. *“Given*

the patient consistently gave differing accounts of history to a multitude of practitioners, the trust should have engaged with other agencies involved in patient care and this will have helped deliver holistic care' – Report 20"

Organisation-related factors

Factors within the organisation identified as root causes included inadequate psychiatric accommodation, a lack of additional support for mental health patients (such as drug and alcohol services) and unsafe wards. At the time this study was conducted, the trust did not have a drug and alcohol service, although patients were often referred to local available services. Nevertheless, patients and their carers often indicated that they were not satisfied with the referred drug and alcohol services and would prefer one within the trust. *"Patient indicated not finding the drugs and alcohol services helpful but was still signposted. It is highly unlikely patient will make self-referral and engage with the services' – Report 9"*

Psychiatric ward bed shortages in the trust can be attributed to high demand, which may be a result of the trust's location in one of the main cities within the West Midlands. It should also be noted that in some cases where psychiatric beds were not immediately available, alternatives such as daily visits within the community or a short stay in a general hospital ward or mental health supported accommodation in the community were provided to patients. Providing such alternatives may be a safe alternative in the absence of the ideal psychiatric ward admission; however, the care and support provided in such an environment may not be suited to the patient's needs. This does not exclude the fact that suicide occurs in in-patient wards. *"The patient had a complex history and had taken overdoses previously, The last contact with the Trust, patient was expressing concerns about sleep again and was on the bed list and daily review with HTT but perhaps would have benefited more as inpatient on the ward' – Report 36"*

In this study, there were two cases of unsafe wards, one an in-patient ward within the trust and the other in prison accommodation. It was further observed that the in-patient death occurred as a result of not adhering to the trust's observation policy. *"Patient had serious mental illness, personality disorder and substance use disorder, There was no observation in last 24 hour before death and no evidence of psychiatric and psychological input' – Report 41"*

Thus, in-patient wards may be a safer option for reducing deaths by suicide; however, if no other patient- and professional-related factors are taken into consideration, in-patient wards may not provide the necessary prevention of suicide among mental health patients.

Discussion

This study confirms views about suicide being a complex problem, with aetiology and predictors that are difficult to identify.^{13,16,17} The root causes considered in this study will provide a more comprehensive understanding of possible underlying causes of suicide than the SAD PERSONS scale. This is because the SAD PERSONS scale appears to focus more on certain patient-related factors,^{9,10} whereas this study identified that underlying professional- and organisation-related factors can also influence suicide rates.

The findings are consistent with those of previous studies regarding acute crisis having a strong association with suicide among mental health patients.^{13,18} Thus, there is a need for continued assessment and support in mental health services. Often, a patient who died by suicide deliberately did not give essential information or denied plans for suicide when assessed by health professionals.^{16,19} This can be particularly difficult, as those patients are very likely to be frequent attendees with a history of self-harm, suicide ideation and multiple suicide attempts. Meanwhile, health professionals want to respect and listen to patients; hence, they work with the details provided by the patient, which might not give a true picture of the extent of their symptoms.

A particularly significant finding of this study is the need for processes, procedures and training that help health professionals to increase their ability to carry out detailed clinical enquiries while assessing and managing patients. Also emerging from this study is the need for an approach to patient and carer involvement that promotes active participation of patients and their carers (family, friends or loved ones) in assessment and management of patients. The National Confidential Inquiry into Suicide and safety in Mental Health (NCISH)³ report also supports this view, stating that clinicians should conduct a robust patient assessment which is person centred and takes into consideration the stressors, support and perspectives of family and carers.

Furthermore, involving family members is particularly useful in corroborating or contradicting the symptoms expressed by patients,²⁰ especially when patients do not willingly divulge information or deny the extent of their mental health crisis. However, confidentiality and carer rights are two factors that can swerve professionals in their decision about the extent to which family members should be involved. Also, clinicians should explore whether family member involvement in patient assessment and management is a potential protective or risk factor.¹⁶

Shortage of beds was not a major reason for deaths by suicide in this study. Since the closure of asylums in the UK in the 1950s, more mental service provision now occurs in the community than on in-patient psychiatric wards.²¹ Thus, it can be presumed that community and outreach services are equally effective in managing mental health patients and reducing avoidable admissions. It can be argued that patients in crisis will receive more effective care and support in a psychiatric unit than at home.²² Nevertheless, each patient should be evaluated based on their risk and triggers, and a decision should be made regarding whether intervention services should be delivered in the community or in a psychiatric unit.

Adherence by health professionals to policies and procedures is a crucial aspect of reducing deaths by suicide. For example, where handover and referral procedures are not adhered to, insufficient details will be passed on, affecting interprofessional communication and collaboration. Ultimately, this may result in patient assessment not being holistic, with a spiral effect on the management of the patient. Perhaps the reason the discharge and handover policies were not adhered to was poor clinical documentation. Fowler¹⁶ emphasises the importance of proper clinical documentation in providing comprehensive and practical patient assessment and management. Thus, this study indicates that clinical documentation can have a spiral effect on the assessment and continuity of care of patients and on suicide prevention.

The NCISH³ report recommends safe wards and early follow-up as key ways of reducing suicide incidence. Considering that hanging is the most common method of suicide in the UK, having safer wards is an essential priority to reduce incidence on the wards. This view is also consistent with the study of Meehan *et al*,²³ who suggested that in-patient wards should be redesigned to ensure safety. However, it appears that more suicides take place at home than elsewhere, as revealed in this study. Although it might not be practical to design or redesign all mental health patients' homes to be safe, other measures need to be put in place. For instance, studies have shown that there is higher risk of suicide in the first 7 days after discharge.^{3,23,24} Thus, carrying out early follow-up should become a priority in suicide prevention.

Summary

Suicide prevention remains a priority globally. Investigating root causes is a step in the right direction in developing strategies that may be effective in reducing the current suicide rate. It is acknowledged that root causes are not conclusive evidence of the reason suicide occurs; nevertheless, they provide an indication of the underlying causes of suicide.

The three major root causes identified in this study are interwoven, and the goal should be for suicide prevention strategies to take into cognisance all three factors. However, it is also recognised that in the present economic situation, resources are scarce. This study adds new knowledge about suicide prevention by highlighting root causes of suicide among mental health patients. It provides insight into the two most likely root causes, which are exacerbated mental health conditions and issues around patient assessment and management.

Moreover, this study indicates that using a robust person-centred approach with involvement of carers (family, friends or loved ones) in assessment and management, especially among frequent attendees, may help to prevent suicide in mental health patients. Furthermore, this study highlights the need to carry out a risk assessment each time a patient presents, in order to have an updated and relevant patient safety plan. Even in scenarios where patients present on several occasions and no new risks or triggers are identified, health professionals should document this, and a rationale for not giving an update should be provided in the patient record.

A limitation of this study was that it was conducted in one hospital trust in the West Midlands region of the UK. Therefore, the findings may not be generalisable to all other mental health services. Nevertheless, the findings are transferrable and could be applicable to other mental health services. Another limitation was the flexibility of the thematic analysis, which allows researchers to use what is deemed applicable to their research aims and objectives. To minimise this limitation, the research team have provided justifications for the choice of this methodology and details of the data analysis, and explained the measures taken to ensure trustworthiness and rigour.

A suggestion for further research is to identify factors that make patients more vulnerable to suicide in non-hospital settings and provide evidence-based strategies to reduce these. Overall, this study provides insight into perceived causes of death by suicide among mental health patients. It is hoped that this will in turn influence the manner in which service providers, researchers and policy makers carry out decisions, policies and resource allocation and implement strategies to further prevent and reduce the incidence of suicide, particularly among mental health patients.

- *Matthew Large*

¹ **Abdi Sanati meets Professor Matthew Large**. Conjoint Professor in the School of Psychiatry, University of New South Wales, and Clinical Director of Mental Health in the Eastern Suburbs Mental Health Service, Prince of Wales Hospitals, Sydney, Australia

pmc As psychiatrists, we engage with risk assessment on a daily basis. I personally have seen an increased emphasis on risk assessment since I started training two decades ago. The question for me has always been how accurate our risk assessments are. I then read the works of Professor Matthew Large and was heartened by his common-sense approach to risk. We met a few years ago in a Maudsley debate on risk. Professor Large has written extensively on risk assessment in psychiatry. Although he holds an academic title, he works in emergency departments and acute wards. He knows the reality of working as a psychiatrist. He lives and works in Sydney, Australia.

Thank you very much for your time, Professor Large. I wanted to start by asking what do you think the place of risk assessment is in psychiatry?

Before answering, I should say a few things. People who read my papers sometimes think of me as a cloistered academic, but in Australia I am a full-time clinician. I mostly work in emergency rooms and observation wards. In the past 2 days I have seen 21 hospital patients, quite a few of whom were new to me. In the Maudsley debate I was criticised for being detached from the reality of day-to-day work, but the opposite is the truth. Perhaps the most fundamental criticism of risk assessment relates to the very nature of day-to-day psychiatric practice. I don't think any of us really work with low-risk patients – I am at a loss to think who these patients even are. Therefore, in our work, risk assessment must have a modest role. Nevertheless, I acknowledge that we can moderately differentiate between people at higher risk and lower risk. My main criticism of risk assessment is not that it gives you no information, but that the amount of information it provides is so slight. The vast majority of people classified as higher risk don't engage in seriously harmful behaviour and in most studies about half of the seriously harmful events occurred in lower-risk people. Taking this one step forward, if you can imagine an intervention that is effective, benign and acceptable to high-risk patients (the vast majority of whom will never experience serious harm), how can such an intervention be rationally denied to lower-risk patients, among whom half of all serious harm events occur?

I remember reading about a paper by Frank Knight published in 1922, where he distinguishes risk from uncertainty, the former being quantifiable, the latter not. The paper was in the context of insurance, but don't you think it has a relevance in the practice of risk assessment in psychiatry?

Uncertainty is a huge driver of medical diagnostics but we do not think about it enough. As a concept uncertainty is more fruitful than risk in psychiatry. Consider the following scenario. A 16-year-old smoker may or may not develop lung cancer. Here the uncertainty is mostly due to chance and more information cannot really help you. Aged 50 the same smoker might develop haemoptysis. Whether or not the person has lung cancer is now a matter of discernible knowledge. These two types of uncertainty, sometimes called aleatory and epistemic uncertainty, are often confused. For example, while we might establish with some degree of certainty that a patient has suicidal ideas, this means surprisingly little about the chance of later suicide. More bluntly, while our risk assessments can tell us something about the patient in front of us, they are not a meaningful prediction. Unfortunately, this is not always understood and can and does have bad consequences for patients. I started thinking about this in relation to mental health law. When a group of patients are detained on the basis of a perceived risk, all higher-risk patients, including the majority false-positive group, share the burden of the resulting interventions. This is actually very old-fashioned collectivism and most of us would much prefer to carry our own risk if we were ever in this situation.

Interesting that you mentioned mental health law. I remember you wrote about the role of the dangerousness criterion. Could this criterion be useful in people like a patient who attacks his mother when he is unwell?

Sadly, we are stuck with the term dangerousness. To answer your question, if you had a patient who you knew attacks his mother when he is unwell this could be considered to be an epistemic dimension for him and might contribute to a treatment decision. However, I think he could be treated when he is so unwell as to attack his mother and because of a lack of mental capacity to refuse treatment. No recourse to risk is actually required. Further, this sort of specific knowledge about one patient is hard to generalise to others. Research invariably shows that if you do generalise a violence risk factor this will only modestly differentiate between higher- and lower-risk patients. Even when risk factors are combined, risk assessment does not work very well – a recent meta-analysis by Seena Fazel's group found that the odds ratio (OR) for violence among higher-risk patients compared with lower-risk patients was 6 under optimal research conditions and 3 under more ordinary circumstances. An OR of 6 sounds high but remember that being male is associated with an OR for homicide of about 10 and an OR for suicide of 4 in most countries. What differentiates maleness from psychiatric risk factors is the negative value or stigma associated with mental illness.

You recently co-authored a study on the relationship between suicidal ideation and later suicide. What intrigued

me was that there was not much difference between the predictive power of risk assessment based on clinical examination and risk assessment based on actuarial tools.

I accept the work of Paul Meehl that found that actuarial assessments are generally a bit more accurate than clinical assessments. What this does not mean is that actuarial assessments are sufficiently good to be a basis for clinical decisions. At least a clinical risk assessment opens some possibility for engagement with the patient and consideration of their unique qualities and needs. If used sensibly, a clinical assessment might even lead to a meaningful or helpful dialogue. A tick-box approach demeans the assessed person's human agency and decision-making and likely does much the same to the risk assessor. Patients have every bit as much human agency as we do. I always try to assess the extent to which my patients are risk assessing me as someone who can harm them by depriving them of their liberty and by enforcing treatments. I am eager to see game theory applied to risk assessment – I think there might be some fruitful work to be done in this area.

One striking feature of risk assessment tools is their poor positive predictive value (PPV). I wonder how you think tests with such a low PPV could help clinical decisions?

Well, I don't think they can. Any test with such a high number of false positives is pretty useless in medicine. I try to focus on clinical needs. Sometimes needs converge with risk but risk rarely tips my decisions. An excessive focus on risk can contribute to unnecessary hospitalisation. Psychiatrists and the media (particularly in the UK) often focus on the very rare event of a homicide by a patient with schizophrenia. My colleagues and I did a couple of studies some years ago and that found that 35 000 patients would need to be detained to prevent one such stranger homicide. Tangentially to this, what we worry about is largely a question of our value systems. I have recently been focusing on the relative risks of suicide and vascular death after discharge from psychiatric hospital: in reality, the risk of vascular death exceeds suicide within months of discharge, yet worries us much less.

There is also the role of politics. A few years ago, the UK deputy prime minister spoke of zero suicide and the focus was mainly on mental health services. Could it be that by putting all the responsibility of suicide prevention on mental health services, the politicians avoid the social changes that are necessary for reducing suicide? Changes such as reducing inequality, helping families, providing meaningful employment, among others.

Let's look at this objectively. The prevalence of mental illnesses does not vary that much between countries but the incidence of suicide varies dramatically. We have made a rod for our own backs by believing that 90% of suicides are *because* of mental illness. While mental illness is associated with suicide, this is not always causal and mental illness and suicide have many common underlying causes, for example social disadvantage, stigma and substance use. Even if we assume a big role for mental illness in suicide, where does this lead us? With the possible exceptions of lithium and clozapine, there is pretty much no evidence that psychopharmacological treatments reduce suicide, and suicide rates in hospital and aftercare are very high, suggesting we are not good at protecting our patients.

In my own experience, I have witnessed some divergence between academics and clinicians. I remember once in a debate an academic quoting research, which I add was not designed to investigate suicidality, to say all suicide was because of mental illness and no one can rationally contemplate suicide.

There is a divide. The question I have is who is a 'suicidal patient'? It is almost insulting to think that the process of listening to patients and observing their unique or idiographic characteristics can be reduced to a few common or nomothetic risk factors. I think risk assessment should be replaced by risk communication – a communication that we must have with patients and their families. We should be open about the uncertainties and the low power of our predictive tools. We need to be honest about our limitations.

One problem that we face is that the inaccuracy of risk assessment tools has to be communicated to the courts, judges and coroners. How do you think we can do it?

The courts can get this very wrong. In the case of Melanie Rabone² the Supreme Court heard expert psychiatric

2

In an important judgment in 2012 concerning the suicide of Melanie Rabone, a 24-year-old woman who was an informal patient, the UK Supreme Court ruled that the state has a duty to all patients under Article 2 of the European Convention on Human Rights. For further information see: <https://www.supremecourt.uk/cases/docs/uksc-2010-0140-judgment.pdf>.

evidence that overestimated suicide risk by two orders of magnitude. We need to explain to the courts that the presence of multiple and statistically valid risk factors does not equal useful knowledge about the future and that we are doctors and not soothsayers.

1.2.83 Gender equality in academic psychiatry in the UK in 2019

Abstract

Aims and method

To investigate whether gender balance in academic psychiatry in the UK has improved since a 2005 initiative to encourage career progression for female academics in UK universities. We surveyed the gender of academic psychiatrists across the UK and compared our findings with our previous 2003 London-wide survey and with the Royal College of Psychiatrists' 2001 workforce census.

Results

The percentage of women in academic psychiatry posts in the UK more than doubled, from 20% in 2001 to 40% in 2019, with increases at senior lecturer (from 25 to 50%), reader/associate professor (from 29 to 48%) and professor level (from 11 to 21%). Outside London, men occupy 72% of all posts and 89% of professorial posts. Within London, men occupy 45% of all posts and 74% of professorial posts.

Clinical implications

The representation of women in academic psychiatry has improved but men continue to dominate at professorial level. Gender equality appears worse outside London. The situation is exacerbated by the diminishing availability of posts across the UK.

pmc The percentage of female medical students in the UK in 1963 (the first year that data were reported) was 29%. It had increased to around 40% by 1980 and, since the mid-1990s, it has been consistently greater than 50%.¹ In 2018–2019, 59% of medical and dental students were female.² However, NHS Digital reported that women made up only 45% of qualified doctors in the UK in 2018 and 64% of consultant posts were held by men.³ This suggests that women are more likely to leave medicine or fail to progress to consultant grade than their male counterparts. Gender balance also varies between medical specialties: in psychiatry women held 45% of substantive consultant posts in 2019,⁴ reflecting a gradual increase from the 34% reported in the Royal College of Psychiatrists' workforce survey in 2004.

Gender balance is worse in clinical academia. A survey published in 2018 by the Medical Schools Council identified 3465 clinical academic posts in the UK,⁵ comprising approximately 2% of the NHS medical workforce.⁶ One-third (31%) of these posts were in London. Most (41%) were in medicine, followed by surgery (9.1%), psychiatry (7.3%) and general practice (7.2%). Men held 72% of all clinical academic posts. Gender imbalance increased with academic seniority, with women occupying 41% of lecturer grade, 34% of senior lecturer/reader grade and 18% of professor grade posts.⁵ In 2003, we conducted a survey of academic psychiatrists employed in substantive posts in London universities and found that only 24% were women, comprising 62% of lecturers, 25% of senior lecturers, 29% of readers and 11% of professors.⁷

Since 2005, higher education institutions in the UK have been encouraged to participate in the Athena Scientific Women's Academic Network (SWAN) charter,⁸ which promotes good practice in addressing inequalities in career progression in fields that have tended to have poorer gender balance – science, technology, engineering, mathematics and medicine ('STEMM' subjects). The programme has been incentivised by awarding academic departments, institutions and universities three grades of charter mark (bronze, silver and gold), with the suggestion that only those that achieve silver will be eligible to apply for certain national research funding streams.

The UK Royal College of Psychiatrists' workforce census of 2019 reported that women held 29% of clinical academic posts in psychiatry.⁴ However, these data were limited by possible double counting of clinical and clinical academic posts, missing data and lack of breakdown by academic grade. We therefore contacted all UK universities known to undertake research in psychiatry to request information about the gender balance of their substantive academic psychiatrists. We aimed to investigate the situation within and outside London universities and to compare our data with our previous London-wide survey results from 2003 and with data from the Royal College of Psychiatrists' 2001 UK-wide workforce census published in our original survey⁷ to investigate whether, in the context of initiatives such as Athena SWAN, there had been any improvement in gender balance in academic psychiatry.

Method

We contacted the relevant heads of departments of all 15 UK universities known to employ psychiatrists in substantive academic or clinical academic posts (Imperial College London, King's College London, Queen Mary University London, University College London, the Universities of Bangor, Cambridge, Cardiff, Edinburgh, Liverpool, Manchester, Nottingham, Oxford, Swansea and Warwick, and Queen's University Belfast). We requested data on the number and gender of academic psychiatrists by grade (professor; associate professor/reader; senior lecturer; lecturer; research fellow). No other data were requested, no individually identifiable data were gathered and data were collated across institutions; therefore no ethical approval was required. Departments that did not respond to the first email received two further reminders.

Analysis

Data were collated using IBM SPSS version 25.0 for Windows. We present descriptive statistics (frequencies and percentages) on the number and gender of academic psychiatrists in the UK and within and outside London. Chi-squared tests were conducted to compare the percentage of women by grade within and outside London, and the change in percentage of women by grade across the UK using the Royal College of Psychiatrists' workforce census data from 2001, and within London using the data from our previous survey of London academic psychiatrists conducted in 2003.⁷

Results

We received responses from 12 of the 15 (80%) universities, including all those in London. The gender of academic psychiatrists by grade is shown in *Table 1*. Overall, 49% of posts were held by women. Although there was equal gender balance at senior lecturer and reader/associate professor level, men occupied 79% of professorial posts. *Table 1* Gender balance among UK academic psychiatrists, 2019

Academic grade	Female, n (%)	Male, n (%)	Total, n
Research fellow	60 (70)	26 (30)	86
Lecturer	34 (64)	19 (36)	53
Senior lecturer	36 (50)	36 (50)	72
Reader/associate professor	11 (48)	12 (52)	23
Professor	21 (21)	79 (79)	100
Total	162 (49)	172 (51)	334

Figure 1 shows the gender balance by grade of UK academic psychiatrists in 2001 and 2019. Research fellow posts are not included as data on these were not reported in 2001. The percentage of female academic psychiatrists has increased from 20 to 40% overall, with the largest increase seen at the level of senior lecturer (from 25 to 50%), a statistically significant increase. Of note, the total number of posts has fallen from 366 to 248 since 2001. *Fig. 1* Percentage of UK female academic psychiatrists, 2001 and 2019.

Table 2 shows the gender of academic psychiatrists by grade in universities inside and outside London, including research fellows. Around three-quarters of all UK posts (252/334) were in London. Women held the majority of more junior posts (research fellow and lecturer) within London, whereas the reverse was true outside London (although the total number of these posts outside London was small). These differences in junior posts within and outside the capital were statistically significant. There was equal gender balance within and outside London at senior lecturer grade, but most professorial posts were held by men (89% outside London, 74% within London). Women occupied 63% of reader/associate professor posts outside London and 40% within London, but, again, the number of these posts was relatively small and thus we need to be cautious in interpreting this difference. There were no statistically significant differences in the percentage of women at these higher grades within and outside London. *Table 2* Gender balance among academic psychiatrists within and outside London, 2019

Academic grade	Female, n (%)	Male, n (%)	Total, n	Female, n (%)	Male, n (%)	Total, n	Chi-squared	P
Research fellow	57 (76)	18 (24)	75	3 (8)	7 (21)	10	110.79	0.001
Lecturer	32 (74)	11 (26)	43	2 (8)	10 (80)	12	101.45	0.001
Senior lecturer	27 (50)	27 (50)	54	9 (50)	9 (50)	18	>1	
Reader/associate professor	6 (40)	9 (60)	15	3 (37)	8 (81)	11	0.60	0.303
Professor	17 (26)	48 (74)	65	4 (11)	31 (89)	35	180.07	4
Total	139 (55)	113 (45)	252	23 (28)	59 (72)	82	18.20	<0.001

Figure 2 shows the gender balance by grade within London universities in 2003 and 2019. Research fellow posts are not included as data on these were not gathered in 2003. The percentage of academic psychiatrist posts in London occupied by men fell from 74% in 2003 to 54% in 2019, with increases in the percentage of women at every grade: a 41% increase at lecturer level, 21% at senior lecturer, 9% at reader/associate professor, and 8% at professor level. However, only the increases in the percentage of women at lecturer and senior lecturer level were statistically significant. *Fig. 2* Percentage of female academic psychiatrists, London universities, 2003 and 2019.

Discussion

We found 49% of all clinical academic posts in psychiatry to be occupied by women, compared with the 29% reported in the Royal College of Psychiatrists' 2019 census.⁴ The disparity may be explained by the limitations of the census noted previously (double counting and missing data). Although we did not achieve 100% response from universities outside London, given that three-quarters of posts were within London, this finding appears robust as well as encouraging. Our results also compare favourably with the figure of 28% reported by the Medical Schools Council for all medical specialties.⁵

Our data suggest that gender equality in academic psychiatry across the UK has improved since 2001, with increases in the percentage of women at all grades and a statistically significant increase at senior lecturer level, where women now hold 50% of posts. This is in keeping with the gradual increase in women achieving substantive consultant posts (an equivalent grade to senior lecturer) in psychiatry over a similar period.⁴ However, there has been a comparatively small rise of only 10% in women at professor grade, with four-fifths of these posts occupied by men. This is particularly disappointing when comparing these figures with other medical specialties, where women still only comprise one-third of senior lecturer and readers/associate professors and 18% of professors.⁵ In other words, the progress made in gender equality at the lower grades of academic psychiatry has not had the same rate of impact on the highest grade. This could be due to the fact that people tend to occupy a professorial post for much longer than lower grade posts and thus vacancies do not arise as often. It might therefore be expected to take longer for gender equality to be achieved at this level than at senior lecturer and reader/associate professor level. Nevertheless, 18 years is surely long enough to infer that this is not simply a 'pipeline' problem that will correct itself over time.

London compared with the rest of the UK

We also found that the situation within and outside London differed, with somewhat better gender equality in the capital, where women held 55% of academic psychiatry posts, compared with 28% elsewhere. Outside London, the majority of more junior posts were occupied by men and, although there were equal numbers of men and women at senior lecturer grade and more women than men at reader/associate professor level, there were very few of these posts. At professor level, men held 31 of the 35 available positions. Within London, although research fellow and lecturer posts were in greater supply and women held the majority of these, the '*pinch point*' in career progression came above senior lecturer level, with women representing only a quarter of all professors. Comparing our results with our 2003 survey of London universities,⁷ we found that the percentage of women at all grades had increased, but statistically significant increases were only evident at lecturer and senior lecturer level. It therefore seems that, although the opportunity for progression in academic psychiatry is improving for women overall across the UK, it remains very challenging to achieve the highest level of promotion, and the situation may be even harder for women pursuing their career outside London.

Barriers to career progression and the Athena SWAN initiative

The barriers to career progression for women in academia have been described previously,⁹ and helpfully summarised by Howard¹⁰ as including 'few visible role models and mentors, the short-term contracts used for relatively senior academic positions, lack of transparency for pay and promotion procedures, gender imbalance in the decision-making processes of promotion and organisational policies, slow setting up and take-up of work life-balance policies and, particularly challengingly, the intangible cultural factors that seem to exclude women from the corridors of power'. Others have also emphasised the importance of unconscious bias as a driver of inequality within academic institutions.¹¹

The Athena SWAN charter established guiding principles to assist higher education institutions in addressing the many barriers to gender equality, with the aim of improving the recruitment, retention and career progression of female academics.⁸ Its bronze, silver and gold accreditation awards provide an incentive to establish and develop key actions and policies to overcome the specific barriers in a particular setting, with the aim of changing cultures and processes that disadvantage female staff. The charter has since been extended to non-STEMM specialties and been broadened to include other aspects of diversity as well as gender.

The implementation of the Athena SWAN initiative was evaluated in five departments of one UK medical school using

a qualitative approach.¹² Although it was felt to have introduced a welcome mechanism to raise the issue of gender equality within the organisation, it was also reported to create considerable additional work for female staff. This included completing the lengthy SWAN application itself, as well as coordinating actions to address specific barriers, and the increased burden on the small number of senior women, who had to take on more committee work to improve gender representation. The authors concluded that the aims of the initiative were undermined by the negative impact on female staff.¹² A separate evaluation found no difference in the career progression of female academics in the 12 UK medical schools that had been participating in the Athena SWAN programme from its inception compared with those that joined after the announcement in 2011 that the award of National Institute of Health Research (NIHR) funding would be contingent on achieving a silver award.¹³

The financial incentivising of the Athena SWAN initiative by the NIHR represents a ‘carrot and stick’ approach which has certainly raised the consciousness of higher education institutions to the pervasive gender inequality they harbour. All the universities we surveyed had joined the Athena SWAN programme and 12 of the 15 held a silver award at the time of our 2019 survey. Our results suggest that in academic psychiatry there has been clear improvement in the representation of women at all grades of academic post since 2001. Nevertheless, even with the support of a national accreditation process and a financial ‘sword of Damocles’ suspended over these institutions, women in academic psychiatry remain disadvantaged in their career progression within them, particularly with regard to the achievement of a professorial post. The ongoing male dominance at the highest academic grade is, put simply, dispiriting.

Reasons for the continued inequality

One possible reason for this continued disparity is that women are not achieving the key metrics that most universities take into account for promotion to professor. Women tend to hold more teaching and pastoral support roles than their male colleagues, areas of responsibility that tend to be valued less than research activities when considering senior promotions.¹⁴ As well as research grant income, publications are a common metric for academic promotion. However, no data are available allowing us to compare the academic credentials of applicants for promotion to professor by gender in psychiatry.

Our data raise a further important issue. The Royal College of Psychiatrists’ workforce census of 2001 identified 218 academic psychiatrists at senior lecturer grade and above, but only 153 in the 2019 census. Our survey identified 195 at these grades, of whom 134 were based in London, and in 2003 we identified 165 London-based academic psychiatrists at the same grades. All these data suggest that the number of academic posts in psychiatry is shrinking. Across the UK we identified 248 posts at any grade, representing a total reduction of one-third since 2001. Although this problem is not limited to psychiatry, it seems to have been particularly badly affected. The Medical Schools Council reported a reduction in all senior lecturer and reader posts of between 25 and 33% across the four countries of the UK since 2004 and highlighted that psychiatry had seen major losses – 84.4 full-time equivalent (FTE) senior lecturer/reader posts between 2007 and 2017.⁵ This clearly adds further pressure and challenge for those hoping to enter and progress a career in academic psychiatry.

Sukriti Dhingra was an MSc student in Clinical Mental Health Sciences in the Division of Psychiatry, University College London, UK from 2018–2019. **Helen Killaspy** is Professor of Rehabilitation Psychiatry in the Division of Psychiatry, University College London, UK. **Sarah Dowling** is Deputy Manager of the Division of Psychiatry, University College London, UK.

Data availability

The data that support the findings of this study are available on request from the corresponding author.

All the authors were involved in the design of the study. S.Dh. and H.K. collected and analysed the data. S.Dh. drafted the manuscript, which was revised by H.K. and S.Do.; all authors agreed the final version before submission.

1.2.84 A qualitative exploration of the barriers to and facilitators of clozapine monitoring in a secure psychiatric setting

Sarah Blagden Jane Beenstock Natalie Auld Steve Noblett Mark LimmerCorrespondence: Dr Sarah Blagden. Email: s.blagden@nhs.net

date

2021-06

Abstract

Aims and method

To explore the beliefs and understanding of staff and patients at a secure mental health unit regarding clozapine monitoring, and to identify barriers to and facilitators of monitoring. Qualitative semi-structured interviews and focus groups were conducted with 17 staff members and six patients.

Results

Six key themes were identified. The key facilitator of effective monitoring was the motivation of staff to help patients to become independent and facilitate recovery. An important barrier was a lack of clarity around the roles of different staff groups in monitoring. Staff and patients widely supported the establishment of an in-patient clozapine clinic and perceived that it would prepare patients for discharge.

Clinical implications

An in-patient clozapine clinic is a robust mechanism for clozapine monitoring in secure settings. The barriers and facilitators identified here could be applied to other secure units to guide their systems of clozapine monitoring.

pmc Clozapine is the only antipsychotic medication with established efficacy in adults with treatment-resistant schizophrenia and is an important treatment option in forensic psychiatric settings.¹ However, it must be used with caution owing to its considerable side-effect profile.¹ Most prominently, this includes a risk of neutropenia and fatal agranulocytosis, cardiac complications and bowel obstruction.¹ Development of the metabolic syndrome, consisting of obesity, insulin resistance (often resulting in type 2 diabetes) and lipid derangements, is common.¹ Consequently, alongside psychiatric monitoring, close monitoring of several physical health parameters is required for patients, as stipulated in the British National Formulary and by manufacturers (*Table 1*). *Table 1* Minimum physical health monitoring required for patients taking clozapine (source: BNF, Lancashire and South Cumbria NHS Foundation Trust¹)

Monitoring for neutropenia	Weeks 1–18	Weeks 19–52	Ongoing monitoring

count Weekly a Every 2 weeks a Every 4 weeks a Other physical health parameters Baseline 1 month 3 months 6 months 9 months 12 months/annually Weight, BMI, waist circumference e b ✓ ✓ ✓ ✓ ✓ Pulse and blood pressure c ✓ ✓ HbA1C or fasting glucose ✓ ✓ ✓ ✓ Prolactin ✓ ✓ Lipids ✓ ✓ ✓ ✓ ✓ ECG d ✓ Liver and renal function Where there are concerns¹²³⁴

Despite being an important line of treatment, it is consistently reported in the literature that challenges remain around the use of clozapine. Previous audits have demonstrated incomplete adherence to physical health monitoring, particularly during the first year of monitoring when the risk of side-effects is greatest.²⁻⁵ Even where abnormalities are identified, this often does not translate into results being communicated or acted upon.^{2,5,6} A previous evaluation of shared-care clozapine monitoring found that implementing a different model of monitoring could feel process-driven and generate anxiety for staff, with a recommendation to identify facilitators and barriers to ensure that change is successful and sustained.⁷ Therefore, in this study, we aimed to explore the beliefs and understanding of staff and patients at a secure mental health unit regarding clozapine monitoring, and to use this information to identify barriers to and facilitators of monitoring.

Methods

Setting

The study setting was a secure mental health unit in north-west England. At the time of the study, approximately 30% of all patients were prescribed clozapine, with an average age of 36 years. This project was nested within a larger service evaluation of clozapine monitoring at the unit, which resulted in a clozapine clinic being recommended.

Data collection

Staff

Semi-structured interviews and focus groups were conducted with 17 staff members. Purposive sampling was conducted in order to represent the different staff groups involved in clozapine monitoring.

First, all junior doctors based at the unit were invited by S.B. to participate in a focus group; all five agreed to participate. The physical health team, encompassing two general nurses and two healthcare support workers, also agreed to participate in a focus group. With regard to mental health ward staff, S.B. attended a selection of in-patient wards and opportunistically asked mental health staff (nurses and support workers) to take part in semi-structured interviews, which were conducted in a private room at the time of recruitment. Eight interviews were conducted. Interviews instead of focus groups were used for ward staff owing to the practical difficulties of multiple staff being simultaneously removed from clinical duties.

¹ More frequent monitoring will be required if abnormal results are obtained.

² Weight should be measured regularly during the first 3 months of clozapine treatment.

³ Blood pressure and pulse must be checked regularly during titration of clozapine.

⁴

If there are clear cardiac risk factors or an established cardiac comorbidity, troponin and C-reactive protein (CRP) should also be checked at baseline prior to initiation.

Patients

Semi-structured interviews were conducted with six patients. Again, purposive recruitment was performed to recruit patients from medium-secure, low-secure and step-down wards. Patients were approached by a mental health nurse, who introduced the project to the patients and accompanied S.B. during interviews. Only those patients that ward staff deemed clinically stable and able to provide informed consent were approached.

In all cases, the project's purpose and voluntary nature were explained, and verbal consent was obtained. As the primary purpose of the project was service evaluation, written consent was not deemed to be required when planning data collection with senior colleagues at the unit. Verbal consent was witnessed and formally recorded. It was required that participants spoke English and could provide verbal consent. Topic guides were used for interviews and focus groups and encompassed clozapine monitoring in general, with a possible clinic discussed at the end (see Appendices 1 and 2). The length of interviews ranged from 5 to 20 min, and focus groups lasted approximately 30 min.

Epistemology

The research was underpinned by an interpretivist approach, which recognises the subjective nature of knowledge and the need to understand situations from the perspective of those involved.^{8,9}

Analysis

The focus group with doctors was audio-recorded and transcribed verbatim. All other data collection took place in clinical areas where it was not permitted to use audio-recording devices. Therefore, extensive field notes were made, and several quotes from each interviewee were transcribed verbatim to ensure data capture. Subsequently, based on field notes, quotes and transcripts, thematic analysis was utilised in the format described by Braun and Clarke.⁸ Thematic analysis is based on finding and interpreting patterns (themes) within the data.⁸ Following data familiarisation and immersion, a list of codes was generated by S.B. Next, themes were searched for, and an analytical framework was constructed by S.B. Where this framework did not fit the data, themes were further refined and alternative explanations sought until a final framework was agreed by S.B., J.B. and M.L. As well as following standardised topic guides, robust and transparent analysis was critical to ensuring reflexivity and minimising the researcher's influence on emerging themes.

Ethics

Formal ethical approval was not required as the project formed part of a clinical service evaluation. Approval for this was provided by the senior leadership team at the unit.

Results

The analytical framework is shown in *Table 2* and discussed below. Themes are divided into those that facilitate effective clozapine monitoring, those that act as barriers and those acting as both facilitators and barriers. Pseudonyms are used throughout. *Table 2* Analytical framework to emerge from qualitative data collection with staff and patients

 There is a lack of formal pathways for clozapine physical health monitoring ✓
 Patients have varied understanding and engagement around clozapine ✓ ✓

Facilitators

Clozapine monitoring as a means of promoting responsibility and independence among patients

Clozapine care was seen by staff as more than just the therapeutic compound, and about supporting the holistic recovery of an individual. Staff believed that a clozapine clinic would increase patients' knowledge and emphasise the importance of monitoring. Utilising a clinic arrangement was perceived by staff and stepdown patients as more equivalent to the community, helping patients to adapt upon discharge. *“Service users would feel that clozapine was being taken seriously and be reassured by this rather than a random person coming to take their bloods at random time points. It would help them to understand about clozapine” (Jim, Mental Health Support Worker)* *“I think it's a really good idea, it'll be like what happens in the community” (Matt, stepdown patient)*

Staff believed that patients would respond to the routine of a clinic. Although there might be some pushback initially, it was perceived that it would quickly become the norm. *“There may be stumbling blocks at the start, as there is for any new thing, but once it becomes more routine, part of every ward's day, it'll just become normal for everyone” (Geoff, Mental Health Support Worker)*

Staff are highly motivated to help patients and to promote recovery, despite competing priorities

Although all staff groups faced competing pressures on their time and worked in sometimes challenging situations, they mutually perceived each other as well trained, highly competent and motivated. Although ward staff would be required to facilitate clinic attendance, the benefits to patients of an organised system and to the wards of being able to reliably get bloods done were felt to outweigh this. In addition, a clinic was perceived to have benefits for staff development in terms of phlebotomy training, where staff struggled to get supervised experience. *“It means the right people will be doing it... it'll be a separate department doing it and will stop the communication problems” (Lucy, Mental Health Nurse)*

Barriers

The roles and responsibilities of different staff groups are not well defined around clozapine monitoring

All staff groups perceived that the roles and responsibilities of different teams involved in clozapine were not well defined. The exception to this was pharmacy, who were seen to have a clear role in delivering patient education at clozapine initiation and coordinating full blood counts (FBCs) thereafter. No staff group saw themselves as responsible for cardiometabolic monitoring and were not able to identify who was. The main barrier to defining responsibilities was that clozapine monitoring spans mental and physical health. As an antipsychotic, the physical health team saw clozapine as a psychiatric responsibility. By contrast, ward staff believed that it was outside the scope of psychiatry, owing to the physical health monitoring and extensive side-effects. *“It's a mental health medication and the responsibility of RMNs. I was always taught that if you're prescribing and administering a medication then it was your responsibility to monitor it” (Sharon, Physical Health Team)*

Going forward, it was believed that any potential clozapine clinic should be staffed by mental and physical health colleagues.

Knowledge about clozapine among staff is sometimes lacking

It was perceived by some staff that certain staff groups lacked understanding about areas not viewed to be their responsibility, particularly cardiometabolic monitoring among ward staff. There was concern about this among experienced staff, who believed that undergraduate training around clozapine had declined. They suggested that robust training was needed for forensic staff, given the widespread use of clozapine. “*It was drilled in when I was training that you had to ask everyone on clozapine about their bowel habit every morning but I’m not sure they’re doing it now*’ (Steve, Mental Health Nurse) *The experienced nurses do this very well. They’re well informed about the importance of monitoring clozapine. The new nurses really struggle, they don’t know the side effects*’ (Kristina, Doctor)”

There are a lack of formal pathways for clozapine physical health monitoring

Just as it was not clear who was responsible, it was also believed that pathways for testing and acting upon abnormal physical health results were lacking. Different wards sometimes had different systems, which made it difficult to keep track of how and whether things were done. Staff widely acknowledged that there was a need to organise monitoring, supported by electronic systems. It was believed that it would be difficult to train all staff to do this, and that a clinic model would create a discrete group competent in this. “*There’s not any formalised process and I think that is probably one of the problems as to why the clinic would be useful I guess*’ (Tom, Doctor) *The same people would be doing it all the time and would know what they were doing*’ (Carly, Mental Health Nurse)”

Both facilitators and barriers

Patients have varied understanding and engagement around clozapine

Although most patients were aware that some form of monitoring was required for clozapine, their understanding varied. This was apparent when discussing the reasons for the regular FBCs. “*It’s for cholesterol isn’t it*’ (Kyle, low-secure patient) *It’s for the white cell isn’t it*’ (Warren, low-secure patient) *It’s for the green light isn’t it?*’ (Elaine, medium-secure patient)”

Aside from regular FBCs, patients had minimal awareness of any other monitoring and were usually only aware of side-effects if they had experienced them. “*I can’t go to the toilet*’ (Colin, medium-secure patient)”

Nevertheless, patients understood why they took clozapine and perceived it favourably for psychiatric symptoms. “*Within a few weeks I was more stable and they [hallucinations] disappeared, I sometimes miss them though. Some of them were my mates*’ (William, stepdown patients)”

Patients were used to a model of care that required little effort, and staff felt that it could be a struggle to engage some. Likewise, some patients described the convenience of the current system. “*We struggle to get patients to go and see the GP. It’s a challenge just to get people out of bed and to come to the ward clinic room*’ (Steve, Mental Health Nurse) *I’m quite happy with how it is at the moment... more convenient*’ (Kyle, low-secure patient)”

Discussion

Effective monitoring of physical health parameters and side-effects is a must-do aspect of clozapine care to prevent serious incidents in the short term, as well as the long-term health effects of cardiometabolic complications. Despite this, studies repeatedly report that adherence to the required monitoring, in both in-patient and community settings, is incomplete.^{2-6,10,11} Although clozapine is widely used in forensic settings, there is very little published literature relating to its use here. This qualitative study has provided valuable insight into clozapine monitoring in a secure unit and has identified facilitators and barriers to effective monitoring. These are displayed in *Fig. 1* in the format of Lewin’s force field analysis, which depicts change as a state of imbalance between driving and resisting forces, with change achieved by increasing the facilitators, reducing the barriers, or both.^{12,13} *Fig. 1* Force field analysis of forces driving and resisting change in relation to clozapine monitoring.^{12,13}

The key facilitator was the motivation of staff to facilitate recovery and prepare patients for discharge. Staff understood the risks of not effectively monitoring clozapine and were keen to implement a more efficient model. This mirrors the findings of a previous evaluation of community shared-care clozapine monitoring, where forensic healthcare professionals were motivated by enabling patients to develop skills for independence.⁷ Both staff and patients believed that physical and mental healthcare were equally important for people taking clozapine.⁷ In our study, there was a range of understanding among patients, with stepdown patients having greater understanding of the associated benefits of monitoring. Their engagement is a further key facilitator to be harnessed. Linked to this, staff noted that patients responded favourably to routine, and that consistency should be a core component of clozapine monitoring.

In terms of barriers, an important finding was that roles and responsibilities for monitoring were not clearly defined and inter-team communication was sometimes lacking. Spanning mental and physical health, clozapine monitoring was widely perceived to be outside the scope of practice of the different teams involved. These factors have previously been identified as key determinants of psychiatrists' practice in relation to clozapine, and major contributors to low rates and inconsistency of follow-up.¹¹ Likewise, there was sometimes a lack of knowledge about clozapine monitoring, particularly aspects that staff did not perceive as their responsibility. Although the FBC component was widely understood, as results must be available to enable clozapine dispensing, some staff perceived understanding of cardiometabolic monitoring to be limited among ward staff, despite the widespread prevalence of these complications. Defined roles and responsibilities must be supported by robust pathways for clozapine monitoring. Inconsistent documentation, limited knowledge about clozapine and a lack of communication between teams have previously been shown to limit improvements when abnormalities are detected.^{4,6} Logistically, access to phlebotomy-trained staff was a key barrier to on-schedule monitoring, which has been highlighted in previous audits of clozapine monitoring.^{2,3} From a patient perspective, monitoring was passive, and many had little insight into the monitoring requirements. Although there were more barriers than facilitators with respect to changing the clozapine monitoring system, the facilitators were strong motivators, so it is anticipated that they will drive the proposed change and allow the barriers identified to be overcome.

Although not widely explored in the academic literature, there is some consensus as to what gold-standard clozapine monitoring encompasses, and this study adds to this. First, it is essential that staff and patients perceive clozapine monitoring as a tool for facilitating patient recovery, independence and safety, and not simply as the process for supplying a medication.⁷ Patient education should not be a one-off event but should be repeated throughout treatment, especially as patients may be unwell at the time of clozapine initiation and have low health literacy.¹⁴ Clozapine monitoring must be supported by care pathways and effective interventions to ensure that, first, monitoring takes place and, second, that abnormal findings are actioned.⁶ Pathways should be standardised so that they can be easily followed by busy staff working across wards. Any system of monitoring must be supported by electronic tools to keep track of monitoring.⁶ An in-patient clozapine clinic is an effective system for clozapine monitoring that is widely supported by staff and patients. This provides FBC monitoring, along with monitoring of other physical health parameters and side-effects. In terms of staffing, multidisciplinary representation is likely to be effective, with mental and physical health co-staffing supported in this study. Several senior staff members in our study raised concerns about undergraduate training around clozapine. Given the complex monitoring and severe side-effects, robust training on clozapine should be encompassed by undergraduate mental health nursing degrees and a mandatory workplace training module. Where establishment of a clozapine clinic is not feasible, it is recommended that, as a minimum, a clozapine pathway is established that defines the roles and responsibilities of different staff groups and triggers appropriate communication and actions where abnormal results are identified. This should be underpinned by an electronic system that simplifies the process and is accessible by the relevant staff.

Limitations

As with much qualitative work, there were small numbers of participants, and they were interviewed in a single location. This restricts the transferability of results, as some may be specific to the individual setting. However, the findings reinforce those from the wider literature, and beliefs and challenges have been identified that are widely applicable to mental health settings.

A further limitation is the possibility that the results were influenced by recall and social desirability bias. Furthermore, as patients were approached by a senior nurse, it is possible that patients with a favourable attitude towards clozapine or a good relationship with staff were recruited.

Summary

Clozapine is widely used in forensic settings, yet considerable challenges remain around its use, particularly ensuring on-schedule monitoring of physical health parameters. The reasons underlying this have not previously been widely explored, and this qualitative study adds to the evidence base by identifying facilitators of and barriers to monitoring. Forensic healthcare staff are highly motivated to promote skills for independence and recovery among patients, and understand the role of clozapine care in this. This motivation and enthusiasm is a core facilitator of positive change and increases the likelihood that change will be sustained. Formal procedures and pathways must be in place to underlie clozapine monitoring, supported by electronic systems and tools. A clozapine clinic is a robust mechanism for providing in-patient clozapine monitoring in secure settings that is widely supported by staff and patients, and prepares patients for transition to the community. These findings can be applied to other mental health units to optimise their systems of clozapine monitoring.

We thank all of the staff who facilitated this project. Most importantly, we thank all of the patients and staff who participated.

Data availability

The data that support the findings of this study are available upon reasonable request from the corresponding author, S.B. The data are not publicly available due to their containing information that could compromise the privacy of participants.

Clozapine monitoring – staff topic guide (interviews and focus groups) Can you tell me about your role? Can you tell what you understand about clozapine monitoring? Prompts: Why do you think clozapine monitoring is important? What are the risks to patients if monitoring is not done correctly? Can you tell me about your role with regards to clozapine? What is your understanding of how clozapine is currently monitored here? Prompts: Full blood counts Physical health parameters, side-effects Patient education Do you think the current system of monitoring works well? Who do you think should be responsible for clozapine monitoring here? Prompts: Full blood counts Physical health parameters Side-effects What do you think is the role of the ward staff, physical health team, pharmacy, consultant and medical staff? What do you think is the role of the service user in monitoring their clozapine? Prompts: Do many patients self-medicate? How are patients on clozapine prepared for discharge? Do you think service users should be more involved in monitoring their clozapine? Do you think service users are given sufficient education about clozapine when they are initiated on it and throughout their treatment? What do you understand about how clozapine is electronically monitored? Prompts: FBCs Physical health bloods, clozapine levels, ECGs etc Side-effects How do you think this could be improved? Are there any aspects of clozapine monitoring that you think work particularly well here? Are there any aspects of clozapine monitoring that you think would benefit from improvement? What barriers do you think there are to clozapine monitoring here? Can you think of anything that could be done to improve the system of clozapine monitoring here? What do you think about the idea of a clozapine clinic that service users attend for all aspects of clozapine monitoring? Prompts: Where do you think this should be? Who do you think should run this? Would this work for all service users? Is there anything else with regards to clozapine that we haven't discussed and that you would like to mention?

Can you tell me what you understand about clozapine? Prompts: Why do you think you take clozapine? How long have you been taking clozapine for? Has clozapine worked well for your symptoms? Did you start clozapine during this admission or previously? When you started on clozapine, what information was given to you about it? Prompts: Who gave you this information? Was this spoken or written information? Can you tell me what you understand about the side-effects of clozapine? Prompts: Were you given information about side-effects before you started taking clozapine? Were you given information about how to prevent any side-effects? Have you experienced any side-effects from taking clozapine? Tell me about this Can you tell me about the monitoring that you have to have for clozapine? Prompts: How often does this happen? Do you understand what they're monitoring for? Do you receive the results of your blood tests? Who do you think is responsible for monitoring your clozapine? Aside from the regular blood tests for the green, amber, red result, do you have any other monitoring for clozapine? Prompts: Do staff on the ward measure your weight and ask about your bowels? Do you have blood tests for other things as part of your clozapine monitoring? (blood sugar, cholesterol etc) Low secure and step-down only – can you tell me what you understand about how your clozapine will be monitored and dispensed in the community when you leave hospital? What do you think about the idea of having a clinic on the hospital site where you'd go to have your clozapine monitoring done? Is there anything else about clozapine that we haven't mentioned and that you'd like to discuss?

1.2.85 More research needed into long-term medical student mental health during COVID-19 pandemic and beyond

Anusha Mahesh Prabhu Intishar Rashad

date

2021-06

Contents

- *More research needed into long-term medical student mental health during COVID-19 pandemic and beyond*
 - *Declaration of interest*

pmc The mental health of healthcare professionals has been significantly affected by the COVID-19 pandemic.¹ We believe that more research focusing specifically on the long-term mental health of medical students is required. Medical students are an at-risk group, with a greater incidence of anxiety² than the general population, and a higher prevalence of suicidal ideation than physicians and nurses.³ The risk is further compounded by being young,¹ having higher awareness of disease severity, and possessing common personality traits such as maladaptive perfectionism and difficulty adapting to disruption in routine.²

Medical students often face a sense of duty to volunteer in hospitals in times of global health emergencies such as the current pandemic, which can bring particular emotional challenges. The subsequent higher risk of transmitting COVID-19 may cause increased social isolation. Uncertainty around medical education due to cancelled exams and placements also increases stress.⁴

Although a recent meta-analysis showed no difference in anxiety during COVID-19 in medical students,² isolated studies worldwide have shown increased anxiety in those whose loved ones had contracted COVID-19 and who had interacted with COVID-19 patients.⁴

Higher levels of baseline stress and depression are negative predictors of poor mental health,¹ so more research must be done to identify those especially at risk. Those with pre-existing mental health issues have reported decreased access to the usual support services during the pandemic.¹ To our knowledge, there is no available literature exploring the impact of COVID-19 on medical students with pre-existing mental illness. Experiences in previous pandemics such as SARS show that long-term mental health issues such as alcohol misuse and post-traumatic stress symptoms can persist for several years in healthcare workers who have been quarantined or have worked in high-risk areas.⁵

The majority of current studies of mental health in COVID-19 have been cross-sectional, and few have focused on medical students. Longitudinal, large-scale, multi-country studies focusing on medical students of all age groups and investigating more variables, such as pre-existing mental illness, are required to identify those most at risk and the long-term effects on this population. The results of these studies could be used to improve future implementation of targeted medical student-specific mental healthcare interventions.¹

Both authors have contributed equally in preparing this article.

Abstract

Aims and method

Radically open dialectical behaviour therapy (RO DBT) is a transdiagnostic treatment designed to address disorders associated with overcontrol, including autism spectrum disorders (ASD). To date, no studies have reported on the effectiveness of RO DBT for people with ASD. Forty-eight patients were referred to a RO DBT programme, of whom 23 had a diagnosis of ASD. Outcome was measured using the Clinical Outcomes in Routine Evaluation – Outcome Measure (CORE) and the Questionnaire about the Process of Recovery.

Results

The intervention was effective, with a medium effect size of 0.53 for improvement in CORE global distress. End-point CORE global distress score was predicted from initial severity and a diagnosis of ASD. Participants with a diagnosis of ASD who completed the therapy had significantly better outcomes than completing participants without an ASD diagnosis.

Clinical implications

These findings provide preliminary support for RO DBT as an effective intervention for ASD in routine settings.

pmc Society generally holds self-control in high esteem and it can lead to better health outcomes.¹ Consequently, high self-control has not commonly been a focus for psychological intervention. However, too much self-control, or maladaptive overcontrol, is associated with a range of problems, including social isolation, poor interpersonal functioning and mental illnesses such as chronic depression, anorexia nervosa and obsessive-compulsive disorder.² Radically open dialectical behaviour therapy (RO DBT) has been developed as an adapted form of dialectical behaviour therapy to directly target overcontrol, and is now supported by several controlled clinical trials.³ The therapy introduces strategies to improve social connectedness and intimacy and to reduce social isolation by improving emotional expression and the ability to respond more flexibly. The primary mechanism of change is through social signalling.⁴ In RO DBT, what matters most is how a person communicates or socially signals their inner experiences to others and the impact that social signalling has on their experience of social connectedness. RO DBT has been delivered in a variety of clinical settings, but there are no published studies of the effectiveness of RO DBT delivered in an adult community mental health team (CMHT).

Autism spectrum disorders (ASD) have also been recognised as disorders of maladaptive overcontrol, but ASD have

not been recorded as comorbid conditions in the studies of RO DBT to date.⁴ In the UK, the Autism Act 2009 requires National Health Service (NHS) trusts to provide access to services for the diagnosis of autism in adults and this has resulted in a large increase in referrals of individuals seeking this diagnosis to explain their difficulties.⁵ However, the National Institute for Health and Care Excellence (NICE) guideline on the management of ASD in adults indicates very limited evidence for psychosocial interventions.⁶

This study reports on the effectiveness of RO DBT for people with maladaptive overcontrol in an NHS adult CMHT setting, with a specific focus on the outcomes of a subsample of these individuals who are diagnosed with ASD.

Method

Setting

The study was undertaken in an NHS secondary care CMHT in northern England providing care and treatment for patients with mainly non-psychotic disorders. The RO DBT programme was open to other adult patients in the trust because it was the only service offering RO DBT, but the vast majority of patients came from the local team. The study used data collected routinely for all patients receiving group therapy in the service and so did not constitute research requiring ethical approval or informed consent from participants. The study was approved by Tees, Esk and Wear Valleys NHS Foundation Trust.

Sample

Patients were considered eligible if their lead clinician considered that they were presenting with maladaptive overcontrol in the context of their mental health problems or following a team case formulation meeting. Patients were identified as meeting criteria for overcontrol using a clinical interview and a range of tools, including the Assessing Styles of Coping: Word-Pair Checklist, the OC Trait Rating Scale, and the Brief Overcontrol Scale.^{2,7,8} We only accepted patients who acknowledged that they had a coping style characterised by overcontrol and that they wanted to change it. Patient diagnosis was identified from the patient electronic record.

Intervention

The typical RO DBT out-patient format is a 30-week programme and involves a 1 h weekly individual session and a 2.5 h weekly skills training session. The primary goal is to decrease behavioural overcontrol and aloofness, rather than decrease behavioural dyscontrol and mood-dependent responding, as in standard DBT.⁹ Patients are encouraged to practice disinhibition, participate without planning and to be more emotionally expressive.^{2,4} In this study, regular individual sessions were not possible because of the limited staffing resource in the CMHT. Occasionally, participants received additional individual sessions, for example, if they started late in the programme as a means of catching up. Delivering a group-only programme is a recognised variation to the standard approach.¹⁰⁻¹²

Five cohorts of patients over the course of 3 years participated in a RO DBT programme consisting of 30 weekly skills training classes. Some started the programme halfway through a cohort and so continued into the next cohort. The fifth cohort programme was cut short by the COVID-19 pandemic, when all group therapy programmes were suspended.

Therapists

Four psychological therapists trained in RO DBT delivered the programme (three psychiatric nurses and one occupational therapist) and they were supported by one psychiatric nurse in co-facilitating some of the skills classes. Clinical supervision was provided during weekly consultation meetings using the model of standard DBT.⁹

Measures

In the first skills class, participants completed the Clinical Outcomes in Routine Evaluation – Outcome Measure (CORE)¹³ and the Questionnaire about the Process of Recovery (QPR).¹⁴ These measures were repeated at mid-point (week 15) and end-point (week 30).

The CORE is a 34-item self-report questionnaire measuring the level of global distress the person has experienced in the previous week, measured on a five-point scale ranging from 0 to 4, and reported as a mean score per item. The measure contains four subdomains: subjective well-being, problems or symptoms, social and life functioning, and risk of harm to self and others. It has become a standard tool for measuring outcome in psychological therapy studies and has good psychometric properties.^{13,15} The recommended clinical cut-off for CORE global distress is a mean item score of 1.0, with scores above this threshold considered to represent ‘clinical caseness’. A mean item score of 2.0 represents moderately severe distress. Reliable change is indicated by a global distress score change of at least 0.5, whereas clinical recovery is indicated by a reduction in the mean global distress score to <1.0.¹⁶

The QPR is a 25-item self-report measure designed to evaluate the achievement of recovery goals in severe mental illness. It was designed collaboratively by clinicians and patients and has been recommended as a tool to promote engagement and a collaborative clinical approach, but also as a method of detecting change in recovery in CMHTs.^{14,17,18} As such, it can measure whether the service is meeting the perceived needs of patients irrespective of their clinical outcome.

Data analysis

Data analysis was undertaken using Real Statistics for Excel 365 for Windows.¹⁹ Baseline characteristics were described comparing differences between those completing the programme to 30 weeks (the per-protocol sample) and those dropping out early or not attending at all (the ITT sample). For the intention-to-treat (ITT) analyses we used the last observation carried forward (LOCF) method. Improvement in outcome measures at 15 and 30 weeks was examined for per-protocol ($n = 21$) and ITT ($n = 35$) samples using analysis of variance (ANOVA). Effect sizes were calculated using Cohen’s d with 95% confidence intervals.²⁰ Predictors of outcome at 30 weeks were examined for per-protocol and ITT samples using stepwise multiple linear regression. As a *post hoc* analysis, we compared the ASD and non-ASD participants for per-protocol and ITT samples for continuous outcomes using the t -test and categorical outcomes using the χ^2 -test.

Results

Sample characteristics

Of the 48 eligible participants, 23 had a confirmed or working diagnosis of ASD, either as the only identified problem ($n = 3$) or as a comorbid condition ($n = 20$). This was the single most common diagnosis among the participants. Thirteen patients from this group had the diagnosis confirmed by the local specialist autism service; the other ten were on the waiting list for specialist assessment, but the working diagnosis was an autism spectrum condition. The primary diagnoses were depressive disorder ($n = 14$), generalised anxiety disorder ($n = 8$), bipolar disorder ($n = 6$), personality disorder ($n = 5$), post-traumatic stress disorder ($n = 4$), schizophrenia and related disorders ($n = 4$), anorexia nervosa ($n = 3$), ASD ($n = 3$) and attention-deficit hyperactivity disorder ($n = 1$).

Participant flow

The flow of participants through the study is shown in *Fig. 1*. In total, 21 participants completed the programme with outcome data recorded at mid-point (week 15) and at end-point (week 30). Participants in the fifth cohort were able to complete only 15 sessions before the sessions were stopped because of the COVID-19 pandemic and so their data are included in the ITT analysis but not the per-protocol analysis. *Fig. 1* CONSORT flow diagram. RO DBT, radically open dialectical behaviour therapy.

Non-attenders and those who dropped out did not differ from completers with respect to age, gender, ASD diagnosis or global severity of problems but reported a higher level of risk and a lower QPR score at baseline (*Table 1*). The sample reflected the CMHT's case-load, with more women than men and overwhelmingly White British in ethnic origin. *Table 1* Participant characteristics according to treatment completion

Treatment completers ($n = 21$)	Treatment non-completers ($n = 27$)	$n\%/n\%$	Comparison between groups
Female	13	61	$1.85^2 = 0.31$, d.f. = 1, $P = 0.58$
White British	21	100	$0.00P = 1.00$
Autism diagnosis	11	52	$1.44^2 = 0.13$, d.f. = 1, $P = 0.72$
Age, years	Mean (s.d.)	Mean (s.d.)	$t = 0.71$, d.f. = 47, $P = 0.24$
Sessions attended	Mean (s.d.)	Mean (s.d.)	$t = 14.98$, d.f. = 47, $P < 0.001$
Baseline CORE global distress score	2.06 (0.68)	2.48 (0.76)	$t = 1.13$, d.f. = 34, $P = 0.10$
Baseline CORE well-being score	2.44 (0.50)	3.02 (1.00)	$t = 1.62$, d.f. = 34, $P = 0.06$
Baseline CORE problems score	2.52 (0.75)	2.93 (1.00)	$t = 0.97$, d.f. = 34, $P = 0.17$
Baseline CORE functioning score	2.19 (1.00)	2.46 (0.75)	$t = 0.53$, d.f. = 34, $P = 0.30$
Baseline CORE risk score	0.64 (0.00)	1.27 (0.23)	$t = 2.16$, d.f. = 34, $P = 0.02$
Baseline QPR score	24.67 (9.91)	15.27 (11.86)	$t = 2.06$, d.f. = 31, $P = 0.02$ ¹²³

The mean CORE global distress score at baseline was >2.0 for both groups, indicating that participants had moderately severe mental health problems. The lower score on the QPR measure in treatment non-completers suggests that this group was less well engaged with their care and treatment at the outset.

The reasons for drop out are reported in *Fig. 1*. External circumstances included starting a new job and taking on childcare responsibilities. Illness/therapy factors included feeling too unwell to continue participation and not being able to grasp the concepts discussed in the sessions.

Participants with a diagnosis of ASD did not differ from those without an ASD diagnosis with respect to mean age (35.6 v. 40.2 years, $t = 0.69$, d.f. = 47, $P = 0.30$), female gender (52 v. 60%, $\chi^2 = 0.30$, d.f. = 1, $P = 0.59$), mean baseline CORE global distress score (2.39 v. 2.06, $t = 0.97$, d.f. = 34, $P = 0.18$) or mean baseline QPR score (21.73 v. 21.18, $t = 1.27$, d.f. = 31, $P = 0.89$).

Outcomes at 30-week end-point for per-protocol and ITT samples

The intervention was effective in both the per-protocol ($n = 21$) and the ITT ($n = 35$) samples (*Table 2*). In the per-protocol sample, five participants (24%) achieved a CORE global distress score indicative of clinical recovery (score <1.0) and nine (43%) made a reliable improvement (reduction in score >0.5). The effect size for change in CORE global distress was medium to large (Cohen's $d = 0.59$). The mean improvement at the 30-week end-point was 0.43 (95% CI 0.09–0.78) for the CORE global distress and the mean increase in QPR score was 8.29 (95% CI 3.00–13.57). *Table 2* Per-protocol and intention-to-treat (ITT) analyses of outcomes

mean (s.d.)Mid-point,

In the ITT sample, 9 participants (26%) achieved a CORE global distress score indicative of clinical recovery and 13 (37%) made a reliable improvement. The effect size for change in CORE global distress was small to medium (Cohen's $d = 0.46$). The mean improvement at the 30-week end-point was 0.38 (95% CI 0.02–0.74) and the mean increase in QPR was 6.69 (95% CI 0.33–13.05).

Seven participants (five with an ASD diagnosis) continued in the therapy group beyond 30 weeks for clinical reasons. The mean improvement for all participants ($n = 28$) with outcome at the end of their intervention was 0.53 (95% CI 0.24–0.82) on the CORE global distress score, which represents a clinically reliable improvement overall.

Predictors of outcome

We used stepwise regression to examine which factors predicted the outcome score at 30 weeks in participants completing the programme to 30 weeks (per-protocol, $n = 21$) and the intention-to-treat sample (ITT, $n = 35$). We entered the following variables into the analysis: age, gender, initial severity (CORE global distress score at baseline), diagnosis of ASD, cohort and number of sessions attended.

Initial severity and diagnosis of ASD were entered into the model in both per-protocol and ITT samples and accounted for a highly significant amount of the variation in the final outcome score – 60% in the per-protocol sample and 55% in the ITT sample (Table 3). Participants with lower baseline CORE global distress scores and a diagnosis of autism were significantly more likely to have a better final outcome score. Table 3 Predictors of final Clinical Outcomes in Routine Evaluation – Outcome Measure (CORE) global distress score Model P Per-protocol sample ($n = 21$) $r^2 = 0.64$ adj. $r^2 = 0.60$ $F = 15.76$ <**0.001** Variables e.95% CI r Constant 0.270.39 Initial severity 0.850.180.54–1.154.81 <**0.001** Autism 0.750.230.34–1.133.27 <**0.01** Intention-to-treat sample ($n = 35$) $r^2 = 0.57$ adj. $r^2 = 0.55$ $F = 21.65$ <**0.001** Variables e.95% CI r Constant 0.080.33 Initial severity 0.950.140.70–1.196.58 <**0.001** Autism 0.370.210.01–0.731.760.09⁶

Comparison between ASD and non-ASD participants at the end of treatment for continuous and categorical outcomes

Participants with a confirmed or working diagnosis of ASD showed clinically reliable improvement and showed better outcomes than non-ASD participants with respect to functioning and perception of recovery (Table 4). Table 4 Comparison of change in continuous outcomes between participants with and without a diagnosis of autism spectrum disorder (ASD) Change in ASD (s.d.) Change in non-ASD (s.d.) T d.f. ⁷ CORE, Clinical Outcomes in Routine Evaluation – Outcome Measure; QPR, Questionnaire about the Process of Recovery.

⁸ Per-protocol sample: ASD, $n = 11$; non-ASD, $n = 10$.

⁹ Intention-to-treat (ITT) sample: ASD, $n = 18$; non-ASD, $n = 17$.

¹⁰

At the end of treatment the ASD and non-ASD participants ($n = 28$) did not differ significantly in the number who met the clinical recovery threshold (CORE global distress score <1.0) ($\chi^2 = 2.01$, d.f. = 1, $P = 0.16$). However, participants with ASD were significantly more likely to have a reliable improvement in CORE global distress score in the per-protocol but not the ITT sample. In the per-protocol sample, 73% of participants with ASD showed reliable improvement, compared with 10% of non-ASD participants ($\chi^2 = 8.21$, d.f. = 3, $P = 0.04$). In the ITT sample, the figures were 56% for those with ASD and 18% for non-ASD participants ($\chi^2 = 4.58$, d.f. = 3, $P = 0.21$).

Among the male participants completing the programme, 4/8 (50%) achieved clinical recovery (a CORE global distress score <1.0) compared with 2/13 (15.4%) of the female participants. However, the difference between men and women was not statistically significant ($\chi^2 = 2.41$, d.f. = 1, $P = 0.12$).

Discussion

The findings from this study provide preliminary evidence for the effectiveness of RO DBT for mental disorders in routine clinical practice, and in particular for adults with ASD without intellectual disability. RO DBT is a treatment for maladaptive overcontrol, which characterises many individuals with autism, and demonstrating that RO DBT is a potentially effective treatment for this population is therefore an important step forward.

There have been three randomised controlled trials of RO DBT for refractory depression^{21–23} and two open trials for anorexia nervosa.^{24,25} The only published study in a mixed diagnostic group is a non-randomised controlled trial in adults with mental health problems related to overcontrol referred to a specialist psychological therapy service.¹⁰ RO DBT has been delivered in a variety of clinical settings, including psychological therapy services, US military veterans services, eating disorder services and forensic in-patient care.¹²

In psychiatric settings, ASD is almost certainly underdiagnosed as a comorbid difficulty or misdiagnosed as a psychotic disorder, personality disorder or obsessive–compulsive disorder,^{26,27} and adults with ASD have high levels of psychiatric comorbidity and dysfunction.^{28,29} ASD is also a significant risk factor for suicidal behaviour.³⁰ Previous studies on treatment for ASD have generally looked at adapting established psychological therapies to treat comorbid conditions in people with ASD as a way of improving their mental health and well-being.^{31,32} There have been very few studies designed to improve functioning in autism itself,^{33,34} and the current NICE recommendations are largely extrapolated from work in adolescent and intellectual disability populations.⁶

Our results can best be compared with two open trials that also used the CORE as a primary outcome measure. A study of modified individual CBT for people with ASD in a specialist psychological therapy service had a larger sample ($n = 81$), but with milder baseline severity (mean CORE global distress 1.79).³⁵ Of the participants completing the therapy in that study, 37% showed reliable improvement and 19% achieved clinical recovery on the CORE global distress score, compared with 73 and 36% respectively for the participants with ASD in our study. A study of RO DBT in in-patients with anorexia nervosa had a sample size of 47 and a baseline severity of 2.21 for CORE global distress, very similar to our study.²⁴ The mean change in CORE global distress in the ITT sample was 0.46, with an effect size of 0.71, thereby showing a more positive outcome overall compared with the current study.

Social signalling, such as social smiling and prosocial body language, has been regarded as a core deficit in ASD that is not readily amenable to change. Our anecdotal impression was that many participants with ASD were able to learn social signalling, and several gave positive feedback. For example one anonymous participant commented, ‘I cannot believe how much it has helped me understand myself, ASD and how to approach the problems I face with the condition’. Given that the treatment is designed to treat overcontrol irrespective of ASD diagnosis, our finding that participants with ASD gained greater benefit requires further exploration.

Strengths and limitations

For any treatment of ASD to be delivered, it must be feasible within the current clinical practice of mental health service delivery. One of the strengths of this study is that it was implemented in a government-funded community treatment team, alongside the routine delivery of care and treatment for a wide range of mental health conditions, and without any additional resources. It is also important to note that the participants treated had an illness of at least moderate severity and were not selected for the likelihood of responding to the treatment.

There are several limitations that we recognise. This was an uncontrolled study and we did not gather data on what other treatment participants might have received. The study sample was entirely White British, so the findings may not be translatable to multi-ethnic populations. The sample size is small, and a large proportion of participants did not complete the 30 weeks of the RO DBT programme. This high attrition rate can at least partly be explained by an apparent lack of motivation and engagement at baseline among the treatment non-completers, as demonstrated by their lower QPR scores. In addition, we did not measure the fidelity of the programme to the RO DBT manual. However, despite the fact that participants in this study received a more limited version of the recommended RO DBT standard of one-to-one therapy in addition to weekly skills classes, positive findings were found in both the per-protocol and the intention-to-treat samples. This in itself is important to note, as most government-funded community treatment centres, like the one in this study, would not have the resources to provide the full programme of RO DBT. Our outcome measures were limited to self-report questionnaires, which might have been biased in favour of the treatment received, and we do not know whether the positive outcomes experienced by the participants were sustained beyond the 30-week therapy programme. We did not record the severity of overcontrol at baseline, which is one possible explanation for the better outcome in participants with an ASD diagnosis.

Implications for future research

Future research needs to examine RO DBT in ASD using a randomised controlled trial methodology and it would be important to record any additional psychological and pharmacological treatments that participants receive for comorbid conditions. Follow-up beyond the end of the therapy programme should also be measured. There are already modified versions of RO DBT being delivered¹¹ and so studies need to carefully describe the content of the therapeutic intervention and compare more and less intensive models of RO DBT. Studies using RO DBT need to report the number of participants with ASD where the treatment is directed at other disorders, as ASD is likely to be a comorbid condition in many disorders of overcontrol.

We thank the participants; Kathryn Stevinson and Laura Morrison, who co-facilitated some group sessions; the clinicians from Redcar & Cleveland Affective Disorders Team; and staff at Tees, Esk and Wear Valleys NHS Foundation Trust who supported this work. We are also very grateful to Roelie Hempel and Kirsten Gilbert for their comments on earlier drafts of the paper.

1.2.87 Impact of homicide by a psychiatric patient on forensic psychiatrists: national survey

Gillian Mezey Renarta Rowe Gwen Adshead

Correspondence

Gillian Mezey (gmezey@sgul.ac.uk)

date

2021-06

Abstract**Aims and method**

To explore the experiences and support needs of consultant forensic psychiatrists, whose patients had committed homicide while under their care. We circulated a survey to all forensic psychiatrists in the UK, through the Royal College of Psychiatrists, asking about their experiences of a homicide by a patient under their care. Respondents were invited to discuss their experiences further in a structured telephone interview and themes were identified from these discussions. Data were analysed quantitatively and qualitatively.

Results

One-third of the 86 respondents had had at least one patient who had committed a homicide while under their care. Of these, over three-quarters (78%) reported that the homicide had a significant impact on their personal life, professional life and/or mental/physical health. For some respondents, the impact was severe and long term. Respondents generally felt that they would have been helped by receiving more support in the aftermath of the homicide.

Clinical implications

Greater recognition is needed of the impact on treating psychiatrists of homicide by a patient and more support is needed for affected clinicians. Further research is necessary, including the effects of such events on colleagues in other specialties and examination of the costs versus the benefits of mandatory inquiries after homicides.

pmc Homicide by patients receiving psychiatric care is a rare event. Between 2006 and 2016, 11% of all homicide convictions in the UK, a total of 785 homicides, were by mental health patients. This is in stark contrast to the high rate of suicide by individuals under psychiatric care: during the same time period, 17 931 mental health patients died by suicide, representing 28% of all suicides in the UK.¹

A recent study by Gibbons et al² found that the death of a psychiatric patient by suicide can have a serious impact on the treating psychiatrist's psychological health, clinical practice and attitude towards their work. Concerns have been expressed about some of the unintended and adverse consequences of a patient-perpetrated homicide, both for the individual clinician and for the organisation,³ but there have been no studies examining these effects directly. In the UK, there have been several cases of psychiatrists being referred to the General Medical Council (GMC) for allegedly failing to prevent a homicide, although as far as we know, no referral has yet resulted in GMC sanction. In France, however, there has been at least one prosecution of a psychiatrist as a result of their failure to anticipate and prevent a patient-committed homicide. The psychiatrist was subsequently convicted of manslaughter, for which she received a suspended custodial sentence.⁴

A mandatory independent inquiry (which refer as the inquiry) into the care of any individual who kills and who has been under the care of psychiatric services at the material time, or the preceding 6–12 month period, was introduced in the UK in the 1990s, following a number of high-profile homicides by psychiatric patients⁵. Concerns have been expressed over the intervening years, about the potential that such inquiries have for bias and errors of judgement, including the shifting of responsibility from the system onto the individual clinician, while failing either to improve patient safety or to reduce risk.^{6–9} Despite this and the acknowledged limitations of accurately predicting risk in psychiatry,^{10–12} the practice of carrying out internal and external (if the circumstances are sufficiently serious) inquiries has continued.

This survey set out to examine the impact on their treating psychiatrist of a patient committing a homicide. Forensic psychiatrists were targeted, as they work with particularly high-risk patients, who have a history of serious violence and who are therefore considered to be at high risk of future violence, including lethal violence.

Method

In 2017 we conducted a national online survey of consultant forensic psychiatrists, asking them whether any of their patients had committed homicide whilst under their care and, if so, how the experience had affected them. An invitation to participate appeared on the Royal College of Psychiatrists website. The survey covered the following areas: impact on personal and professional life, mental and physical health; support sought or received; experience of the mandatory inquiry and associated processes and coping strategies. Everyone who completed the survey was subsequently invited to discuss their experiences further in a structured telephone interview with one of the three authors. The telephone discussion was led by a topic guide, at least in part informed by the areas covered in the quantitative survey. The discussion was recorded contemporaneously by the interviewer and themes and subthemes were identified and then discussed and refined by the three authors, until a consensus was reached. Data from the survey and transcripts are presented quantitatively and qualitatively, in terms of the main themes emerging from the interviews.

Results

In total, 86 consultants completed the survey, of whom 26 had experienced at least one patient-perpetrated homicide.

Quantitative data

The results of the survey for the 26 respondents are summarised in *Table 1*. Where a respondent had experienced more than one homicide, they were asked to comment on their worst experience. Table 1

Survey data for the 26 respondents who had experienced patient-perpetrated homicide and their patients	Respondents	Consultant gender, <i>n</i> (%)
Male	19	(74)

Adverse impact on personal life, <i>n</i> (%)	20	(77) ¹

The majority of the 26 respondents ($n = 18$; 69%) had experienced one patient-perpetrated homicide; however, just over one in four reported more than one homicide. Half of the 26 consultants had been in post for more than 15 years at the time of the homicide. The homicides had taken place between 4 weeks and 30 years earlier (mean 7 years). The majority of perpetrator patients were male and were living in the community at the time. Half the victims were family members; in only 15% of cases was the victim a stranger.

Just over three-quarters ($n = 21$; 81%) of the respondents reported that the homicide and its consequences had affected their mental health, and around one in four psychiatrists described these effects as having been ‘very significant’. Almost a half ($n = 11$; 42%) experienced physical health effects and just over three-quarters ($n = 20$; 77%) reported a negative impact on their personal life. Half the cases had been reported in the local and/or national media and three of the

1

Data (for both consultants and patient-perpetrators) relate to the homicide with the worst impacts on the respondents, if respondents experienced more than one.

psychiatrists were named in the media. Two individuals were also subsequently referred to the GMC. Ten psychiatrists (38%) reported that their career had been adversely affected as a result of the homicide.

Qualitative data

Eight of the twenty-six psychiatrists who had experienced a patient-perpetrated homicide participated in a further qualitative telephone interview.

The following themes emerged from an analysis of interview transcripts. Themes were identified through independent coding and discussion among the three authors, until consensus was reached.

Homicide as a traumatic event

All consultants recalled the moment they were informed of the killing and the emotional and psychological impact this had on them at the time. Recall of this event remained vivid and painful, despite the homicides having taken place, for the most part, years or decades earlier. Respondents clearly recalled where they were, what they were doing and what they had felt on first hearing the news. In most cases, they had been informed about the homicide through a telephone call. Some consultants had received the news at work, others while they were at home or away on holiday: “‘It happened 18 years ago ... but I still remember clearly how it made me feel.’ ‘My blood ran cold ... it was the most devastating experience of my career ... everyone’s worst nightmare.’ ‘It was harrowing, horrible, the worst experience of my life.’”

Impact on mental health

Following the homicide, consultants described a range of emotional and psychological problems, including: depression, anxiety, anger; confusion; sleep and appetite disturbance; loss of interest and enjoyment, poor concentration, social isolation and constant ruminations about what had happened. For some respondents the emotional and psychological impact of the homicide had persisted for years: “‘I became suicidal, low mood, more alcohol, anxiety, high arousal, poor sleep, anxious.’ ‘I still feel a strong sense of injustice ... bitterness and resentment.’ ‘Looking back, I got quite depressed ... not knowing what was going to happen next ... assuming the worst ... assuming my career was over, before it had even started ... I kept thinking I should have done more ... it was a potentially career-ending event.’”

Symptoms of post-traumatic stress disorder, including reliving and re-experiencing symptoms, avoidance and hyper-arousal, were common: “‘Even now if my mobile phone goes off if I’m at home, relaxing with the children/family ... my heart misses a beat ... in case someone telling me that a patient has killed ... committed suicide ... or escaped.’ ‘I thought about this case a lot and for years afterwards ... I still have images in my head of the photos of [the victims] who were killed.’”

Despite very significant distress, none of the doctors interviewed had sought medical help for their symptoms or been formally diagnosed as suffering from a mental illness. Few of them had even previously admitted to themselves the personal toll that the experience had taken on them.

Impact on relationships and family life

Respondents described feelings of personal as well as professional isolation, following the homicide. Most of them had not discussed what had happened with family members or friends, because of feelings of shame, or because they feared that they might be blamed or seen as a failure. Some doctors did not talk about what had happened, out of a wish to protect their family from such a frightening and distressing experience and to retain their home as a safe and protected space, uncontaminated by their work.

Some respondents actively avoided talking or thinking about what had happened, because it only intensified feelings of distress and helplessness. However, this avoidance also resulted in them feeling more isolated and cut off and, in some cases, misunderstood by friends and family members: “‘The killing ... had a more profound effect than I would have admitted at the time ... I only realised what a personal and professional toll it took on me, my home life and relationship with colleagues years later.’ ‘I couldn’t really talk to family, I kept to myself for months.’ ‘I coped by switching off emotionally ... It had a terrible impact on my relationship with my partner.’”

Increased use of alcohol was also reported in the months following the homicide, largely as a strategy to block distressing thoughts and to manage anxiety levels and insomnia: “‘I started drinking too much ... and it got a bit out of control.’”

Impact on clinical practice and career

Some of the direct professional consequences of the homicide included: being suspended; being referred to the GMC; being named in the local or national media; repeated appearances at internal and external inquiries and in court; change of job; and loss of income.

All respondents felt that the homicide had posed a specific challenge to their professional identity and role, including their clinical judgement, competence and confidence: “‘I felt isolated and frightened ... but I put on a good show as I had been trained to do.’”

Most consultants considered that their clinical practice, as well as the way they thought about their work, changed following the homicide. In most cases these changes were felt to be negative. The most commonly described changes were: feeling more anxious about and avoidant of risk; increased caution and lack of confidence in clinical decision-making; reduced willingness to rely on and trust colleagues; and increased cynicism about the concepts of multidisciplinary team working and collective responsibility: “‘It gave me a heightened sense of just how risky this work is ... made me less tolerant of risk.’ ‘It made me more twitchy about patients and risk averse.’ ‘I now cannot delegate and I am picky about documentation.’”

Respondents frequently expressed a sense of bewilderment about the fact that they alone, rather than any other member of the multidisciplinary team, had been held responsible for what had happened: “‘No other member of the team was singled out for similar treatment ... it was me on my own ... nurses claimed to have been frightened, intimidated, claimed no role.’ ‘I felt exposed ... and responsible ... worried I would be blamed ... that this would affect my career. I felt very alone and vulnerable.’ ‘As doctors – we think we ought to be unbreakable ... I ended up professionally isolated.’”

Despite feeling professionally and personally vulnerable and isolated, all respondents had carried on working and supporting their teams as usual in the aftermath of the homicide.

Scapegoating and professional isolation

Although some respondents felt that colleagues had been supportive, others felt that they had been treated like pariahs following the homicide, which reinforced feelings of shame and stigma. It was not uncommon for colleagues and managers to decline to discuss the case with them, ostensibly on the grounds that they might end up a witness in any future inquiry process or legal action.

Inquiries and hearings

One of the most traumatic consequences of the homicide were the lengthy, complex and often obscure inquiry processes that followed. These included not only the internal and external disciplinary processes and the mandatory inquiry process at trust level, but also frequently a public inquiry, criminal proceedings or coroners' courts in which the respondents were witnesses. Inquiries were experienced as being highly adversarial and potentially career-ending ordeals, with hidden agendas and obscure rules of engagement, over which they had no control.

Regardless of the outcome, the various internal and external reviews and the inquiry process were emotionally and physically draining. Moreover, the fact that the inquiry processes were commonly extremely prolonged, with lengthy delays between the hearings and the outcome, made it more difficult to begin to recover and move on following the experience: "I learned the meaning of the term Kafka-esque ... being prosecuted for something but you don't know what, and ... things around you keep changing in an inexplicable way." "The internal inquiry blamed everyone and was poorly managed. The interview was very traumatic ... a panel of 8 people, arguing with each other ... I physically collapsed afterwards ... I had no solicitor, no support." "It was like a big dysfunctional family ... a bird's nest of bad relationships ... where the abused children turn on each other."

A number of consultants described how they had been being expected to express remorse and contrition for the homicide, even where there appeared to be a consensus that the homicide could not have been prevented or predicted: "You had to throw yourself on your sword and go quietly, rather than whinge or complain ... even if you feel you have been treated unfairly." "The whole experience was negative, humiliating, criticising." "Ultimately you are on your own ... you need to be prepared to defend yourself ... whatever you think, you have got to say you're sorry."

None of the consultants was able to identify any positive aspects of the inquiry, in terms of learning for themselves, answers being provided to the victim's family, righting wrongs, or driving improvements in patient care and safety: "I don't think it changed practice ... it was unpredictable, there was not much more I could have done ... I didn't learn lessons at all, just made me very anxious." "... other people picking over the bones ... it was all hindsight bias." "I saw them as biased and unfair ... it was not until many years later that I could look at ... what had happened ... and think about whether there was something to learn."

Respondents frequently referred to the outcome of the inquiry being entirely and arbitrarily dependent on the individual panel members, over which they had no say or control. One consultant felt they had been lucky in having had two psychiatrist members of their panel, whose input had been helpful and constructive: "The saving grace of the independent inquiry was that there were two psychiatrists on the panel who were well disposed ... the psychiatrist on the panel was a life saver ... however, the outcome could have gone either way."

Another consultant, however, described the psychiatric input in a much more negative way: "I was very struck by the medical member's punitive approach and the rush to judgement. I also thought that there was some sadistic pleasure in shafting another colleague."

The psychiatrist member of the inquiry panel was often well known to the respondent, thereby increasing unease about the lack of impartiality. A number of consultants expressed a wish for greater transparency and clarity about how psychiatric and lay members of homicide inquiries are appointed and what training they receive prior to performing this role: "There is a need for panel members to have appropriate training for the role ... lack of due process in the homicide inquiry."

Respondents who considered the homicide and subsequent inquiry to have had no significant effect on their clinical practice or approach described this as being a matter of luck, rather than due to anything that they personally had done,

or had felt able to influence: “It had no effect on my career ... but I missed a bullet ... it could so easily have destroyed everything.”

Support sought, offered and received

Although a couple of consultants felt that they had been reasonably well supported by their NHS trust in the aftermath of the homicide, most felt that that their trust had been more concerned about protecting the reputation of the organisation, even when this meant blaming the doctor. Expressions that were frequently employed by respondents were being ‘scapegoated’ or ‘thrown to the lions’ by their employers following the homicide: “employers gave no support ... just worried about bad publicity for the Trust.’ ‘Some people contacted me spontaneously and offered commiseration, including unexpected folk ... But ... managers were defending the organisation.’ ‘There was no support of any kind or advice from colleagues or the employer ... I was made to feel like a pariah ... the Trust saw me as a threat ... I was not provided with any information about the Trust response to the SUI [serious untoward incident] or the inquiry, although ... later informed that an inquiry had reported.”

In general, consultants were left to work out for themselves who to talk to and where to seek help: “My organisation turned on me ... The College’s psychiatrists support network ... listened but was not really supportive ... I just had one phone call ... no debrief or support within the team ... I just carried on.”

Only one of the respondents reported being offered time off or counselling following the homicide.

Coping and how to survive

When asked ‘What helped you get through this?’, most respondents cited support from friends, family and close colleagues. However, feelings of shame and an understandable desire not to have to dwell on distressing events often stopped consultants from asking for help even where this might have been on offer: “I only got through because I was resilient and tough ... but I also did not talk to anyone about how I was feeling, and that had negative effects.”

Most respondents attributed their ‘survival’ to their own personal resilience and luck: “[Psychiatrists] are so tough emotionally – you have to be very resistant to stress to survive.’ ‘I learned that how you are finally dealt with depends on what you do afterwards, how you conduct yourself in the aftermath. People like a survivor.”

As regards support during the inquiry processes, good legal representation was felt to be essential, as well as access to a sympathetic colleague, who had gone through a similar experience. Several respondents suggested that it would have been helpful to have been provided with a ‘road map’ of possible outcomes, to help prepare them for what was to come: “It would help to know what to expect, what about GMC referral, what do I do to prepare?’ ‘Need to instruct a barrister – best you can get.’ ‘Need for a mentor – someone who has gone through a similar experience ... who will understand what a doctor might be feeling and give practical advice as well as emotional support.”

Suggestions were also made about the need to reconsider how homicides by psychiatric patients are perceived, reported and responded to in the UK: “The [Royal College of Psychiatrists] needs to stand up against a mob rule mentality ... needs to make sure the public understands that psychiatrists sometimes make mistakes, they do not get it right all the time and are not infallible ... just to understand how complex these issues are.”

Discussion

The psychiatrists who completed this survey described feelings of depression, anxiety, guilt and responsibility, shame and self-doubt following patient-perpetrated homicide. Professional and personal isolation, including scapegoating, were common.

Although some of these responses and experiences are similar to those described by psychiatrists following a patient suicide,^{2,13} there appear to be some important differences in the way that psychiatrists react following a patient-perpetrated homicide compared with a patient suicide. These differences may reflect the way in which society views the killing of a third and 'innocent' party, as opposed to self-inflicted harm; the relative rarity of homicide compared with suicide; and the organisational, societal and legal repercussions following homicide.

The homicide itself represented a psychological trauma similar to that following a traumatic bereavement.¹⁴ For many consultants, it led to a shattering of basic assumptions¹⁵ about the world as benevolent, meaningful and controllable and about the self as worthy. Consultants who had previously thought of themselves as being 'good doctors' found themselves defined, judged and found wanting by this single event. They were transformed overnight from confident and effective clinical team leaders to negligent, reckless and incompetent, and clinical liabilities.

As with many victims of trauma, a sense of actual or threatened loss – loss of job, loss of career prospects, loss of reputation, loss of sense of professional competence and identity – featured prominently.

The parallels with victims of psychological trauma are stark, and yet doctors who found themselves in this position were extremely reluctant to present themselves as vulnerable or distressed. The narrative commonly adopted was that the only people deserving of sympathy were the victim and their family members. Any attempt to usurp that role was felt to be both self-indulgent and distasteful. Moreover, as clinical team leaders, there was often a sense that they needed to be able to support and shield their team and to lead from the front.

Many respondents described a disconnect between the widely proclaimed mantra of multidisciplinary teamwork and collective responsibility and the way in which, in the aftermath of a homicide, they had been held responsible, above all others, for what had happened. They frequently found themselves depicted in the aftermath as dictators and autocrats, which led to feelings of disillusionment and betrayal.

For our respondents, the homicide represented just the start of what was experienced as a long, confusing and painful journey of recovery and redemption, for them as much for the patient perpetrator. Chief among the post-homicide hurdles to be negotiated and survived were the numerous legal and quasi-legal proceedings, such as coroner's courts, perpetrators' trials, GMC referral, disciplinary hearings and the inquiry.

The inquiry process and associated processes were generally experienced as frightening, confusing, punitive and humiliating. Although the process is understood to be inquisitorial in nature, it was in reality experienced as highly adversarial, with the outcome appearing to be entirely and arbitrarily dependent on the experience and beneficence, or otherwise, of individual panel members.

The way forward

The value of post-homicide Inquiries, as currently constituted, has been repeatedly questioned over the years.⁶⁻⁹ However, the social imperative to identify a cause and to be able to hold someone responsible appears to outweigh any objections on the basis of lack of fairness or transparency or even due process.

The experience of our respondents suggests that it may be time for NHS England to carry out a cost-benefit analysis of such inquiries and to review the mandatory inquiry policy. It is clearly important for the families of victims to be able to express feelings of grief and anger and to understand why the killing has occurred and what, if anything, could have been done to prevent it. However, it is also important to convey the message that such tragic events are, thankfully, exceptionally rare,^{16,17} that not all of them can be predicted or prevented^{1,7} and that there is rarely any single cause or individual responsible for them. More consideration could also be given to alternative ways to help victims' families, for example using mediation or restorative justice approaches,¹⁸ although it should also always be remembered, when thinking about who does the 'restoration', that the offender in this case is the patient who killed, rather than the doctor who was looking after them.

As with psychiatrists whose patients kill themselves, the psychiatrists in this survey had been offered no or little support following the homicide.² Trusts may need to be reminded that they have a duty of care to their employees, who require support following an event of this nature. There needs to be more open discussion about how to weigh up the doctor's duty of care towards their patient with their responsibility to protect the public, including the acknowledgement that the two may sometimes appear to be in opposition.¹⁹ The Royal College of Psychiatrists could also play a more active role in supporting its members following a patient-perpetrated homicide, such as by providing confidential telephone support and advice about where to get help and identifying colleague 'buddies' who have been through similar experiences and can provide guidance and support through the process. Early advice from defence unions and identification of senior legal experts are also clearly essential for survival.

The strength of this study is that we were able to elicit qualitative as well as quantitative responses from forensic psychiatrists. Although we focused on forensic psychiatrists, the majority of homicides by psychiatric patients are carried out by patients who are under the care of general adult psychiatrists. It is not clear whether responses of general psychiatrists following a homicide would be any different, and this survey would be worth repeating with a larger sample of psychiatrists from all disciplines to explore potential similarities and differences.

Gillian Mezey is Emeritus Professor of Forensic Psychiatry in the Population Research Institute at St George's, University of London, and an honorary consultant forensic psychiatrist at South West London and St George's Mental Health NHS Trust, UK. She is a psychiatrist member of Practitioner Health, an NHS service to support doctors and dentists who experience mental health problems, and a specialist member of the England and Wales Parole Board. **Gwen Adshead** is consultant forensic psychotherapist at Broadmoor Hospital, West London NHS Trust, and an honorary consultant forensic psychotherapist at Central and North West London NHS Foundation Trust, UK. She is a health associate for the General Medical Council. **Renarta Rowe** is a consultant forensic psychiatrist and Deputy Medical Director for Quality and Safety at Birmingham and Solihull Mental Health NHS Foundation Trust, UK.

Data availability

The data that support the findings of this study are available from the corresponding author, G.M., upon reasonable request.

The contribution of all three authors is compliant with ICMJE requirements. All three authors devised the survey, conducted interviews, carried out the analysis of data and contributed to the writing of the paper.

Declaration of interest

R.R. and G.M. have both had experience of a patient committing a homicide while under their care. Neither of them completed the survey and their experiences do not constitute part of the results.

1.2.88 Sentience and transcendence: personal reflections on physical and mental adaptation from a near-death event and life-limiting surgery

James Ramsay

James Ramsay (ramsay.jas@gmail.com)

date

2021-06

Abstract

In this article I reflect on my experience of adapting physically, mentally and spiritually to a medical trauma that had life-changing consequences. I consider how, over 7 years to the time of writing, mental difficulties were inseparable from the physical; and how, for me, both are aspects of a form of understanding knowable only as mystery. Writing from a position of religious faith, I try to convey my experiences in a way that will be of interest to others regardless of their views. At the end, I reflect on aspects of my care that might be particularly relevant for a holistic, person-centred therapeutic approach.

pmc In 2012, while working as a vicar in Newham, East London, I suffered an ‘abdominal catastrophe’ necessitating emergency resection of most of my small bowel and a portion of colon. I now live on intravenous nutrition (TPN, total parenteral nutrition, fluids and chemicals pumped direct into the bloodstream through a tube – in my case a Hickman line – permanently inserted into a central vein, thus bypassing the digestive system). The crisis occurred out of the blue. I was 60 years old and in good health.

On the way from Accident and Emergency to be prepared for theatre I had a cardiac arrest, triggered, it was subsequently concluded, by disruptive electrical impulses owing to bowel ischaemia. I was revived after 6 minutes of cardiopulmonary resuscitation (for days after the operation I was puzzled why, in addition to the pain in my abdomen, my chest hurt so much). From a side room, as she was being warned of a not very hopeful outcome, my wife Celia saw me being wheeled in an oxygen tent for a second computed tomography scan.

The operation was completely successful, and physical existence felt near-miraculous as I came out of the crisis. Over the following months and years, however, as TPN became normality, my memory of the trauma lost much of its emotional resonance and life began to feel as mundane as if nothing had happened. Faith sustained me through physical challenges and depressive periods, return to work and early retirement, but I found myself asking age-old questions: Is there meaning to all this? What is it to ‘live’ rather than merely ‘exist’? How can life be at once so cruel, so tedious, so

beautiful? Far from abstract, this questioning was visceral: gut experience (recognising the irony of the image) striving for conceptualisation. Pre-catastrophe faith had to engage with both a new wilderness of meaninglessness within myself and a baffling sense of transcendent blessedness – experiential encounter with the teaching (e.g. *Mark 8.35*) that we must lose our life to find it, a maxim I return to later in this article.

The anaesthetist and the chaplain

As I was being prepared for theatre, consciousness was a floating state anchored to a locus of morphine-dulled pain I knew to be my body. ‘I’ was an internal voice observing, joking about signing (scrawling, on my back) the consent form in such circumstances, and instructing Celia where the church wardens would find the service sheets I had prepared for Christmas in 4 days’ time.

The anaesthetist chatted to put me at my ease. “‘What do you do?’ she asked. ‘Your job?’ ‘I’m a vicar.’ ‘That’s nice.’ ‘Not everyone thinks so.’ ‘Well, I do! I’m Orthodox.’”

I tried to sit up, but movement was no longer possible. It was the beauty of the Eastern Orthodox Liturgy that, years before, had attracted me back to Christian faith.

My next recollection is of the anaesthetist saying, close beside me, “‘I’m very worried.’ ‘I know.’ From the outset she had voiced anxiety about the situation. ‘They’ve told you this is a major operation. But I don’t think they have really ... You do realise, don’t you? It is ... very serious.’”

The rhetorical question and understated comment were exactly what I needed: they enabled my instinctive knowledge that I might die to surface fully into consciousness. Our earlier exchange had (I think) permitted her to follow her hunch that, although ‘the patient’ must not be distressed, ‘the priest’ would wish to be alerted to the prospect of dying. “‘Can I see a chaplain?’ I asked.”

The on-call chaplain was Brother Julian, a Franciscan who ran a local hostel for homeless people, and whom I knew well. His usual beaming smile brought into the room the whole universe of faith – in which pain, fear and death are embraced within an infinitely vaster continuum of grace, compassion and joy. There was neither time nor need for words beyond thanks, prayer and a blessing. Having come straight to the preparation room, Brother Julian offered to fetch the oil of anointing from the multifaith room the other end of the hospital, but I heard Celia say, ‘Can we get on?’ and I was happy with this. Were we not ‘one flesh’? Everyone then withdrew for Celia and me to say our maybe/maybe-not goodbyes. I entered sedation in a state of great peace and awareness of love, confident that whichever way the operation went, it was toward life.

Religious experience, faith and spiritual context

A conventional English private education had ensured I knew my Bible and Book of Common Prayer. At home, however, although there was no active hostility to faith, religion had not been part of life. At university I became gripped by theology, but almost as if ‘I’ were another person: real spiritual life was art, music and pleasure, with a lazy inclination toward Taoism. Then, at 27 years of age, I had an overwhelming inner experience that rid me of suicidal fantasies I had entertained since adolescence. Although disliking the phrase ‘born again’, which I associated with people who seemed stuck in their conversion experience, this event felt indeed like re-birth, in line with Jesus’s dictum: ‘I tell you, unless someone is born from above, he cannot see the Kingdom of God.’ (*John 3.3, The New Testament, A Translation* [David Bentley Hart]).

Spiritually I felt most at home in the mystical tradition of patristic and Orthodox writers, The Cloud of Unknowing and St John of the Cross. The theology of the Vedas and traditions of contemplative prayer in all faiths brought spiritual enrichment. Denominational Christianity seemed cramping. But hearing my default Anglicanism described somewhere as ‘the most spacious mansion in Christendom’, that is where I committed myself.

Ordained at 34 years of age, I had served most of my ministry in institutionally marginal parishes with wider community commitments: in Newham, these included work with refugees; and when I was in Accident and Emergency, stories of people elsewhere in the world suffering atrociously without medical support played in my mind like a kind of mantra, sustaining me in my own lesser experience of pain and powerlessness.

Short bowel syndrome, TPN and therapeutic context

It transpired my abdominal catastrophe had been caused by a section of small bowel becoming trapped in a caecal hernia, of which I had been unaware, starving my whole gut of oxygen. Yet this functionally useful explanation (no further investigations needed) did not satisfy my hunger for an explanation at a holistic rather than instrumentalist level.

Through parish work and ministerial training, I was acquainted with the National Health Service at every grade and had visited nearly every kind of hospital ward. A patient's view is radically different. Nevertheless the Gospel imperative to visit the sick had prepared me in the sense that, through empathy and compassion, however partial, I brought better informed awareness to the experience.

It took time to get the hang of TPN. I now infuse 6 days a week, for 14 hours each infusion. The aseptic procedure for connecting and disconnecting is fiddly and time-consuming. Of several side-effects, the most immediately disagreeable and socially awkward is constant diarrhoea – despite having virtually no appetite, I have to eat to maintain other organ functions (my surgeon had expressed pleasure that, with still just enough jejunum to connect to my colon, I did not need a colostomy).

Thankfully I can walk about with pump and fluids in a backpack during infusions. However, with the functions of physical existence taking up so much time, every day I face the question of what makes existence *meaningful*. In that confrontation faith is a compass and map, as well as emotional sustenance, toward an answer that (as, since my conversion, I no longer give credence to the existentialist Absurd) must necessarily be greater than existence: God, obviously. Yet the word 'God' has become so commodified it is ever more incapable of bearing the weight of its own meaning.

From theological college I had gained outline familiarity with psychotherapeutic theories and praxis, and over the years had myself undergone two periods of counselling in relation to stresses present and past. I also regularly talked with a spiritual director. In the parish I offered a listening ear to people going through difficult times, some of whom found the feelings stirred up in clinical therapy sessions hard to handle (my role being to support a parishioner, not intrude upon therapeutic ground). However, in the aftermath of abdominal catastrophe I needed first and foremost to recover a sense of myself simply as a human being, rather than an *object* of surgical, therapeutic, caring or technological intervention.

Only gradually did I come to recognise this feeling of being less than fully human. Poor communications across the National Health Service, management muddles and homecare company inefficiency compounded mental stress. Lacking strength to 'think positive', however, I rediscovered a sense of agency through silent, often wordless prayer. Acknowledging Christ in all I met, from consultants to cleaners and names at the bottom of emails, I regained a sense of humanity and joy. Holding prayerfully in mind the millions around the world enduring infinitely worse, I outfaced the petty humiliations of dependency.

Curiosity about my condition helped combat spiritual stasis and temptation to self-pity. Although not disabled, I have lost an essential organ. A plastic tube sprouts from my chest. I receive artificial nutrition. Certain activities are now problematic or impossible: risk management is self-conscious, psychological nervousness or cavalier overcompensation hard to avoid. After two bouts of septicaemia (the second time, going into septic shock within hours), I agonise about carelessness. Having also suffered nerve damage in my right hand and developed atrial fibrillation and low thyroid on top of normal ageing problems like arthritis, my body clamours for attention. Yet all remind me ... I am ALIVE!

The body as a spiritual organism

Bodily demands are depressing; at the same time, off the flint of faith, so to speak, they spark amazement (as in 'amazing!', 'wow!' or religious 'Amazing Grace'; but also an inner maze of numinous darkness, struggle and trust, wilderness and promise). Christianity proclaims 'the Word' – the cohering principle of the cosmos – revealed in the uniqueness of an individual historically existent human being. Incarnation, sometimes termed 'the scandal of particularity', defining Jesus as both human and divine, makes for a faith in which at one level the spiritual is set aside. In the mystical tradition particularly, the body can become the entire focus of the transcendent.

Vital to my progress was and is contemplative prayer: a spirituality, sharing similarities of practice with other faith traditions, in which the body is not merely a transient vehicle for spirit but, in its very mortality, a 'temple' (*I Corinthians*

3.16) of glory, of the eternal nature and identity of the divine indwelling time. Jesus tells his disciples that to find life they must lose their lives for his sake and for the sake of the 'good tidings'. The Greek word translated as 'life' here is *psyche*: meaning not only body (*soma*), but also intelligence, imagination, feeling, intuition, consciousness, all that constitutes personal identity – soul (somewhat like Hebrew *nephesh*, not disembodied Neo-Platonic soul).

My catastrophe made me experientially aware of my disposability. However, survival brought an intimation, equally intense, of the transcendent *soma pneumatikon*, the resurrection body of divine 'breath' or spirit, *pneuma* (*I Corinthians 15*). Insofar as faith is an owned creaturely experience, diverting one, at the level of will, from unconditional openness to the love of God, I realised that losing one's *psyche* entails losing faith itself.

Near-death experience and sentience

My cardiac arrest was accompanied by no near-death experience in the normal sense of extraordinary feeling or vision. Such experiences inspire considerable popular and research interest. However, any near-death event (most people who recover from a near death event do not report a near-death experience) raises important questions about human *being* at a liminal juncture.

At a brain-conscious level there may be nothing; yet our being in its wholeness is more than consciousness: the fact of existence is inseparable from individual and communal *identity*. As a priest, I find it significant that a body before burial or cremation is (to relatives and friends) still 'her' or 'him' rather than 'it'. This reflects the subjective emotions of the living; yet at the same time, disposal of human remains has archetypal cultural significance, suggesting that a human corpse cannot be totally reified without violation of some quality essential to human being. Can that quality be pinned down?

My 6-minute outage from normal existence is a blank to me. However, my sense of who I am also has an unconscious relational, narrative dimension. My consultant tells me that the physiological effects of cardiac arrest are not easily identifiable, and personal realisation of what I had been through had a psychological effect on me. The event of which arrest was part had, in its wholeness, a drama incommunicable through empirical analysis. Comprehension ('grasping together') requires comprehensive assimilation: epistemic integration of experience at every level, including that of the basic organic matrix of existence, the fundamental conditionality of experience.

I had not been dead for 6 minutes, but what had I been? 'Near death' sounded banally quantitative, avoiding qualitative definition. 'Clinical death' was portentous, but did not help me understand. 'Understanding' would require, I felt, not merely an empirical cognitive account, but some sapiential *event* at the level of my whole being, resonant of the all-affecting nature of a personal crisis.

It was in remembering back to recovery of consciousness in intensive care that I came to the notion of sentience. That moment also represented final return to consciousness from the cardiac arrest: realisation that I was, indeed, alive.

I had gone into theatre knowing that I might not come out alive. At the moment of reactivating consciousness, I simply remember a sensory experience of whiteness, whether from something external or from within, like a screen coming to life, making me wonder, 'Where am I?' Then I recalled being told, as I was being wheeled into theatre, that after the operation I would be taken to intensive care. So ... that must be where I was. Which meant I must be alive. 'That's nice', I thought.

The trite words reflected a two-dimensional state of awareness: the cognitive intensity of the moment precluding reflective consciousness. Meanwhile, the felt question 'Where am I?' presupposed, at a purely sentient level, trust in the fact of my own existence.

Can there be any form of consciousness without that fundamental level of existential trust? How does simple animate matter relate to the phenomenon of consciousness? From a position of faith, philosophical discussions of the nature of mind and consciousness in relation to matter, in particular the brain, are reminiscent of pre-scientific attempts to locate the seat of the soul. Confidence in one's own existence seems to me now, at a distance from intensive care, the pre-condition of any capacity for ideation; a synergy of different aspects of being that, if it can be conceptualised at all, would require so to speak quantum rather than Newtonian understanding.

The body and mystery

Jesus wept. This manifestation of divine vulnerability precedes the raising of Lazarus from the dead (*John 11.1–44*). In hospital, more than once in emotional shock I pulled the bedding over my head and cried. When the Muslim chaplain, whom I knew through interfaith work in Newham, visited, I cried – and apologised. What is the power and shame of tears? This purely physical ‘welling up’, a universal human experience, brings what is highest and deepest within us unavoidably to consciousness.

For over a year after leaving hospital, several times a day, without warning, with no conscious emotional desire to weep, I experienced a kind of hyperventilation like a child sobbing. Initially these spasms felt consistent with an underlying emotional state; but as they continued even after my emotional condition had stabilised, it occurred to me my body held memories that consciousness had either successfully processed or, as a result of the anaesthetic, never directly experienced. My sentient being had suffered more trauma than my ‘self’.

Although I had no near-death experience during cardiac arrest, my ‘conversion’ over 30 years previous had been precipitated – the details are beyond the scope of this article – by a frightening out-of-body experience in which I saw my body as a *thing* separate from me. The thing was discarded and I felt (as I articulated it at the time) that I had ‘jumped into my own body’, a new body, the true me.

Sentience may affect us in ways we cannot be conscious of, rather as cancer or medication are already at work before symptoms manifest. It may at some point become empirically explorable. Yet, more significantly for whole-person understanding, we already know it as mystery. Mystery can become glib, just as certainty, incurious about its own nature, can foreclose on open-minded experience; but as the liminal zone of our being, it transcends apprehension, interfaces with the transcendent ... guiding the anaesthetist’s hunch, informing the chaplain’s smile.

In hospital after my operation a young doctor appeared one day: ‘You’ve been given a second life’, he said, hurrying off. I suspect it was he who had resuscitated me. The distinction between a second life (of extended mortality) and new life (qualitatively changed spiritual life) in Christ became crucial for me. Lazarus was not raised to immortality, and my bodily survival was a medical success story. So what?

My first near-death event was, in terms of *life*, more significant than the second; yet the quasi-miracle of physical survival years later brought life alive to me again. A vehicle of agony and abuse, delight and wonder, even at its most basic level of sentience the body is to the eyes of faith a sign (theologically, a sacrament) of a quite other order of being: a new mortality that is eternal, in tune with angelic intelligence (the substantiality of inexpressible communications), and destined for glory (the holistic experiential, philosophical and ethical ground of dignity of every human life).

In physically ingesting the body of Christ in the bread of the Eucharist we participate in the Body that is the Church – a communion of minds and affections, vision and hope, compassion and concelebration, transcending its own fatal debilities. TPN sustains my second life, but it is the *mystery* of the body, new life, that makes that life worth living.

Concluding reflections on care

In risking crossing the clinical boundary to address me personally, the anaesthetist transformed the crisis for me. The prayer with Brother Julian meant that I went into a dangerous operation with a sense of complete preparedness. But had I not myself known about chaplaincy, this care would not have been offered.

As a patient I was also conscious of the emotions and energy levels of carers – professionalism cannot eradicate human relationship. I was touched and intrigued by the young doctor’s visit, and longed for a chance to thank him properly.

Patients are the *objects* of medical professionals’ care. We are in their power: most of the time I experienced this as beneficent objectivity. Equally, however, I felt both we and they were caught in an under-resourced system that claims too much, creating depersonalising reification. COVID-19-era precautions will presumably make it even harder to maintain the personal relational care I found, and still find, so vital to well-being.

1.2.89 The sociocultural and behavioural characteristics that patients want in psychiatrists: cross-sectional survey of patients' views

Richard Laugharne Stefan Priebe Agnes Chevalier Catherine Paton Rajaei K. Sharma Allison O'Kelly Giles Richards

date

2021-06

Abstract

Aims and method

There appears to be no research to date investigating patients' preferences for sociocultural characteristics or behavioural qualities of psychiatrists. We aimed to assess which are most important to patients. Patients (132) in community mental health teams across two sites (East Cornwall, East London) completed a questionnaire ranking the importance of different sociocultural characteristics and behaviours of psychiatrists.

Results

Patients cared more about age and gender than other characteristics. Four preferences (from a choice of ten) regarding behavioural qualities were clearly identified as important: explaining things clearly, dedication to personal treatment, being friendly and polite, and being up to date with medical knowledge.

Clinical implications

Patients are fairly unconcerned about the age, gender, religion and social background of psychiatrists. Characteristics they care about most include communication skills, competence, dedication to personal treatment and friendliness. Explaining things clearly is particularly important. This indicates specific areas of improvement for training and further research.

pmc Patient preference is a central principle in healthcare. Both patient views and satisfaction are recognised as important as expectations of standards of care rise.¹ Studies on patient satisfaction with care have shown that the therapeutic relationship between patient and doctor and the interpersonal relationship with staff are important to patients.²

The evolution of patient-centred care means that patient involvement is increasingly integral to health services research and development, demonstrated by a rapidly growing literature base of patient views. However, there is still a dearth of literature examining patient involvement for improving professional performance in medicine.³ The literature that does exist largely focuses on communication skills during consultations. This scarcity means that we cannot yet state whether patient feedback can affect performance and what the influential factors are.⁴

We know that judgements are made on the basis of initial perceptions;⁵⁻⁷ these perceptions are based on easily identifiable features such as gender or age, and on traits judged to be important by each individual, such as standing within

society. Gledhill et al found that psychiatric in-patients prefer psychiatrists to wear smart attire and to call them by their first name, although this research was conducted in 1997.⁸ However, the smart attire may also lead to patients viewing their psychiatrist as less friendly and approachable.

Patient preference regarding a doctor's gender is an obvious and better explored example of consideration of patients' attitudes. It has been found that significant gender preference is low but trends for same-sex doctors are seen in specific scenarios, including choosing a primary care doctor.⁹

A study undertaken in The Netherlands in 1993 by Kerssens et al used a general household survey to investigate gender preference for 13 different medical specialties and explored possible reasons for any preferences arising. They found that gender preference was stronger in specialties more likely to be engaged in intimate and psychosocial health problems, such as general practitioners (GPs) and gynaecologists. They found that individuals who indicated a preference for a female physician did so on the basis that they found it easier to talk to a female and felt more comfortable being examined by a female and the same reasons were cited by those indicating a preference for a male doctor. For women, 81% had no gender preference for psychiatrists, 4% preferred a male and 15% a female psychiatrist. For men, 91% had no preference, with 3% preferring a female and 6% a male psychiatrist. This was a population, not a patient, survey.¹⁰

More recently it has been suggested that gender is likely to continue to influence the doctor–patient relationship more in psychiatry than in most other specialties. This may be due to the many entrenched social perceptions and stereotypes that we are still too unaware of.¹¹ It has also been found that female psychiatrists are still at an advantage when it comes to developing a working relationship with their patients.¹²

Patients are also likely to have strong views on how important various behaviours and skills of clinicians are. When examining communication, there is clear evidence that modifiable human behaviours can have positive or negative effects in consultations. Yet even when specifically examining empathy, Derksen et al found that, although widely promoted as a fundamental skill in clinical practice, evidence is scarce for the effect of greater empathy.¹³ A commonly identified negative characteristic of healthcare professionals is paternalism. The desire for an equal power dynamic is one theme that frequently arises in studies examining the patient–medical professional relationship.¹⁴

Evidence suggests that patients attending out-patient psychiatric services are generally satisfied with the care they receive from their psychiatrists.^{1,12} There is some evidence exploring patient satisfaction pertaining to particular qualities in their psychiatrists, such as whether they are attentive, caring in demeanour, knowledgeable about an individual's illness and able to explain conditions well.^{15–17}

There is little literature on any aspect of how the patients' role is integrated.⁴ Even when patient involvement is promoted, many assumptions are made as to the scope, such as how, when and on what they can give feedback. Indeed, it has been seen that there is sometimes a misalignment between patient priorities and changes put into effect.¹⁸ For example, as part of the revalidation cycle in the UK's National Health Service (NHS), doctors are mandated to submit and evaluate patient feedback. This has been found to have a positive influence overall although its exact purpose and use remain a point of contention for many.³

It is also important to question why patient involvement in the development of professional performance has been lacking. Recent analyses have found that negative attitudes of doctors may in fact be a key barrier preventing systems development, thus hindering performance improvement.³ It is still important to generate the evidence, as clinical outcomes are likely to be affected.

There is also some indication that a therapist's perception of the patient's priorities can be incorrect. When there is a developing relationship, this failure can strongly affect the patient's confidence in their therapist.¹⁹ However, there appears to be no research to date specifically investigating patients' preferences for the sociocultural characteristics of their psychiatrists.

It can take up to 17 years for research to translate into practice in the UK health service; by developing and improving patient involvement we may be able to improve this implementation process and decrease the time frame.²⁰

Aims

This study aimed to explore the characteristics and qualities of psychiatrists that are most important to patients. We asked the following research questions: What sociocultural characteristics about psychiatrists are important to patients? What behaviours are most important to patients in their psychiatrist?

In addition, we hoped the data would be able to shed light on the following gender-based question: Are female patients more likely to want a female psychiatrist?

Method

Setting

The study took place in community mental health teams (CMHTs) across two UK NHS foundation trusts. The sites were a general CMHT and a complex care and dementia team in East Cornwall and a CMHT in East London. We therefore approached patients across very different environments – a deprived rural area in south-east Cornwall, which is predominantly White in ethnicity, and a deprived urban area in London, which is significantly ethnically diverse.

Design

This was an exploratory cross-sectional survey of patients' views.

Participants

Patients were identified from the team case-loads. They were included if they were over the age of 18 years, had contact with a psychiatrist within secondary mental health services and were classified as having a severe and enduring mental illness, which included patients with a psychotic illness (for example schizophrenia or bipolar affective disorder), a severe depressive disorder, a personality disorder or dementia. Patients were excluded if they were acutely unwell and therefore lacked capacity to give consent and if they were unable to speak English.

Data collection

In East Cornwall, patients were initially approached via their care coordinator during a pre-existing appointment or following an appointment with their psychiatrist. This initial approach resulted in a fairly low response rate, so an amendment to the study's ethical approval was sought and patients were also approached by a mail shot. In East London, patients were approached via a mail shot after they had been identified by a researcher in conjunction with their care coordinator.

Participants completed a brief questionnaire which asked them about several non-modifiable sociocultural characteristics of psychiatrists, including age, gender, religion, social background and marital status. They were asked to state whether or not they had a preference with regard to the gender, age or level of experience of their psychiatrist. Then the participant was asked to state how important each characteristic was. Finally, they were asked about modifiable characteristics. The participant was asked to select and rank the three qualities/behaviours most important to them from a list of ten: the psychiatrist is friendly and polite in manner, the psychiatrist is recommended as good by other patients, the psychiatrist is recommended as good by my GP, the psychiatrist is actively involved in scientific research, the psychiatrist is up to date with medical knowledge, the psychiatrist has a professional appearance and is well dressed, the psychiatrist is dedicated to my personal treatment, the psychiatrist is positive and optimistic, the psychiatrist explains things to me, the psychiatrist has a similar social and cultural background to me. This list of behaviours was generated from discussions within the research team and consideration of the literature.^{1,13,15}

Researchers then collected sociodemographic details about the patients from computerised medical records, including their age and gender.

All data collected were strictly anonymised to prevent patient identification.

Data analysis

The overall results were compiled to reveal: preference for genderpreference for agepreference for experienceimportance of the sociocultural characteristicsranking in importance for the ten characteristics.Comparison was then made to see whether female patients had a preference for seeing a female psychiatrist.

Ethical approval

The study received research ethical approval (REC reference number 13/EE/0230) from the National Research Ethics Committee East of England.

Gratuity

Participants were offered £5 (cash in East Cornwall and a voucher in East London) as a token of appreciation for their time. This was not advertised in the patient information leaflet, to reduce potential response bias.

Results

We received 132 returns of the questionnaire across all sites (76 from the East Cornwall CMHT, 28 from the East Cornwall complex care and dementia team and 28 from the East London CMHT). Participants were aged over 18 years, treated in secondary mental healthcare and were diagnosed with a severe and enduring mental illness.

The sociocultural characteristics important to patients

Participants cared more about the age and gender of their psychiatrist than their religion, background and marital status, but the majority of participants were not concerned about any of these factors (*Fig. 1*). With regard to age, 28% of the total sample expressed a preference regarding the age of their psychiatrist: 16% preferred a psychiatrist under 40 years old, 73% a psychiatrist 40–55 years and 11% a psychiatrist over 55 years. A larger proportion of the total sample (61%) expressed a preference regarding the level of experience of their psychiatrist, with 79% of them stating a preference for a psychiatrist who had been qualified for some time. *Fig. 1*Participants' rating of the importance of their psychiatrist's sociocultural characteristics.

Behaviours most important to patients

When asked to rank the three most important qualities/behaviours from the list of ten, there were four clear preferences (*Fig. 2*): the psychiatrist explains things to me (more than two-thirds had this in their top three rankings)the psychiatrist is dedicated to my personal treatmentthe psychiatrist is up to date with medical knowledgethe psychiatrist is friendly and polite. *Fig. 2*Participants' ranking of the top three (out of ten) preferred qualities/behaviours shown by their psychiatrist.

Additional results regarding gender preference

In total 73 women completed the questionnaire; 73% expressed no preference regarding the gender of their psychiatrist (*Fig. 3*). A similar percentage was observed among the 59 men who completed the questionnaire: 75% expressed no preference with regard to the gender of their psychiatrist. There was no significant difference between genders at the 5% level on statistical analysis (chi-squared test of independence, 5% confidence value). *Fig. 3* Female participants' preference for the gender of their psychiatrist.

Discussion

Main findings

In this study the characteristics of psychiatrists that patients cared most about included communication skills, competence, dedication to personal treatment and friendliness. Being able to explain things to patients was particularly important. Of note, being recommended by GPs and other patients was not as important, nor was appearance or being positive and optimistic. The importance of 'dedication to personal treatment' supports early findings by Johansson & Eklund that a common priority of psychiatric patients is the development of a therapeutic relationship.¹⁹

Participants did not express strong preferences about the age, gender, religion, social background or marital status of their psychiatrist.

As regards the modifiable characteristics analysed, participants did not identify optimism as being important. This aspect of the therapeutic relationship is a quality assessed in some consultant 360-degree appraisal systems. Our finding may be due to a desire for the clinician to be realistic and a feeling that being unduly optimistic can give false hope. As the survey population was patients in secondary care, there may be contributing factors that were not taken into account. These might include the chronicity of specific conditions and the amount of time that the participants have been receiving care.

Another postulation is that the questionnaire asked about a psychiatrist being positive and optimistic; patients might construe a combination of positivity and optimism as lacking in empathy and not understanding their suffering or recognising the impact their presentation/illness is having on their life.

In terms of non-modifiable characteristics, none were found to have significant importance. The preference for age and experience was of note, as it suggests that more senior clinicians have characteristics desired by patients.

With gender preference, the female participants did not show an overall preference to see a female psychiatrist. This is a comparable finding to the population survey undertaken in The Netherlands in which the majority of both women and men expressed no preference about the gender of the psychiatrist seen.¹⁰ The conflict with more recent studies into gender bias among psychiatric patients may be due to the disparity between preconceptions and outcomes with male/female psychiatrists. This warrants a focused analysis that could be instrumental to professional improvement.

Limitations

We must consider the potential limitations of the study, in particular response bias. One of the factors specifically commented on by the researcher based in East London was the fact that patients were more likely to return a questionnaire if they had previously met her in an earlier role running therapeutic groups in a hospital setting. In conjunction with patient-experience surveys generally having low response rates, this bias may be notable.²¹

The study was also limited to people who spoke English: although this may not have had a significant impact on the results in the East Cornwall sites (nobody on the East Cornwall CMHT case-load required the use of an interpreter or did not speak English as a first or second language at the time of the study), there is a considerably more culturally diverse population in East London who could not then be approached.

In terms of study design, there is no validated questionnaire specific enough to the aims of this survey and applicable to the setting. The behavioural qualities listed in the study were determined through discussion among clinician-researchers. The list might have been strengthened with input from patients.

We did not use a mixed-methods approach owing to limited study resources. Analysing the data by patient characteristics, including experience of services and diagnosed disorder, would have given more insight from a patient perspective, and may be an opportunity for future research.

Implications

Although we may worry about a patient's perception of us based on physical, usually unchangeable characteristics, our focus should be on how we communicate with our patients, as this appears to have more importance for patients. We should not underestimate the significance of being friendly in our clinical work, but also remember that patients value the time-honoured importance of up-to-date knowledge and being dedicated to their personal care.

This research focused on patients in secondary care, many of whom are already experienced with regard to psychiatric treatment. With this in mind, consideration should be given to repeating the research with newly referred patients.

It should also be considered that, in circumstances where the relationship between a patient and their psychiatrist has broken down and a new psychiatrist is to be allocated, attention to matching the psychiatrist and patient on the basis of sociodemographic characteristics is not merited by the evidence.

Some of the behaviours that were identified as important can be trained and regulating authorities such as the General Medical Council and the Care Quality Commission may wish to consider greater encouragement in developing these skills. Psychiatrists are already expected to update their knowledge through continuing professional development, but there is limited systematic training or supervision on how psychiatrists should explain treatments to patients. These communication skills are important to patients.

1.2.90 Being positive on disability in medical education

Elliott Carthy

date

2021-06

Contents

- *Being positive on disability in medical education*
 - *Declaration of interest*

pmc The world is a diverse place. The patients we treat are a diverse group. The same can't be said for the medical profession that represents them. I would argue that positivity regarding disabilities in medicine starts with us as educators. My favourite aspect of being a medical educator is what I as a teacher learn from my students. I, like most doctors and medical students, do not have a disability. However, I communicate with and advocate for people with intellectual disabilities, autism and learning difficulties such as dyspraxia and teach about these topics as routine practice to students and the wider multidisciplinary team. This is not just about reducing discrimination and promoting equality but also about appreciating the value that such people add to society.

General community estimates within the UK suggest the prevalence of disability in working age adults to be 19% in the UK,¹ yet in medical schools, it is estimated that only 4.1% of students have a disability.² Even accounting for potential non-disclosure, these numbers show substantial underrepresentation. The British Medical Association recently published a report titled *Disability in the Medical Profession*³ that highlighted the paucity of doctors and medical students with disabilities who felt safe to disclose their condition or felt supported by their institution or colleagues. Despite widening participation programmes, medicine can still be discriminatory towards those with disabilities. It would not be unreasonable to suppose that such reluctance to seek support or have the need for this recognised could be extrapolated to our patients.

The term disability is broad, both in nature and degree. This is often poorly reflected in medical guidelines, whereby our lack of understanding can contribute to the pre-existing stigma. The title of the General Medical Council's *Welcomed and Valued*⁴ guidance for those with disabilities in the medical profession gives the impression of framing inclusivity in a positive light. However, the persistent use of terms like 'support', 'student needs' or educators and institutions applying their 'duties' means the focus is on reducing discrimination and making reasonable adjustments to allow for

an assessment of competence. The presumption is that disability may be a threat to competence and to patient safety. In fact, disability may give lived experience that improves competency through empathy and understanding. We need to start focusing on what such students, doctors, educators and, crucially, patients can add, not simply what they need.

If we provide a safe space for those with lived experience of disabilities to share their experiences and the impact on their life, then each one of us can improve our understanding. Indeed, more doctors being open about their visible and invisible disabilities mean more positive role models for students. Widening participation can then move from just implementing anti-discrimination legislation to appreciating the value that diversity adds and the grassroots barriers to entering and thriving in the profession of medicine. Every medical educator can contribute by providing a safe space for disclosure and a willingness to learn and be educated by our patients and students.

1.2.91 Difficulties in interpreting patient-reported outcome measures in the absence of a gold standard: the meaning of Clinical Global Impressions scores in liaison psychiatry

Rajalakshmi Valaiyapathi Kezia Smith Ksenia Marjanovic-Deverill

date

2021-06

Contents

- *Difficulties in interpreting patient-reported outcome measures in the absence of a gold standard: the meaning of Clinical Global Impressions scores in liaison psychiatry*

pmc As a part of routine clinical care, the Ealing Liaison Psychiatry Service (ELPS) uses the Clinical Global Impressions (CGI) scale to assess patient-reported outcomes. We would like to share our findings and the challenges in interpreting CGI ratings.

CGI scales in psychiatry were initially used to assess efficacy in clinical drug trials¹ and have since been adapted for use in liaison psychiatry as a part of a nationwide evaluation. The Framework for Routine Outcome Measurement in Liaison Psychiatry² proposed that all liaison psychiatry services use CGI scales for consistent data collection and national reporting of outcomes, although there is no guidance on a standard to aim for.

Our methodology involved patients and their ELPS clinicians providing a CGI rating on whether the patient's mental health had improved, not changed or become worse after ELPS contact. This study looked at all 205 patients between January 2018 and November 2019 who had filled out a CGI questionnaire, and the following analyses were made: percentages of patients reporting changes in their mental health and potential reasons for this; concordance between patient and clinician ratings. Fifty-nine per cent of patients reported an improvement in their mental health, although the reasons for this were unclear, given that the CGI questionnaire has no section for patients to justify their rating. A

variety of factors may be involved, including having a focused consultation with a clinician, a decrease in symptom severity, and improvements in physical or social symptoms during the hospital stay, as these are often inextricably linked with mental health.

Forty per cent felt there was no change after ELPS intervention, and 1% (three patients) indicated feeling worse. Of the latter, two patients had to be admitted to an in-patient psychiatric unit, which could suggest that their lack of improvement was due to the severity of their mental health condition itself. There was 91% concordance between patient and clinician ratings, suggesting that subjective ratings from patients may not be needed if clinicians' objective ratings are so closely tallied.

The CGI scale has been correlated with more time-consuming rating scales used in psychiatry,³ and its advantages lie in its ease of understanding by both professionals and lay people, its ability to track progress across time and its swiftness of application. On reflection of our findings, we are unable to comment on our performance given the dearth of literature discussing what constitutes the gold standard. However, encouragingly, most patients reported improvement while only a very small minority reported deterioration, indicating that liaison psychiatry interventions are effective and largely beneficial.

By nature, the liaison psychiatry population comprises patients with both physical and mental health conditions, causing relative difficulty in teasing out which of the two issues is better manifested in the desirable outcome. In addition, the heterogeneity of the liaison psychiatry population makes it difficult to make direct comparisons of validity between different psychiatric conditions.

This simple service evaluation suggests that ELPS improves patients' well-being according to CGI scales. Nevertheless, wider-scale studies should be performed to elucidate how liaison psychiatry interventions are beneficial and to inform what the standard of care should be.

experiencing anorexia nervosa. She explores her own experiences of anorexia through a portrait depicting the duality of the disorder.

Contents

- *A portrait of anorexia nervosa*
 - *‘It’s all inside your head’*
 - *Unlocking the chain*
 - *The journey of creation and the journey of recovery*
 - *Data availability*
 - *Declaration of interest*

pmc What I like most about art is that it enables me to express complicated thoughts and emotions that often feel impossible to communicate verbally. Not only is it expressive, it is also fluid and its effect on others is completely subjective. It has no concrete rules, methods or regulations. It is completely versatile, and for a sufferer of anorexia nervosa, that freedom is certainly relieving. Defining my disorder for others has often been difficult for me as I find it cannot be categorised by a standardised list of reasons or symptoms. I believe it parallels art in that it is subjective to an individual, it has so many loop-holes and complexities. And so with that, my disorder will be different to the girl who sits opposite me in class or the boy who goes to my gym. We are all dealing with our own specialised disorder and that is something I wanted to express in my artwork.

‘It’s all inside your head’

Since finishing this piece (*Fig. 1*) I have listened to a lot of people’s interpretations of it and I love how everyone came up with a different approach to what it represents. The two sides of the portrait are meant to represent what is visible of an individual with anorexia and then the complexities that lie below the surface. While creating ideas for the visible side of the portrait I thought about what a typical sufferer of anorexia is perceived to look like. As a society we automatically assume the individual to be underweight, malnourished, pale and quite frankly on the cusp between life and death. Unfortunately, statistical research will show that in a lot of cases these features are disturbingly common. But I have always held on to the belief that these visible symptoms are not the determining aspects that separate a sufferer from a non-sufferer. When I asked my Mum about the time I was in the deep throes of anorexia she said something that has stayed with me throughout my recovery. She simply told me ‘there was no one there’. That idea of an absence of self being a major symptom of anorexia is definitely something I believe fellow sufferers will identify with. The defensive remarks, spiteful comments and the extreme memory loss are all evidence that the person I knew I was, was no longer present. A lot of sufferers will personify their illness to detach it from who they are as an individual. In the case of anorexia, this person is commonly referred to as ‘Ana’ and this double identity was an important idea that I wanted to feature in my artwork. *Fig. 1 It’s all inside your head* (2020). Lily Aston.

My personal interpretation of the piece is that the black and white side represents this ‘absence of self’. The lack of colour and detail establishes the loss of personality, it is what others may see when they face an anorexia sufferer. The coloured side then represents what lies below the surface, the complexity of emotions: confusion, anger, sadness, resentment. These all combine to create this explosion of chaotic colour. They are the emotions that sufferers will tend to hide from the outside world in order to remain ‘undercover’. That is why many victims of anorexia will go through a major period of denial, convincing others and quite often themselves that they are ‘fine’, ‘I couldn’t be happier’, ‘I feel so much healthier now’, ‘oh no thank you, I’m not hungry’. Humans are emotionally complex beings and expression of these emotions is necessary to maintain our sanity. So in the case of an anorexia victim going through denial, it is only a matter of time before this wall is broken and these emotions come flooding out, quite often with a vengeance. I remember very clearly when my wall broke down. I came home from school and went straight to my room to lie on my bed. I had eaten about 600 calories worth of food in the span of three days and by that point my body was too weak to feel the hunger pains. I lay there for a couple of hours until my Mum called me down to say ‘We’re going to order

a takeaway’. And I was – furious. My perfect utopian façade had loosened at the seams and all this hate, fury and fear came bursting out in all directions as I screamed at these people who I loved more than anything in the world. I am ashamed to admit that in that moment I cursed their existence and wished they would disappear.

Unlocking the chain

That evening was a turning point for me, it was as if my double identity had begun to reveal itself to those around me, including myself. And it was important for me to convey this duality in my portrait. I considered doing two different faces as I hated the idea of anorexia being a part of me. But the harsh reality is that it doesn’t become a part of you – it overcomes you. Recovering from an eating disorder is like peeling a hundred layers of your skin from your body. It is extremely painful, both physically and mentally. But this shedding of skin is absolutely essential in order to detach yourself from the grip of anorexia. Throughout recovery, it is so important to realise that an eating disorder does not become a permanent part of your skin. I view it as a locked chain that is wrapped around your body, constricting your movements. It feels impossible to escape and your situation feels hopeless for quite a long time. But it is through deep inner strength and the support of others that we are made to realise that we had the key in our back pockets all along. However, recovery is not as brief and straightforward as unlocking a chain. Our chains are quite often tangled and complicated. It takes a lot of time and patience. But I say from experience, it is a challenge worth taking.

The journey of creation and the journey of recovery

The process of making this piece of art was a long and tough journey but I hope others who are currently battling with their own demons will be able to identify with it. I welcome and encourage people to interpret it however they like. For all our journeys are different in their many complexities, but I hope we will all end up at the same destination. Content and healthy.

I must also mention an incredible artist called Shawn Coss, whose interpretations of mental disorders truly touched and inspired me to create this piece. The haunting figures that are scattered around the portrait are features of his work. His talent for expressing such complex emotions encouraged me to express my own, and I hope that others will be inspired to do the same.

Lily Aston is a student currently on a gap year. Due to study Psychology at Bristol University in 2022 but currently resides in Eastbourne, UK.

1.2.93 Art and psychiatry in the 21st century: here's to more messy – and magical – entanglements

Kai Syng Tan

Correspondence

Kai Syng Tan (kai.syng.tan@mmu.ac.uk)¹

date

2022-04

Abstract

In a volatile world, during a time of multiple crises and amid a projected upsurge in mental illnesses as an aftermath of the COVID-19 pandemic, now is a critical time to consider how art and psychiatry can entangle with each other. Submissions like that of Lily Aston can create new spaces for conversation, reflection and constructive collisions. This can help disrupt and extend the state of psychiatry, management of psychiatric services, and education and training in mental healthcare, and advance how we understand other bodies and minds around us, and how knowledge can be created.

pmc .. _sec1:

What can anorexia (actually) look like?

It has been more than 150 years since 'anorexia nervosa' was first termed.¹ But what do we *know* about what anorexia is, and in what ways could art related to anorexia confirm, complicate and/or extend this discussion?

For instance, how will someone with anorexia express what anorexia (actually) feels and looks like in a painting (or poem, rap song, film, tango dance, etc.)? What do our observations about artworks say about us? As importantly, what does that which is not depicted and omitted reveal? How does one's subjective lived experience inform the artwork? How does this relate to (their and/or the viewers') learned (mis-)conception of what 'anorexia' *should* be and that of another person with anorexia or those with other 'non-standard' relationships with food? How does the narrative compare with that created by their healthcare provider and that which is described/prescribed within textbooks, papers

and policies? What new insights and indeed new knowledges – including the tacit and embodied – can art that entangles with psychiatry create?

Art – like culture or baldness² – escapes easy definition. But can art help to raise the visibility of mental processes – literally and metaphorically – and reveal new insights into them? Can art open up new spaces for the patient and psychiatrist to engage with each other beyond the clinical and/or pharmaceutical? How does this irritate the patient–doctor dynamics and divide? What sort of productive antagonisms can arise when psychiatry engages with artistic practice and research? How can this disrupt dominant narratives around (dis-)order and (ab-)normality? To what extent does artistic quality come into play?

And how can the new culture section in an established platform accessed by researchers and practitioners in psychiatry entangle with some of the above-described tensions, to challenge, *and indeed advance*, ‘the state of psychiatry, management of psychiatric services, and education and training’³ in mental healthcare?

Fluidity and freedom

The above are some of the questions that Lily Aston’s submission can evoke. Alongside the submitted drawing/painting is a written commentary. The latter provides a level of contextualisation and what Aston has described as ‘my own interpretation’ of the painting as a ‘sufferer’ of anorexia nervosa.

So what can we see, and what does Aston say about what we are looking at (or looking for)? The artwork is dominated by a face which is divided diagonally. This illustrates what Aston has described as her ‘duality’. One side of her face and paper is in an ‘explosion of colours’, in paint, to depict ‘what lies beneath’ (flowers, pills). The other is in black and white, drawn in pencil, to depict an ‘absence of self’ and ‘loss of identity’. Yet, this isn’t a hard binary the way Descartes reduces the human body and mind. Instead, like how many understand gender today, the division is ‘fluid’. Perhaps like the *yin-yang* symbol, we are looking at complementary, not contrary forces at play. There are figures in black and white in the side that is colourful, while butterflies – coloured, in black and white, and some both coloured and in black and white – punctuate the entire composition.

Indeed, Aston’s work is one of contradictions. While ‘surrealistic’ (skeletal figures hovering around the skies), it is enthusiastic about realism (meticulous facial make-up and follicular luxuriance). It is not saying much (the subject glances nonchalantly into the distance). At the same time, it seems overtly literal, as if an illustration, a confession or a plea to be heard/seen (the words on the wings of butterflies read ‘It’s all inside your head’, and words on figures in the foreground say ‘trapped’ and ‘I’m sorry’).

The commentary also includes Aston’s thoughts about the role of art. While the process of making the piece was a ‘long and tough journey’ for her, what Aston likes most is how art allows her to ‘express complicated thoughts and emotions’ that ‘lie below the surface’, which are ‘impossible to communicate verbally’. At the same time, she seeks to be non-prescriptive: ‘I love how everyone came up with a different approach [to the piece]’. It is the ‘completely subjective’ nature of art, absence of ‘concrete rules, methods or regulations’, that opens up a space of ‘freedom’ for Aston.

Beyond art therapy, inspiration porn and ‘public engagement’?

There *are* rules and regulations in art – but of course. Like those in psychiatry – and any other facet of human endeavour – these rules and regulations are above and below the surface, written and unwritten. Fortunately, like they are elsewhere too, and especially given the year of reckoning that was 2020 (with the COVID-19 pandemic exposing endemic structural inequalities), these rules and regulations are not stagnant. Instead, they are evolving, questioned and get rewritten, as we learn, unlearn and grow, as individuals and with others, within and across disciplines, communities, societies, cultures, species and so on.

More than 170 years have passed since the *BJPsych* dropped ‘Asylum’ from its title. Fewer years have passed since it introduced artworks for its covers. Still, a lot has happened in the practice and discourse around the messy – and magical – entanglements of art and mind.

Tropes such as the ‘hysterical female’ – unsurprisingly, anorexia nervosa was previously known as ‘anorexia hysterica’ among other terms¹ – and ‘mad artist’ have been popularised, then troubled. Once mocked and ostracised – as reflected in its name – ‘outsider’ art is now the *lingua franca* alongside double kisses of arts royalty (Grayson Perry is but one prominent example), institutionalised (with Headway East London, a charity for people with brain injury, shown at London’s Barbican, and Project Art Works, a collective of neurodiverse artists, nominated for the 2021 Turner Prize).

Gone were the days when the only kids on the block were ‘art therapy’ and ‘artistic expression by patients’ and the often-associated charitable, curative and voyeuristic aspects reminiscent of freak shows of world expos and circuses of the old world (the late Stella Young’s Ted Talk on ‘inspiration porn’ is a good start for the curious on the objectification of alterity⁴). Instead, we can now turn to burgeoning discourses and practice in inter- and transdisciplinary fields, especially following the All Party Parliamentary Group on Arts, Health and Wellbeing report proposing ‘creative health’.⁵ They include: visual medical humanities⁶ and medical humanities,⁷ disability arts (such as the extensive multidisciplinary artistic practices of The Vacuum Cleaner⁸ and Dolly Sen⁹). There is also the blockbuster that is ‘arts in health’ (led by Daisy Fancourt, as reflected in her extraordinary ascent¹⁰) and critics pointing out its fatal flaws and blind spots (read the review by Stephen Clift, Emeritus Professor for the Sidney De Haan Research Centre for Arts and Health¹¹ and arts and activism veteran Frances Williams’s sharp comparative analysis across Greater Manchester and North Wales¹²).

To bring in perspectives that lie beneath, between and behind the surface, new generations of psychiatrists are increasingly emboldened to ‘out’ their own stories about their mental illnesses and to advocate new, bold ways of doing psychiatry using art (such as in PsychArt¹³). Those with hybrid backgrounds are also finding ways to converge ideas across boundaries (such as artist-psychotherapist Patricia Townsend’s study¹⁴ of the creative process through psychoanalysis and psychiatry-trained philosopher Mohammed Abouelleil Rashed on mad activism, anti-psychiatry and *avant garde* cinema¹⁵).

Arguments are being made for the need to use art to make attention-deficit hyperactivity disorder (ADHD) and other processes ‘more visible, that is, more seen, more heard, more talked about, not avoided, not dismissed, not spoken about in hushed tones, not just a specialist subject discussed by experts, and not only spoken ill of, because there is always more than one side to any story’.¹⁶ So too are proposals to foreground quality, ‘lofty’ art to build cultural intelligence and fuel quality conversations.¹⁷ Artists are increasingly infiltrating mental health research groups and professional bodies (such as the UK Adult ADHD Network¹⁸). Artists are also using artistic and creative research to engage in critical discourse with psychiatry on the cultural and medical constructs and pursuits of ‘normativity’,¹⁹ and not just as vehicles of communication or public engagement to make ‘serious’ research accessible.

Terms have been reclaimed (such as ‘sick’, for Sick! and Sick of the Fringe festivals). Others have been given new breaths of life, key of which is ‘neurodiversity’, which will be significant and exciting moving forward. First proposed by Australian sociologist Judy Singer in the 1990s,²⁰ the term has, over the years, been contested, protected, discussed, fought over and championed (including by researchers of autism²¹). The term is gaining attention as it is increasingly co-opted and objectified by the global elite as a ‘next business advantage’ and more.^{22–25} Fortunately – and as testament to the inclusive nature of the term – yet other counter-narratives are surfacing. These include the alignment of ‘neurodiversity’ with ‘biodiversity’.^{26,27} There are also countless new narratives and new creative research methods (such as ‘dyspraxic dysco’ and ‘neurodivergent leadership’) by some 300 researchers and artists worldwide who themselves have ‘non-standard’ cognitive modes, in the Neurodiversity In/And Creative Research Network (of which Singer and several psychiatrists such as ADHD expert Philip Asherson are also members).²⁸ With openly neurodivergent artists increasingly sharing their visions for social change,^{29,30} it is no wonder that those who had studied neurodevelopmental processes as medical deficits are increasingly interested in engaging in the positive aspects.^{31,32} In a recent keynote presentation, a well-respected leading clinical psychologist in ADHD even coaxed his audience of nearly 900 mental health researchers and professionals to no longer ignore but actively engage in the discourse on neurodiversity.³³

Cultural and academic institutions – historically conservative and slow-moving – are starting to catch up with some of these developments too. Collections (such as Wellcome and Thackery) are being updated with ‘woke’, more inclusive and decolonised frameworks, and are foregrounding voices previously deemed to be without agency. Increasingly, there are arts programmes in medical settings (such as in University College London Hospital), arts in health enterprises (such as Aesop) and galleries (such as artist-led Bethlem Gallery, which supports and exhibits artists who are current or former patients of the South London and Maudsley NHS Foundation Trust³⁴). Universities are training the next generations of ‘boundary spanners’, through new interdisciplinary arts–(mental) health programmes (such as at King’s

College London, Queen Mary University of London, Birkbeck and St George's University of London; artist Deborah Padfield's health humanities programme at St George's, for instance, was developed from her award-winning doctoral and post-doctoral interventions in the clinical space³⁵).

Widening the conversation and extending the possibilities

We are at an exciting juncture of multiplicity, fluidity and new possibilities with regard to culture, art and psychiatry. *BJPsych Bulletin's* entry into the conversation with a new culture section² is belated. This will be critical, particularly amid a volatile world in a period of multiple crises, and amid a projected upsurge in mental illnesses globally as an aftermath of the COVID-19 pandemic.^{36,37} There aren't any magic bullets – not even art¹⁷ or psychiatry! – for our challenges, which aren't described as 'wicked' for no reason. Works of art that have continued to intrigue are not those that provide or claim to provide answers, but those that problematise, interrogate and provoke.³⁸ Submissions like Aston's can thus open up spaces for reflection, connection and constructive collision to challenge and extend the state of psychiatry, management of psychiatric services, and education and training in mental healthcare. This can advance how we think about and relate to other bodies and minds around us, as well as advance how we understand how knowledge can be created.

1.2.94 Religion and mental health: a narrative review with a focus on Muslims in English-speaking countries

Ahmed Ibrahim Rob Whitley

Correspondence

Dr Rob Whitley (robert.whitley@mcgill.ca)

date

2021-06

Abstract

Numerous commentators have noted a historic ambivalence between religion and psychiatry. However, a growing body of evidence indicates an association between mental health and various religious activities, both private and public. As such, there are growing calls for greater religious sensitivity among mental health clinicians, to help unlock the potentially healing aspects of religiosity. So far, most literature from English-speaking countries has focused on Christianity and mental health, with little attention paid to Muslim mental health. This is the fastest growing religion in English-speaking countries, and the mental health of Muslims in these countries is under-researched. As such, the present paper summarises new directions in the mental health and religion literature, with a focus on the mental health of Muslims in English-speaking countries.

 - *Conclusion*
 - *Declaration of interest*

pmc Numerous commentators have noted a historic ambivalence between religion and psychiatry.^{1–4} This can be traced back to the writings of formative figures in the early decades of psychiatry; for example, Freud argued that religion was a delusional infantilism that could be disabused through therapy.⁵ Other magisterial figures such as Ellis and Skinner also considered some aspects of religion to be antithetical to positive mental health.^{6,7}

More recent studies indicate that this ambivalence continues to the present day. For example, one study found low levels of religiosity among psychiatrists compared with other physicians,⁸ while another study found a lack of integration of religious variables into psychiatric research.⁹ This may signify a continued uneasiness within psychiatry about incorporating aspects of religion into psychiatric research and practice.

Religion and mental health

That said, a growing body of research suggests a positive association between mental health and religious activities, known in the social sciences as ‘religiosity’.¹⁰ This literature indicates that religiosity is positively associated with prevention and recovery.^{1,11} For example, a large corpus of research indicates that religiosity is moderately associated with greater well-being, lower rates of depression and anxiety, and lower rates of suicide.^{12–14} Similarly, other studies suggest that both public and private religiosity is associated with recovery from a range of mental illnesses, including depression, schizophrenia and substance use disorder.^{15–17} Of note, many of the studies examining religiosity and mental health are cross-sectional, meaning that reverse causation is possible. However, the consistency of the findings has led researchers to further investigate religiosity to examine specific factors that may be associated with mental health.

Public and private religiosity

Some scholars divide religious practice into private (interiorised) or public (exteriorised) religiosity.^{12,13} Private religiosity refers to factors occurring alone or in the family home, for example, reading scripture or private prayer. Public religiosity refers to communal religious activities such as attending a place of worship or group study of a sacred text. Some religious activities are transversal across both those domains. For example, adherence to a moral code or a deep religious faith could manifest in both public and private domains.

Research indicates that these aspects of religiosity are associated with better mental health. For example, some anthropological literature indicates that participation in rituals can influence mental health through release of positive emotions.¹⁸ Moreover, public religiosity provides a community of believers, which can reduce loneliness and bring beneficial social support.¹² Private religiosity can help solidify family cohesion and provide ontological security during difficult life situations and transitions.¹⁷ All this can provide a sense of meaning and purpose, as well as a hopeful yet realistic view of life, which can be an ongoing resource for resilience, recovery and positive mental health.^{19,20}

Negative aspects of religiosity

In acknowledging these positive aspects of religiosity, it is important to consider other research indicating the potential harmful aspects of religiosity. For example, some research indicates that religiosity can lead to excessive feelings of guilt, fear, shame and death anxiety.^{21,22} Similarly, high levels of religiosity may lead some people to consult religious leaders in lieu of seeking help from a mental health professional in the presence of mental distress.²³

Some religious leaders may encourage such consultation, believing themselves to be better placed than clinicians in the process of ‘diagnosing’ distress and facilitating mental healing. For example, some faith leaders may impute mental illness to a spiritual weakness or insufficient religiosity. Likewise, mental illnesses may be attributed by these leaders to supernatural forces such as the ‘evil eye’ or ‘spirit possession’. This can lead to religiously inspired actions such as exorcism and the discouragement of mental health service utilisation.^{23,24} Research on Muslim chaplains in the USA, for instance, found a low rate of referral of congregants to mental health professionals among chaplains.^{25–28} This indicates the need for increased understanding in order to build better bridges between Muslims and mental health services. The next section thus focuses on Islam, Muslims and mental health.

Islam and mental health

As English-speaking countries become more diverse, with increasing proportions of the population following non-Christian faiths, the relationship between mental health and religion becomes more complex. Most notably, the Muslim population of many English-speaking countries is rising, with Muslims now making up 3.2% of Canada’s population,²⁹ compared with 5% in the UK.³⁰ According to the Pew Research Center, there were about 3.5 million Muslims living in the USA in 2017, making up around 1% of the population. By 2040, Muslims will replace Jews as the second largest religious group in the USA.³¹

There may be a differential effect on mental health according to religious affiliation, belief and practice; however, this has been understudied. For example, religions have many commonalities but also many differences.³² These differences manifest themselves in a variety of ways, including notions of morality, theodicy and supernatural intervention.

These differences may have a direct influence on seeking professional mental healthcare, for instance, by channelling people towards religious solutions to the exclusion of seeking psychiatric help. One broad difference between religions relates to the notion of spirit possession.³³ Possession refers to the belief that an individual has been entered by an alien spirit that controls or alters their actions, manifesting as an altered state of consciousness.³³ It is often found among Muslims but less so among Jews or Christians in English-speaking countries. Possession is frequently used as an explanatory model in some religious communities and among religious individuals to interpret illnesses such as epilepsy, panic and depression.^{33,34}

In Islam, supernatural beings that can take possession of humans are known as jinn, who are conceived as a race of intelligent beings that possess rational faculties. They marry, reproduce and die. According to Islamic doctrine, unlike humans, they have extraordinary powers. They can take different shapes, such as birds, animals and humans, and can move instantly from one place to another.³⁵ Jinn are discussed in Islam’s scripture, the Qur’an, as well as in the hadith literature.

Although the majority of Muslims believe in the presence of jinn, there is heterogeneity of belief regarding how much they can influence the human world.³⁵ Conducting ethnographic interviews with East London Bangladeshis, one study found that the community was split into two main groups. The older generation believed in the power of jinn and often attributed sickness to jinn, whereas the younger second- and third-generation Bangladeshis considered their parents’ beliefs to be superstitious and ‘non-Islamic’. Despite the younger generation’s sceptical comments about the older members of their community, almost all informants cited instances related to jinn’s malevolent power.³⁵

The aforementioned study of Bangladeshi Muslims in East London^{35,36} also indicated that some sufferers of ‘jinn’ and their families are likely to seek help from their religious leaders rather than mental health clinicians, even though the latter may be better placed to diagnose and treat any underlying mental health issues. This could be because people commonly perceive religious solutions as the answer to what they perceive to be religious problems.¹⁷ As such, Littlewood advises psychiatrists to be sensitive to such cultural beliefs by not contradicting any statements made by the patient and their family about jinn or spirit possession.³³ Instead, he recommends involving ‘culture brokers’ such

as an imam from the culture in question to provide contextual information on local beliefs and practices. This could positively affect the therapeutic alliance when authorised by the patient.¹⁵

It is important to recognise that broad religious traditions such as Islam contain much internal heterogeneity. Anthropologists have tried to capture this heterogeneity by devising the concepts of Great and Little Tradition. The Great Tradition in Islam is the textual, intellectual tradition of the towns, whereas the Little Tradition is the traditional, ritualistic religion of the countryside.³⁷ Beliefs in exorcism and jinn tend to be more prevalent within the Little Tradition.³⁸ Importantly, both these traditions may exist among immigrant and minority communities in English-speaking countries.

This example of belief in Jinn indicates how religious variables can influence explanatory models and mental health service utilisation. These religious beliefs and explanatory models often traverse time and geography. This brings us to the second part of this paper, which examines practices that can integrate religious variables into clinical care.

Integrating religion into clinical care

Clinicians can harness helpful aspects of religiosity to foster recovery in patients where appropriate. Moreover, clinicians and clergy can collaborate in the holistic care of patients. However, many clinicians are understandably wary of engaging in such activities, perhaps owing to the aforesaid complexities, as well as unfamiliarity with the diversity of religious experience.³⁹

Existing examples of positive collaboration tend to stem from cooperation between clinicians and Christian clergy. This is not necessarily because of anything inherently conducive to this form of cooperation within Christian theology or praxis; it may simply be due to strength of numbers in English-speaking countries. One example of clergy–clinician collaboration is Hope Haven, a private agency in Iowa that has been providing psychosocial rehabilitation services for many years.¹¹ The agency combines spirituality with mental health services in various ways. For example, the Religious Services department at Hope Haven seeks to engage area churches in welcoming and including people with psychiatric disabilities into the life of the church.⁴⁰ The agency offers daily devotions for patients, as well as spiritual support and prayer for those going through difficult situations. In a similar vein, Muslims in the USA and UK have established small-scale centres of psychotherapy such as the Khalil Centre and Ihsan Centre, where Islamic spirituality is integrated into care.⁴¹ However, such initiatives remain isolated examples.

This raises the question of what can be done to better equip everyday clinicians in routine practice to deal with religious patients and religious issues, especially those from minority faiths such as Islam. Some researchers have speculated whether mental health practitioners should receive training in the spiritual and religious beliefs of major religions so that they can better distinguish religious beliefs from psychopathology.^{42,43} This may be impractical, given the heterogeneity and diversity within and between religions previously described.

An alternative approach is the adoption of a set of attitudes and processes that facilitate the integration of spirituality and religion into clinical care. This could involve working with ‘culture brokers’ such as chaplains or community-based key informants in the treatment of religious patients, depending on the spiritual profile and wishes of the patient in question. This is the approach taken by the Cultural Consultation Service in Montreal, which has a bank of culture brokers that can be accessed by clinicians facing complex religious issues in the treatment of patients.⁴⁴ These culture brokers can offer perspectives and interpretations based on their locally grounded community experience, which may be especially effective if the culture broker is recommended by the patient and involved in their follow-up care. This approach can be a useful adjunct to standard clinical care; however, the provision and training of culture brokers can be a difficult task, meaning that more practical approaches are often necessary.

Instead of relying on abstract nomothetic knowledge or the intervention of third parties, a more practical approach may involve clinicians making conscious efforts to gain an idiographic understanding of the patient’s religious worldview during the clinical consultation. Importantly, researchers have developed a number of simple and generic tools and procedures that clinicians can use to elicit information about patient religiosity (or lack thereof), sometimes known as a ‘spiritual assessment’. These tools can be used by psychiatrists in clinical settings to enhance understandings and decision-making, and can be applied to Muslims as well as others.

This includes the Outline for Cultural Formulation and the Cultural Formulation Interview (CFI) contained in the DSM-5.⁴⁵ Supplementary modules to the core CFI include the ‘Spirituality, Religion, and Moral Traditions’ module, which provides 16 useful questions for the deep and meaningful probing of religious issues where appropriate.⁴⁶

Another of these well-known tools is known as the Faith, Importance, Community, and Address (FICA) instrument.⁴⁷ The FICA inquires into the following four domains: (a) *Faith and belief*, ‘Do you have spiritual beliefs that help you cope with stress?’; (b) *Importance*, ‘What role do your beliefs have in regaining health?’; (c) *Community*, ‘Are you part of a religious or spiritual community? If so, is this of support to you and how?’; and (d) *Address in care*, ‘How would you like me as your healthcare provider to address these issues in care?’.

Importantly, the short and neutrally posed questions allow atheists and non-religious people to quickly express a lack of interest in these issues and move onto other topics. Of note, there has been little research on the use and effectiveness of such tools and instruments among Muslim patients. This is an important area for future research.

Interestingly, some researchers have proposed specific procedures for clinicians working with Muslim patients. Abu Raiya and Pargament⁴⁸ proposed a series of recommendations including: (a) asking about the place of religion in patients’ lives; (b) educating themselves about basic Islamic beliefs and practices; (c) helping patients draw on Islamic religious coping methods; (d) referring to a clergy member if appropriate; and (e) participating in educating Muslims about mental health. These recommendations overlap with the above-described generic advice for clinicians dealing with religious patients and could be a useful tool for working with Muslim patients.

All these tools have the potential to foster what has been termed ‘existential recovery’, defined as ‘having a sense of hope, empowerment, agency, and spiritual well-being’.⁴⁹ For example, clinicians may refer an isolated patient of faith to a sympathetic chaplain for spiritual and social support, who may in turn link the patient to a community of believers. However, such actions must be tailored to individual need and preferences, and may be more difficult for patients who are members of minority faiths such as Islam, where access to Muslim chaplains is more limited.

Indeed, research shows that Muslim chaplains are underutilised in English-speaking countries such as the USA.^{25–27} In Britain, one study of the provision of spiritual and pastoral care facilities in a high-security hospital revealed that demand for pastoral care could be significantly higher among Muslim patients compared to Christian patients. With one Muslim chaplain employed part-time, the authors argued that the allocation of chaplaincy resources should be re-examined in light of the multi-faith nature of modern Britain.⁵⁰ This is an area in need of further discussion and research.

In addition, clergy–clinician collaboration could be better attained by giving mental health training to clergy and other religious leaders. In fact, there are now a number of pastoral counselling programmes training clergy and others to help people with mental health issues, using evidence-based psychotherapies nested within a religious framework. Such programmes can be found at prestigious US universities including New York University and Northwestern University. Again, such initiatives have predominantly involved Christian clergy; training of Muslim religious leaders is lacking.²⁷ Likewise, counselling courses are offered to the clergy by the Association of Christian Counsellors in the UK, among others, but not for Muslim clergy *per se*.

Despite these efforts, there is a need for further research and action in this regard. For example, a study of British clergy representing Christianity, Judaism and Islam revealed that most members of the clergy had received little or no training in mental health as part of their ministry training.⁴ The clergy members interviewed seldom differentiated between psychotic illness and common mental disorders such as depression and anxiety. Some members of the clergy interpreted unusual or disturbing behaviour as a religious problem provoked by a curse, witchcraft or spirit possession. In these cases, prayers and exorcism were considered an appropriate response.⁵¹

It is unlikely that mental health training for the clergy will cause these religious interpretations to disappear, because people may draw upon more than one explanatory model at a time to explain distress. However, training may give a more holistic understanding, and research indicates that people often hold coexisting religious and psychiatric explanatory models of mental illness, which can lead them to use various modalities of healing in cases of mental distress.^{17,52}

Indeed, it is important to communicate to clinicians and clergy that religious and psychiatric intervention is not an ‘either-or’ scenario; both deployed simultaneously could produce effective results. For example, anthropological research indicates that certain rituals such as prayer may be beneficial to the healing and recovery of some individuals.¹⁸ Thus, it is not advisable to reject such practices out of hand without learning about the preferences and worldviews of individual patients. This is where ‘spiritual assessment’ tools can be useful, even necessary.

Conclusion

There is growing evidence that the influence of religion on mental health is largely positive. This research supersedes outdated notions perpetuated by figures such as Freud about the negative effects of religion on mental health. Moreover, this growing evidence gives impetus to new models of cooperation between religious leaders and mental health professionals.

In an ideal world, this would involve a bidirectional system of cooperation and education. On the one hand, clergy could receive basic training and education in mental health. This could improve understanding of mental illness and increase referrals from clergy to mental health professionals. Similarly, educational and public outreach campaigns could be targeted at religious and minority communities, with cooperation and participation from the communities themselves. On the other hand, there is still a need for better education of mental health professionals in religious matters. This includes training in areas such as taking a spiritual history and working with culture brokers and community religious leaders. Such training could be co-delivered by clinical experts and religious leaders.

At the policy level, administrators may reconsider their chaplaincy resource allocation to ensure that minority faiths, whose adherents tend to have greater religious counselling needs, are proportionately resourced. Importantly, new action and research that responds to the growing religious diversity of English-speaking societies is necessary, with particular focus on the growing and heterogeneous Muslim community to ensure that policy and practice are based on evidence rather than stereotypes. This could ultimately lead to more supportive and tailored treatment options that harness, rather than ignore, patient religiosity and spirituality, thereby promoting a holistic recovery in religious patients.

1.2.95 Psychiatrists should investigate their patients less

Matthew Butler Fraser Scott Biba Stanton Jonathan Rogers

Correspondence

Matthew Butler

(matthew.butler@kcl.ac.uk)

date

2022-06

Abstract

Psychiatrists often order investigations such as blood tests, neuroimaging and electroencephalograms for their patients. Rationales include ruling out ‘organic’ causes of psychiatric presentations, providing baseline parameters before starting psychotropic medications, and screening for general cardiometabolic health. Hospital protocols often recommend an extensive panel of blood tests on admission to a psychiatric ward. In this *Against the Stream* article, we argue that many of these investigations are at best useless and at worst harmful: the yield of positive findings that change clinical management is extremely low; special investigations are a poor substitute for a targeted history and examination; and incidental findings may cause anxiety and further unwarranted investigation. Cognitive and cultural reasons why over-investigation continues are discussed. We conclude by encouraging a more targeted approach guided by a thorough bedside clinical assessment.

pmc The Royal College of Psychiatrists’ *Standards for Inpatient Mental Health Services* require a ‘comprehensive physical review’ to be initiated within four hours of admission to a psychiatric inpatient unit, which is to be completed within one week.¹ In practice, this means that inpatients are often subjected to a battery of admission blood tests that are directed without regard for the presentation. Routine blood tests on admission remain a requirement in local trust policies,² and clinical evaluations indicate that the majority of patients receive them.³ In addition, selected psychiatric patients may have further investigations, such as a magnetic resonance imaging (MRI) of the brain for those with a first psychotic episode, or an electroencephalogram (EEG) to rule out seizures.

In this article, we consider some of the reasons why investigations might be requested by psychiatrists and why they are often inappropriate, and suggest an alternative approach.

The case for investigating

There are several (non-exhaustive) reasons why investigations might be requested for psychiatric patients: to screen for contributing physical factors in the acute presentation, including concern that rare but serious causes are not missed to provide baseline levels that may be relevant when starting particular psychotropic medication to screen for a range of chronic physical illnesses that might otherwise be missed because psychiatric patients may not present as often to healthcare professionals or are treated differently when they do to screen for health problems that are more common in those with severe mental illness, such as diabetes and liver disease.

Here, a distinction should be made between screening tests and diagnostic tests. Screening tests are those performed at population or subpopulation level to detect presymptomatic disease with the aim of early intervention. An example of this may be routine prediabetes screening in a patient on chronic antipsychotic treatment. Screening tests have been used in medicine since the middle of the 20th century (an early example being the successful screening and treatment of

syphilis) and have undoubtedly improved diagnosis rates for medical and psychiatric patients.⁴ Despite this, there are a number of strict criteria that a screening test must meet before it is acceptable for use, including prior implementation of cost-effective primary prevention, a validated test, agreement on further investigation, good evidence for intervention at the presymptomatic phase, and evidence that benefits outweigh harms.⁵

Screening tests are distinct from diagnostic tests, which aim to accurately diagnose a condition for which there is clinical suspicion. An example of this may be positive antineuronal antibodies in the cerebrospinal fluid of a patient with clinically suspected autoimmune psychosis.

Although there are undoubtedly many cases where screening and diagnostic tests are entirely justified, we believe that investigations are often inappropriate because they have a low yield, poor sensitivity and specificity, limited interpretability without clinical correlation, and the potential to cause serious harm.

The case for not investigating

Tests may miss what they are looking for or not alter management

For an investigation to be useful, it should have high sensitivity (the ability to correctly identify patients with a given disease) and specificity (the ability to correctly identify patients without said disease). Distinct but related clinically useful concepts are those of positive predictive value (the probability that someone with a positive test has the disease) and negative predictive value (the probability that someone with a negative test does not have the disease). It is of note that even when tests do have high reported sensitivity and specificity, there may be additional complexities in real-world settings. This is in part because when developing tests, figures of diagnostic accuracy are calculated in a specific context, which is often obviously symptomatic individuals compared with obviously healthy controls.

Many diagnostic investigations used by psychiatrists fail to meet these criteria, and many have such a low probability of a clinically relevant result that it is hard to justify their routine clinical use. Systematic reviews have found that routine blood tests rarely alter the management of patients due for admission to psychiatric hospital, even when abnormal results are found.^{6,7} In one of the included studies of 500 patients, only one individual had an abnormal result that mandated urgent medical intervention. Notably, this patient was obviously symptomatic.⁸

Imaging and physiological investigations may not fare better. EEGs show interictal epileptiform discharges (IEDs) in only 29–55% of people with epilepsy,⁹ so it is inappropriate as a rule-out test for complex partial seizures presenting with psychotic symptoms. In contrast, EEG abnormalities (broader than just IEDs) occur in 19% of those treated with antipsychotics, so an abnormal EEG is not specific to a neurological cause of psychiatric symptoms.¹⁰ Similarly, one study found that 6% of healthy controls have at least one abnormality on an MRI of the brain, so the presence of an abnormality *per se* has a poor specificity for determining a neurological cause for psychiatric symptoms. This same research also concluded that none of 349 individuals with first-episode psychosis had MRI findings that necessitated a change in clinical management.¹¹

Investigations are no substitute for history taking and physical examination

Psychiatric patients invariably present in complex and myriad ways. In a minority, there is a recognisable physical cause for the psychiatric symptoms. For a physical illness to lead to psychiatric symptoms, there must either be a pathophysiological process (e.g. neoplastic, endocrine, autoimmune, metabolic, epileptiform, infective, neurodegenerative or metabolic) that is affecting the central nervous system and/or psychosocial mechanisms resulting from the physical illness. In each of these cases, it is very unlikely that a patient would present as entirely physically asymptomatic to an appropriately curious and observant clinician.

To put it another way, we might be surprised to see such physical illnesses presenting ‘occultly’, in the sense that a case would be missed after a thorough history and examination but picked up on a routine blood test or other untargeted investigation. Where psychosocial mechanisms predominate, these generally occur via experience of symptoms or via knowledge of a diagnosis, both of which can be elicited through an appropriate history or examination. In the specific

case of functional disorders (such as functional neurological disorders), these are diagnosed through eliciting positive clinical signs, rather than being ‘diagnoses of exclusion’ which require investigation to exclude other causes.¹²

Even for tests with extraordinarily high sensitivity and specificity, there are further interpretative difficulties that arise in the absence of clinical suspicion. If a condition is very rare, then an abnormal investigation result may not be as diagnostic as is intuitively suspected. This is known as the ‘false-positive paradox’, or the ‘base rate paradox’, and occurs when the prevalence of a condition is lower than the test’s false-positive rate (in these cases, the test will give more false positives than true positives). Crucially, the calculation is entirely different in populations who are already suspected to have the disease based on history and examination. In these cases, the pre-test probability (and thus the post-test probability after a positive test) would be much higher, and a resulting abnormal test much more clinically useful.

Take hypothetical blood test A which has a specificity of 99% for condition X. If condition X has a population prevalence of 1% and there are no additional features to increase the clinical suspicion of the condition (e.g. the patient has not been examined), we can assume the pre-test probability is 1%. In this case, an abnormal result from blood test A translates to a chance of having the condition (i.e. post-test probability) of only 50%. Most physicians, including us authors, would probably overestimate the post-test probability following a positive result on blood test A.

Investigations can be harmful

Investigations often have attendant risks, which are seldom adequately considered. In some circumstances, taking blood can be painful or uncomfortable (particularly in a distressed, paranoid or disoriented patient), risking injury for patient and clinician. The noise and enclosed environment of an MRI scanner can be frightening for an anxious patient. Over-investigation may also contribute to the development or perpetuation of health anxiety, as it can serve to confirm a patient’s fears about a serious undiagnosed illness.¹³ This may be particularly pertinent for individuals with somatoform or hypochondriacal disorders, who psychiatrists may encounter more often than might clinicians in other specialties.

A further important consideration is the impact of false positives. When tests are ordered in the absence of a clinical suspicion or hypothesis, a positive result inevitably returns the question: what next? In many cases, this might be further investigation, leading to a non-negligible potential of harm. Take the case of creatine kinase (CK), which is sometimes recommended as an admission blood test for psychiatric in-patients,² despite being incidentally and benignly raised in many patients, and even being a poor discriminator for neuroleptic malignant syndrome.¹⁴ When faced with a raised CK in an asymptomatic patient, most of us feel that we should do something, so patients are frequently subjected to further blood tests and sometimes intravenous fluids for a test that should never have been done. More dramatically, if ten people are treated with endovascular coiling for an incidental unruptured intracranial aneurysm detected on MRI, one will end up disabled or dead within one year, all for a lesion that probably would not have caused any harm.¹⁵

Readers may be familiar with ‘incidentalomas’, an all-encompassing term for non-specific lesions seen on medical imaging. Incidentalomas have dubious clinical relevance, but often prompt further investigations and cause anxiety to patients and professionals alike. Relatedly, the phenomenon of non-specific abnormal results also occurs with blood tests. One study of healthy adults receiving a routine battery of blood tests found that over one-third had at least one abnormal result, of which only 7% were deemed to require a medical review (none of them urgently).¹⁶

Finally, in the context of limited healthcare funding, expensive investigations divert resources from more worthwhile causes. Discounting the cost of staff time, a simple routine battery of blood tests is likely to cost in the region of £15–20.¹⁷ The number of psychiatric admissions needed to screen to find a positive serum free thyroxine (FT4) is in the region of 127, which corresponds to a cost of around £400 per abnormal result.¹⁸ MRI brain scans cost in the region of £200. Cost-wise, there is likely more benefit from a five minute clinical history and examination.

Cultural and psychological factors

Psychiatry is a medical discipline and there are, without any doubt, physical causes of psychiatric presentations. In addition, patients with severe mental illness are far more likely to die early, in part owing to huge over-representation of physical comorbidities such as cardiovascular disease. Psychiatrists should be attuned to physical health problems in in-patients as much as mental health problems, and we should feel confident in routinely performing thorough physical health histories and examinations.

The historical and ongoing divide between mental and physical healthcare is also likely to be a factor in over-investigation of psychiatric patients. Psychiatrists do not always have easy access to opinions from other specialties, and it is unusual for a physician to be integrated into psychiatric services. Psychiatrists may utilise unnecessary investigations when they are worried about patients, instead of being able to access a clinical opinion from specialist physicians. If physical and mental health services were better integrated, this could be avoided.

However, the overuse of investigations is a common theme in much of medicine and often functions more as a ‘psychological comfort blanket for clinicians’ rather than providing any tangible benefit to our patients.¹⁹ It may also stem from ‘addition bias’, the human tendency to try to solve challenging problems by adding something in rather than taking something away.²⁰ Ordering an investigation may make us feel as though we have addressed the problem we were trying to solve, when in fact we might not have. For instance, if the problem is poor physical health outcomes in people with severe mental illness, admission blood tests are unlikely to be an answer. Focusing on this superficial attempt at joined-up healthcare perhaps distracts from other solutions, such as addressing stigma and reducing inequalities.

Furthermore, the familiar feeling that we must ‘do something rather than nothing’ may stem from a human tendency towards action, which is also known as intervention bias.²¹ Of course, as we have seen, there are scenarios where doing nothing is just as good, or even better, than doing something. The Hippocratic oath reminds us that our primary role as doctors is to first do no harm.

Overuse of investigations in psychiatry may also represent part of a wider risk-averse culture in medicine, which is sometimes referred to as ‘defensive medicine’. Defensive medicine is costly to healthcare institutions.²² Many doctors, including ourselves and three-quarters of all psychiatrists, admit to defensive medicine to some degree, including the ordering of clinically useless investigations.²³ The reasons why clinicians may practise defensive medicine are myriad; however, the most commonly cited reason is fear of litigation resulting from malpractice hearings, particularly as the majority of cases of litigation stem from doctors missing diagnoses, rather than actively causing harm through the use of treatments.²² There are some (albeit incomplete) data that some aspects of defensive medicine may stem from physicians struggling to tolerate uncertainty in patient diagnosis and care.²⁴

Concluding remarks

We suggest six points to keep in mind when considering an investigation for our patients.

Limitations of tests: Have we examined the patient and taken a history? Without a thorough examination, performing an investigation may not provide any useful information. Is the disease common enough that this test will be useful? If the disease or condition is rare, there is a high probability of false positives. How would we need to act if the test were to return an abnormal result? Additional interventions or investigations that may result could be harmful.

Limitations of human psychology: Am I doing this test to resolve my own anxieties, or will it benefit the patient? Sometimes doing nothing rather than something is in the patient’s best interests. Can I tolerate the uncertainty of not knowing? Reaching after false certainty is not in anyone’s interest. Is there any chance the test or the results could lead to negative outcomes for the patient? First, do no harm.

We support attempts to integrate the body into mental health and illness. We believe that a good means of helping to achieve this is to ensure that we conduct thorough histories and examinations. This allows us both to request the appropriate investigations and to know how to interpret them once we have the results. This approach is supported by the American Psychiatric Association, which discourages routine laboratory testing,²⁵ and by the National Institute for Health and Care Excellence (NICE), which does not recommend neuroimaging in first-episode psychosis.²⁶ However, too often doctors are still faced with incidental findings on tests that should never have been requested. Psychiatrists should investigate their patients less and examine them more.

The apocalypse is trending. Climate catastrophe looms, end-times movie scenes spool out in real life all around us, and like a portent of our worst fears the COVID-19 pandemic is now upon us. As the scions of Big Bog Roll count their lucre, I've one pressing question for psychoanalyst Anouchka Grose – why toilet paper?! 'It's like the last thing between us and barbarism' she laughs, 'once that's gone and you have to touch your own shit, it's like the whole of culture's collapsed then'!

Grose is refreshingly unguarded and swears liberally (a sign of her honesty and intelligence I think, as well as her Antipodean roots). She came to London from Sydney in the 1970s, aged 2, to live in 'an Australian ghetto' as she puts it. Her new book, *A Guide to Eco-Anxiety: How to Protect the Planet and Your Mental Health*, is to be published in May 2020, and she does worry a bit about how her irreverent tone will be received.¹ It has tongue-in-cheek chapter titles like 'Anxiety: freaking the fuck out' and 'Pleasure yourself: you know you want to'. She wrote it like that partly so the act of writing wasn't unbearable, 'There's the question of how do you talk about something that's intolerable? And the climate thing *is* intolerable'. I think she's struck the balance in tone, which mitigates the nagging sense of fear.

Grose describes herself as a Lacanian psychoanalyst, who also lectures on Freud. She writes novels, non-fiction books, and journalism. Her new book originated from a piece she wrote in *The Guardian* in 2019, on the ecological crisis making Greenlanders depressed. However, she has long been an eco-warrior. She's been *mostly* vegetarian since 1985 and is a supporter of XR (Extinction Rebellion), the environmental movement that encourages 'non-violent civil disobedience'.

The movie *Apocalypse Now* is based on the novel *Heart of Darkness*, Joseph Conrad's racist fever dream. His tale of rapacious Belgian colonialism in the Congo seems a fitting allegory for Grose's left-leaning world view. Like many, she links our rapacious consumerist culture both to the climate and COVID-19 crises, 'Everyone seems as if they've seen behind the scenes of capitalism suddenly, like this window's open and you can see that it's just a stage'.

Thoughts on humans and other animals

The parallels between climate-change anxiety and that related to COVID-19 have triggered a glut of hot-takes. I discuss with Grose that these crises induce an existential kind of dread. In the language we use about them, we hear the echo of primitive fears. Take the phrase ‘herd immunity’, for example. Grose says, ‘The word [herd] was shocking because it was dehumanizing. I mean, the idea that we’re just a herd and some of us will be lost and that’s fine. Like watching a nature documentary’.

In the language of scientists, however, she thinks there is a disconnect between their cautious approach and epoch-ending events like the climate crisis. She’d like them to be a little *more* alarmist, ‘I suppose they’re trained not to, because of the idea of the impartiality of science, but it turns out that science is political’.

She lauds the approach of people like Professor Jem Bendell, a sustainability academic. His viral essay² on climate-induced societal collapse didn’t pull any punches. He writes, ‘With the power down, soon you wouldn’t have water coming out of your tap... You will become malnourished... You will fear being violently killed before starving to death’.

The struggle is real

I’m Skyping Grose at her home in London on a beautiful, clear, sunny Spring morning. I can hear birds chattering and see daffodils in bloom from my window beside the river in Belfast. It’s hard to believe there’s a deadly virus out there.

Grose recounts the story of a fellow analyst, who continues to see patients face to face (despite social distancing advice) because ‘he didn’t want to get sucked into the hysteria’. Philosophical abstraction, Grose admits, can be unhelpful in dealing with concrete problems. This sometimes makes it difficult not to treat *all* prophets of doom as Cassandras, she thinks.

Do we have a duty as clinicians and therapists to protest the climate emergency? She thinks we do, ‘You know, if you’re going to have subtle arguments, you need to have a world in which to have them. And so protecting that world, you know, it is absolutely primary’.

No man is an island, and this is where the COVID-19 crisis diverges sharply from the environmental one. XR, for example, is conspicuously a mass enterprise. ‘That’s been one of the big things with the climate movement, that we have to collectivize’ she says, ‘we love each other, we have to be there for each other, touch each other. That’s one of the pillars of the advice - to be communal. And suddenly that’s been really, really problematized’.

The social isolation and poverty induced by the COVID-19 ‘lockdown’ may not bode well for our mental well-being. However, for some of Grose’s patients, their anxiety has gone right down: “‘They don’t have to make choices. They don’t have to think they need to have a better job, look for a boyfriend, you know, all these sort of horrible choice making things have gone. ... They’re just thinking, well, whatever it is, you know at least it’s interesting.’”

No pills for the pain

In her book on eco-anxiety, Grose says fear is a rational response to environmental Armageddon. ‘It’s the people who aren’t worried who are crazy’ she writes. The trick, she says, is to manage our anxiety so that we’re on the helpful side of the Yerkes–Dodson stress curve. Her take-home message is to ‘... be anxious, be very anxious, because your anxiety can be a brilliant resource’.

She recognizes the paralysis that often comes with eco-anxiety, as we feel stuck between a compulsion to act and the futility of our individual efforts. She suggests a piecemeal approach to tackling climate change and also gives us permission to breathe. ‘It’s vital to accept that there isn’t a correct level of activity with regard to the climate’ she writes, ‘each person has to gauge what they can bear’.

In her book, she blends practical tips on environmentalism and personal anecdote, with strategies to soothe mind and body. As you would expect, she has some difficulty with cognitive–behavioural therapy framing real-life problems as something you can think yourself out of. About psychoanalysis, she says: “‘It’s not that I think psychoanalysis has

brilliant answers to everything. But I suppose the anti-normative thing and the idea that a cure doesn't have to be a quick fix, that you have these very open-ended speculative treatments, seems to me quite a good way to approach this stuff [eco-anxiety]. And it's counterintuitive because you think just calming people down would be a good thing to do. But actually sometimes opening up questions or sort of encouraging people to tolerate the possibility of pain and the possibility of not knowing, yes, that might be a good way to come at it."

Man's search for meaning

The tectonic plates of our civilization are shifting uneasily against each other, fault lines exposed. Although there is nothing unique about this pandemic in the course of human history, Grose thinks humans need to tell stories to impose meaning on the chaos. Narratives abound of an anthropomorphized wilderness striking back, to punish us for our destruction of the world.

Grose hates some climate activist's actions that feed into this narrative, '[They] were putting up posters saying "human beings are the virus", and I just thought that was such a nasty way to treat people'. She says, 'It seems to have been some people in the Midlands trolling XR' and is upset about how so-called 'eco-fascists' use the well-intentioned movement with nefarious intent.

She suggests some alternative narratives: "'We could say we don't know why it's [the pandemic] happening, but there are ways we could soften the blow. By treating each other well and seeing what we can do and being much more tolerant of each other and prepared to share, less self-interested.'" Extreme messaging may be crude, but it certainly gets people's attention. I ask what is better to inspire behavioural change: appeal to people's desire to protect themselves or to protect others? Grose thinks there are two different types of people, who need different messages. On vegetarianism, she says 'It's like, you know, meat will give you bowel cancer for one lot. Meat will bring about the apocalypse for the other lot'.

Like many, Grose sees opportunities for our civilization in the 'Coronapocalypse', 'I mean, I just don't see how the world could just slip back to before... Like what is big enough to make people see?'

'An emissary of pity and science and progress, and devil knows what else'

Kurtz, as portrayed by Joseph Conrad, exposes the myth of the Western man's 'progress'. Grose says that in today's world, we have fooled ourselves into thinking that our technology makes us gods, so that we are estranged from our own mortality. We defend ourselves with material and mind-numbing things. She says: "'None of these defences are, in themselves, necessarily all bad, but they become a problem when the fantasy solution is opted for so enthusiastically that fashion and cars start clogging up the planet, causing people to feel anxious, and then to vote for yet more of the sorts of leaders who promise an endless supply of fashion and cars.'"

She asks that we wean ourselves off 'these pacifying myths, in order to pave the way to ask proper, difficult questions about life, death and the ethics of coexistence'. She does stress, however, that, 'It's absolutely vital that environmentalism doesn't equate with miserabilism'.

Grose agrees with the view that eco-anxiety can be a luxury, for those who don't have to worry about their basic survival needs being met. She is clear-eyed about the XR movement being predicated on privilege, in that '... being arrested if you're a black person is not the same thing'.

Racism in the discourse around climate change and COVID-19 has been inescapable, Grose agrees. Does our tendency to 'other' people, to deny reality until it happens to people like us, betray something about our society? Our tolerance of institutionalized racism shows we have a huge capacity for denial of the 'other', Grose thinks: "'But you're haunted by the fact that your defence isn't working and you know that those people are human. You know that they suffer... And actually, what I hear from people is that the better defended you are in material terms, the more haunted you are.'" Grose looks to Freud to understand why COVID-19 has triggered a retreat into isolationism and jingoism in some countries. The insularity he saw in Germany after World War One represented 'a state of mourning for what has been lost', he wrote. She proposes that instead of saying xenophobes and climate change deniers are 'simply idiots... we could say their minds are somehow in revolt... they don't know what to do about the things they risk losing, or have already lost'.

Suffer the little children

Babies, says Grose, are ‘the main reason I wanted to write this [eco-anxiety] book’. As a psychotherapist, she has been ‘...dealing for years with people who think it’s too risky to have children because the world’s going to end’. She has a 19-year-old daughter, so admits that she is biased.

David Attenborough gets some polite digs in her book for his arguments about slowing population growth. It’s not poor people in Africa we need to worry about, she says, ‘It’s careful, rich people with 1.87 children (or fewer) who constantly upgrade their iPhones...and go on yoga retreats in the Himalayas... An Australian Aboriginal baby has quite a different carbon footprint from, say, a middle-class British one... It’s consumerism, not babies, that we need to place the limits on’.

Which brings us to children in general, who are particularly vulnerable to the apocalyptic messaging around us. In her typically frank manner, Grose says there’s no easy way to tell children about the climate crisis, just like sex and death: “‘If we’re sort of busy pretending it isn’t happening and the information’s arriving from elsewhere, which it is, then that’s not helpful to children...but things that are awful you can only get it wrong. I mean I grew up in a sort of seventies, cool family where sex was completely out there, where, you know there was arty porn around the house. There was the idea that you’d be less traumatized if it was more out in the open. But obviously, it was horrible!’”

She thinks we can smooth the conversation by showing it’s not completely hopeless but, ‘You can’t not get it wrong. Don’t be upset if your kids clock you as a worrier – that’s just part of being a real parent, rather than one in an advert’.

Not with a bang but a whimper

It’s helpful when overwhelmed, to contemplate your own insignificance, Grose says. ‘When terrestrial life gets too much for you’ she writes, ‘let your mind drift up to the stars. It’s so easy to forget they’re there’.

I suggest to her that the danger in this is nihilism. Thinking we are unimportant and transient might lead to thinking nothing really matters.

Freud’s theory of ‘pre-emptive mourning’ can protect us against this, she says. We are prevented from enjoying the world if we are preoccupied with being ‘fated to extinction’, he observed. Grose offers comfort that ‘...the inevitability of loss and death needn’t make us value things any less’. She quotes Freud, ‘A flower that blossoms for a single night does not seem to us on that account less lovely’.

In the rush of COVID-19 think pieces, it’s customary to end on a note of optimism, which alleviates the discomfort of our fear. But let’s not. Grose reminds us that anxiety is a powerful adaptive force when used productively. ‘The horror, the horror’, Kurtz whispered at the last. Let’s sit with that horror and channel it, in the best way that we can.

1.3.2 Mild cognitive impairment: narrative review of taxonomies and systematic review of their prediction of incident Alzheimer’s disease dementia

Nicholas I. Bradfield David Ames¹

Correspondence

Dr Nicholas I. Bradfield

(nicholas.bradfield@svha.org.au)

date

2020-04

Abstract

Early detection of Alzheimer’s disease is vital for developing novel treatments. Attempts to identify the intermediate state between normal cognition and dementia have evolved over the past 50 years.

¹ **Declaration of interest:** D.A. reports personal fees from the Howard Florey institute sponsored by Eli Lilly, outside the submitted work.

Current taxonomies of mild cognitive impairment (MCI) may be criticised for their imprecise operationalisation. With the advent of biomarkers such as amyloid-beta positron emission tomography imaging in established Alzheimer's disease, much research has focused on establishing which factors predict progression from MCI to Alzheimer's disease dementia. In this review, we discuss the historical context of MCI before reviewing the literature of MCI subtypes and their risk of progression to Alzheimer's disease dementia. Finally, we summarise the literature and discuss limitations and weaknesses of how the construct is operationalised and implemented, before offering suggestions for development of the concept of MCI. We conclude that MCI must be empirically defined for the sake of its predictive validity to identify Alzheimer's disease before dementia develops.

Dementia (in this review, we will use the term dementia because of its ubiquity, the fact that it is still used by ICD-10 and historically many studies have used the term dementia), now also known as major neurocognitive disorder,¹ is a common clinical syndrome that is characterised by progressive cognitive impairment that is severe enough significantly to impair daily functioning.² Much research effort has been directed towards Alzheimer's disease, which is the most common cause of dementia.^{3,4} Despite its tremendous burden, no disease modifying treatments for Alzheimer's disease are available.^{5,6}

The dominant theory of Alzheimer's disease pathophysiology implies that amyloid-beta (A) is central to the upstream mechanism of disease.⁷ Recent trials with monoclonal antibodies against A, such as solanezumab, have proved unsuccessful in mild to moderate Alzheimer's disease dementia⁸ and in mild Alzheimer's disease dementia,⁹ although the negative results may relate to the late disease stage at which the treatment was applied. With A deposited in the brain for over 20 years before the development of the clinical syndrome of Alzheimer's disease dementia,¹⁰ early recognition will be key to developing potential disease-modifying therapies and secondary prevention, as well as making lifestyle and medico-legal decisions while cognitive faculties are still sufficiently intact.

Efforts to identify early or even pre-dementia patients with some very mild degree of impairment have been underway for over 50 years,¹¹ and this thinking has evolved through several iterations to arrive at the current term of mild cognitive impairment (MCI).¹² The concept of MCI has several similar but importantly different definitions and taxonomies,

which will now be discussed systematically.

The review begins with a background consideration of Alzheimer's disease and an historical overview of MCI. This will be followed by a systematic review of the literature comparing the various taxonomies in their usefulness in predicting progression from MCI to Alzheimer's disease dementia. Finally, we discuss the state of the current literature and its limitations with a view to early identification of Alzheimer's disease to allow the testing of novel putative disease-modifying treatments.

Alzheimer's disease

Alzheimer's disease is a progressive neurodegenerative condition that is the most common cause of dementia, accounting for approximately 50–70% of cases.^{13–17} Its clinical hallmark is impairment of memory and new learning with rapid forgetting of newly learned information.¹⁸ Diagnostic criteria emphasise impairment of memory with insidious onset and gradual progression, as well as impairment of at least one other cognitive domain, which are severe enough to impair functional abilities significantly.^{1,18–21} The most recent iteration of the DSM has adopted the term 'major neurocognitive disorder due to Alzheimer's disease', while retaining the essential diagnostic criteria.¹

Mild cognitive impairment

MCI is an intermediate state between cognitively intact persons and those with dementia. This concept has evolved over time with various taxonomies, nomenclatures and definitions, which are summarised in *Table 1* and described in an historical context below. *Table 1* Various definitions of cognitive impairment that is not dementia

Term	BSF	ICDR	QD	34AAMI	24AACD	31CIND	41Petersen MCI	39Winblad MCI	12NIA-AA	43mNCD	1 Cognitive complaint																
	Self- or carer- complaint about memory	Self- or carer- complaint about cognition	Self-complaint about memory	Self- or carer- complaint about cognition	Self- or carer- complaint about cognition	Self-complaint about cognition	Psychometric impairment	—1 s.d. below healthy young adults	1 s.d. below age-matched sample	Battery of neuro-psychological tests	1.5 s.d. below age- and edu- matched sample	No cut-off specified															
	Typically 1–1.5 s.d. below age- and edu-matched sample	Modest impairment; typically 1–2 s.d. below age- and edu- matched sample	ADL—Slight or mild change	—Normal	Minimal impairment in complex instrumental ADL	Mild change, but still independently functioning	Independent, but possibly with greater effort or strategies	Dementia	No	No	No	No	No	No	No	No	No	No	No	No	Notes	Mild dementia may have CDR = 0.5	At least 6 months duration	Does not exclude non-dementia causes	AKA Mayo criteria	AKA Revised Mayo criteria or revised Petersen criteria	Biomarker criteria not presented here ²

Historical development

The concept of pre-dementia causing subsyndromal symptoms was described as early as 1962, when Kral¹¹ described 'benign senescent forgetfulness'. This encompassed mild fluctuating retrieval-based memory impairment, which he speculated could be a mild early form of senile atrophy that spared the Papez²² circuit. A shortcoming of Kral's description was that it lacked operational criteria, which can impede diagnostic reliability.²³

Over 20 years later, Kral's concept was extended and operationalised by Crook and colleagues; they labelled their concept age-associated memory impairment (AAMI), which they defined as subjective memory complaint and objective memory impairment on a memory test at least one standard deviation below the mean for young adults.²⁴ By using healthy young adults as a reference sample, this definition lacked specificity, given that performance on psychometric tasks of memory declines with healthy ageing²⁵⁻²⁷ and up to 90% of elderly individuals would fulfil this criterion.²⁸ A further criticism was that AAMI exclusively focused on memory, although other cognitive domains, such as visuospatial abilities, language or executive functions, may be affected principally early in Alzheimer's disease.^{29,30}

Addressing both of these criticisms, the International Psychogeriatric Association broadened the concept to include other cognitive domains and also defined objective impairment with reference to an age-matched sample.³¹ They labelled this age-associated cognitive decline (AACD), defined as subjective cognitive decline as observed by the individual or an informant; gradual decline over at least 6 months; and impairment in a cognitive domain with performance one standard deviation below the mean of an age- and education-matched normative sample.³¹ AAMI and AACD appear to be distinct clinical entities with only approximately 50% overlap in concordant diagnosis and AACD participants showing more extensive cognitive impairment.³²

The term 'MCI' was first described by Reisberg and colleagues with the development of the Global Deterioration Scale.³³ This was a seven-point ordinal scale from 'no cognitive decline' to 'severe dementia' that defined MCI as one or more of several examples of cognitive lapse such as becoming lost in an unfamiliar location, word-finding difficulty, forgetting names or misplacing objects, or as concentration deficit with clinical testing.³³

Concurrently, the clinical dementia rating (CDR) scale was developed,³⁴ which was also an ordinal scale ranging from 'no impairment' to 'severe dementia'. Although not directly referring to MCI, the CDR introduced the importance of daily functioning into the concept. A person scoring 0.5 or 'questionable impairment' on the CDR may have slight impairment of community affairs or home life but would be fully independent with self-care.³⁴ Flicker and colleagues used the term 'MCI' when they showed that psychometric impairment at baseline could predict subsequent decline in elderly patients after 2 years.³⁵

Ronald Petersen, a major developer of the concept of MCI through the Mayo clinic, developed his original definition of MCI based on patients recruited from a community-based medical clinic.³⁶ They identified people who were themselves concerned about their cognition, or whose carers or physicians were concerned. These patients then had an extensive battery of physical examination, cognitive assessment, investigations and neuroimaging to rule out dementia as determined by expert panel consensus. These patients by definition had 'normal' scores on the Mini-Mental State Examination³⁷ and Short Test of Mental Status.³⁸ Petersen and colleagues (1995) observed that this cohort tended to perform 1.5 standard deviations below the age-matched mean performance on memory tasks such as auditory verbal learning tests, and activities of daily living (ADL) were generally preserved, corresponding to a CDR rating of 0.5. By employing age-corrected, but not education-corrected, normative data, it introduced confounding difficulties with patients with low education or low IQ.

These criteria were more formally proposed and became known as the Mayo Clinic core criteria or the Petersen criteria.³⁹ The criteria were restricted to memory impairment rather than impairment of other cognitive domains, and thus were subject to similar criticism to that of AAMI; that Alzheimer's disease may principally affect other cognitive domains.²⁹ In 2003, a key symposium of experts revised the Mayo Clinic criteria to include domains other than memory.¹² Referred to as the Winblad criteria, these defined MCI as: (a) the person is neither normal nor demented; (b) there is evidence of cognitive deterioration shown by either objectively measured decline over time and/or subjective report of decline by self and/or informant in conjunction with objective cognitive deficits; and (3) ADL are preserved and complex instrumental functions are either intact or minimally impaired.¹² Subcategories of MCI were established based on the pattern of cognitive domains affected: amnesic single-domain, amnesic multiple-domain, non-amnesic single-domain and non-amnesic multiple-domain.⁴⁰

The concept of ‘cognitive impairment, no dementia’ (CIND) was introduced in the context of the need for early recognition of dementia.⁴¹ CIND was identified on the basis of a consensus conference of physician, nurse and neuropsychologist, integrating all available information from clinical and psychometric assessment.⁴² It includes individuals with non-dementia-related aetiologies such as delirium, chronic alcohol and drug use, depression, psychiatric illness, intellectual disability and circumscribed memory impairment; this results in high prevalence estimates⁴¹ and many CIND individuals will not develop dementia. A criticism of CIND is that it does not provide operational criteria, which may jeopardise its reliability.

Recent definitions and developments

In the context of emerging biomarkers, the National Institute on Aging and the Alzheimer’s Association (NIA-AA) convened a workgroup to revise the diagnostic criteria for pre-dementia Alzheimer’s disease.⁴³ Not long thereafter, the DSM-5¹ abandoned the term ‘dementia’ and replaced it with ‘major neurocognitive disorder’, while adding the term ‘mild neurocognitive disorder’ (mNCD), which has similarities to MCI including cognitive complaint, psychometric impairment and relative preservation of ADL.

The NIA-AA and DSM-5 mNCD both refrained from offering a strict cut-off score for psychometric impairment, instead suggesting that typical levels of impairment would be 1–2 or 1–1.5 standard deviations below the mean, respectively, for age- and education-matched normative data. Instead of arbitrary cut-offs, these criteria advocated for an individualised assessment that incorporated all available evidence.

The NIA-AA criteria⁴³ combined core clinical criteria with clinical research criteria, which incorporated biomarker evidence of disease. In doing so, these criteria moved beyond MCI as a pre-clinical definition incorporating history and examination findings to a prodromal state with biological evidence of incipient disease. The NIA-AA workgroup explicitly focused on MCI due to Alzheimer’s disease and used biomarkers to stratify the likelihood that the cognitive change is due to Alzheimer’s disease. Biomarkers indicating a high likelihood that MCI is due to Alzheimer’s disease are an abnormal A marker (e.g. positive PiB (Pittsburgh compound B) scan or cerebrospinal fluid (CSF) A₄₂) and a positive biomarker of neuronal injury (e.g. CSF tau, FDG-PET (Fluorodeoxyglucose Positron Emission Tomography) or structural magnetic resonance imaging). MCI unlikely to be due to Alzheimer’s disease is determined when A markers and markers of neuronal injury are both negative. MCI due to Alzheimer’s disease with intermediate likelihood has either A markers or neuronal injury markers as abnormal, while the other is untested. Recent studies suggest this taxonomy is useful in predicting Alzheimer’s disease.^{44,45} However, the invasiveness, cost and availability of these biomarkers may limit their widespread implementation in clinical settings.

Subjective cognitive decline is incorporated into modern definitions of MCI.^{1,12,24,31,36,43} MCI may be preceded by a state in which the individual experiences subjective cognitive decline that is too subtle to be detected on psychometric testing.⁴⁶ The Subjective Cognitive Decline Initiative working party have conceptualised this as a pre-MCI state on the same spectrum towards Alzheimer’s disease dementia and provided definitions⁴⁶ that have been operationalised for research purposes.⁴⁷

Prevalence of MCI

Since their publication, the revised Mayo clinic criteria¹² have been commonly adopted in the literature, and studies reported in this section used these criteria unless otherwise stated.

Prospective population-based studies show that the prevalence of MCI ranges from 15 to 22% in elderly individuals.^{48,49} Prevalence increases with age, decreases with education, and is more common in males, unmarried people and carriers of the APOE-4 allele.^{49,50} Prospective population-based studies have estimated incidence rates of around 6% per year, although the rate in men (over 7%) was slightly higher than that in women (under 6%).⁵¹

Progression of MCI to dementia

Estimates of progression rates to dementia or Alzheimer's disease dementia are important for advising patients about prognosis and have implications for conducting research in this population. Individuals with MCI have a higher risk of developing dementia compared with the general older population incidence of 1–2% per year,⁵² although estimates vary depending on the definition or subtype of MCI, study design and follow-up period.^{52–55} Earlier definitions using the Petersen amnesic-only MCI criteria estimated rates of progression to Alzheimer's disease dementia to be 10–15% per year.⁵² A randomised controlled trial reported a progression rate of 16% per year.⁵⁵ A meta-analysis of studies using Mayo clinic criteria for MCI suggested that over 10 years, 33.6% will cumulatively progress to Alzheimer's disease dementia in specialist settings versus 28.9% in population settings, which translated to an annual progression rate of 8.1% in specialist settings and 6.8% in community studies.⁵⁶

There is some criticism of the utility of MCI as a diagnosis given its heterogeneous nosology,⁵⁷ variable prognostic significance^{58–60} and the various ethical issues it raises.⁵⁷ We would counterargue that these issues provide impetus to refine the definition of MCI, as doing so will allow identification of a group that could be identified for treatment of modifiable risk factors that may decrease the risk of developing dementia, such as diet, diabetes mellitus, hypertension and hypercholesterolemia.^{61,62}

The present study aimed to review the evidence with regards to which taxonomy of MCI was more useful in predicting incident Alzheimer's disease dementia. We hypothesised that amnesic MCI (aMCI) and multiple-domain MCI would be more likely than non-MCI controls to progress to Alzheimer's disease dementia.

Methods

Search method

Medline was searched via PubMed on 28 February 2017 using the search terms 'MCI or Mild Cognitive Impairment' and 'Alzheimer's disease' and 'progression or conversion', identifying 2583 studies. The search was restricted to articles in the English language and studies conducted on humans aged 65 years and over, resulting in 1674 studies. See *Fig. 1* for the PRISMA diagram.⁶³ *Fig. 1* PRISMA diagram of study selection.

Selection criteria

Studies were selected if they performed longitudinal follow-up of at least 3 years, reported on the incident development of Alzheimer's disease dementia using established criteria, and explicitly compared two definitions of MCI. The 3-year duration was selected because of the lower specificity associated with shorter follow-up.⁶⁴

Data extraction

All titles were reviewed and the abstracts of all potentially relevant studies were assessed. The identified full papers were assessed for eligibility and data were extracted. Study quality was assessed using the Newcastle-Ottawa Quality Assessment Scale.⁶⁵

Results

There were 15 studies included in the final analysis, all of which were classified as ‘good’ according to the Newcastle-Ottawa Quality Assessment Scale.⁶⁵

MCI subtype and progression to Alzheimer’s disease dementia

Only a single study explicitly examined differences between various classification systems of MCI and progression to Alzheimer’s disease dementia. In a large population-based study of 4057 individuals with 4.5 years follow-up, DSM-5 criteria gave a higher annual progression rate than Petersen criteria for progression to Alzheimer’s disease dementia and to all-cause dementia.⁶⁶ However, the majority of people who developed Alzheimer’s disease dementia were classified as normal controls at baseline. The DSM-5 criteria were more restrictive, with only 139 cases meeting criteria, whereas 303 cases met criteria for Petersen aMCI. The authors do not stipulate why, but a possible contributing factor to this is that the DSM-5 criteria explicitly exclude people with severe depression, psychosis or delirium, whereas the Petersen criteria do not. Marcos and colleagues (2016) noted that most of the MCI cases did not progress to Alzheimer’s disease dementia or dementia during the 4.5-year follow-up; indeed, only 15% of the DSM-5 defined MCI cases progressed to dementia.

Twelve studies explicitly examined differences between various subtypes of MCI, usually within the Winblad taxonomy.¹² The most consistent finding was that aMCI is associated with an increased risk of progression to Alzheimer’s disease dementia.^{53,67–77} Individuals with aMCI are more likely (18–19% per year) to progress to Alzheimer’s disease dementia than non-amnesic MCI participants (10–11%) in community-⁵³ and healthcare-based cohorts.⁷⁸

Ten studies compared progression rates between various subtypes within the Winblad taxonomy. Seven of these studies show that multiple-domain aMCI has the best predictive accuracy for progression to Alzheimer’s disease dementia,^{54,67–69,73,74,76} with annual progression rates ranging from 4 to 25%. However, two studies found that single-domain aMCI was associated with the highest risk of progression to dementia due to Alzheimer’s disease,^{70,77} and one found no difference between single- and multiple-domain aMCI.⁷¹ A challenge to the discriminative validity of the Winblad taxonomy is that multiple-domain aMCI was also the best predictor of progression to vascular dementia.⁷³

Although all studies purported to employ the revised Mayo criteria, these were operationalised in different ways, for example, using hierarchical cluster analysis of neuropsychological data rather than clinical judgement⁷⁰ or not including information about subjective memory complaint.⁶⁷ Moreover, psychometric impairment was defined in one study as at least 1.5 standard deviations below the mean for an age- and education-matched sample on a neuropsychological battery⁷⁷ or as at least 1.0 standard deviations below the mean for an age- and education-matched sample on indices derived from the Montreal Cognitive Assessment.⁶⁸

Discussion

The concept of MCI has evolved from a vague clinical observation to a diagnosis that can incorporate disease biomarkers to predict the likelihood of developing Alzheimer’s disease dementia. There have been at least nine different attempts to define the intermediate state between cognitive health and dementia. However, only a single study has explicitly compared different taxonomies in terms of their usefulness in predicting incident Alzheimer’s disease dementia.⁶⁶ This study showed that DSM-5-defined mNCD had better positive predictive value than did Petersen criteria, although the majority of people who developed Alzheimer’s disease dementia were classified as normal controls at baseline. Of the studies comparing various subtypes of MCI within the Winblad taxonomy, aMCI better predicts progression to Alzheimer’s disease dementia than does non-amnesic MCI.^{53,78} This is consistent with the observation that memory impairment is the hallmark clinical feature of Alzheimer’s disease.¹⁸

Although there was not consensus, 7 of 10 studies found that multiple-domain aMCI was better than single domain aMCI in predicting progression,^{54,67–69,73,74,76} two showed the opposite^{70,77} and one showed no difference.⁷¹ A possible reason for the discrepant findings regarding single-domain aMCI and multiple-domain aMCI in the prediction of

Alzheimer's disease dementia is differing definitions of the subtypes. The inconsistent findings within this area highlight the variable implementation of the criteria. Although all studies purported to employ the revised Mayo criteria, these were operationalised in different ways, such as not including subjective memory complaint,⁶⁷ different psychometric cut-off z-scores ranging from 1.0⁶⁸ to 1.5,⁷⁷ different psychometric tests^{68,77} or even hierarchical cluster analysis of neuropsychological data.⁷⁰

This review suggests that aMCI is superior to non-amnesic MCI and that multiple domain aMCI is probably superior to single domain aMCI in predicting progression to Alzheimer's disease dementia. It may be that involvement of cognitive domains in addition to memory in MCI implies more severe or advanced disease that is closer to the emergence of dementia. Despite these findings, the predictive validity of MCI is limited, as up to 60% of MCI individuals will not develop dementia in the following 10 years.⁵⁶

We suggest that the concept of MCI may be improved in three ways. First, criteria should be operationally defined. Second, criteria should be empirically defined. Finally, the MCI group should be stratified for likelihood of progression to Alzheimer's disease dementia. These will now be discussed in turn.

Several taxonomies of MCI have suggested explicit cut-off scores on cognitive measures. Despite this, more recent taxonomies from the DSM-V and NIA-AA have dispensed with cut-offs for cognitive impairment. Although this approach has the merit of tailoring assessment to the individual, it may introduce issues with interrater reliability, which may further undermine the reliability of MCI in the research literature. We suggest that criteria for subjective and objective memory impairment should be operationalised to ensure reliability of the concept.

This raises the question of which cut-off should be adopted. We suggest that the utility of MCI may be improved by providing operational criteria that are empirically defined by their prediction of Alzheimer's disease dementia. There have been only a few attempts to use such data-driven definitions of MCI. For example, MCI subtypes identified with latent profile analysis outperformed Winblad criteria⁷⁹. Other studies have shown that the severity of memory impairment^{80,81} and the base rate of memory impairment⁸² offer an advantage over the common taxonomies. We propose that cognitive impairment used to identify MCI should be empirically defined, whether it be in terms of the lowest performance,^{80,81} base rate of impairment,⁸² or possibly average memory score or some other method.

These same factors may then be used to stratify the severity or grade of MCI. All current taxonomies treat MCI as a categorical entity, which is not consistent with a longitudinal model of Alzheimer's disease pathophysiology. Although the clinical manifestation of Alzheimer's disease exists on a spectrum from asymptomatic to severe dementia, MCI is not staged as such. We propose that MCI should be stratified by factors such as severity^{80,81} or base rate of impairment⁸² to indicate increased risk of progression to Alzheimer's disease dementia. This may allow individuals to be selected for more intensive monitoring, for secondary prevention techniques such as control of diet and cardiovascular risk factors,^{61,62} and for recruitment into clinical trials of putative treatments for Alzheimer's disease.

Conclusion

The current literature suggests that MCI individuals with memory impairment and impairment of multiple domains are at increased risk of progression to Alzheimer's disease dementia. We suggest that the concept of MCI should be improved by offering operational criteria of memory or cognitive impairment that are empirically defined. Furthermore, we propose that MCI should be developed from a singular categorical diagnosis to a graded diagnosis that indicates increased risk for progression to Alzheimer's disease dementia. In this way, MCI may become a more reliable construct with better predictive validity that will be more useful in understanding the natural history of Alzheimer's disease. This in turn will allow better targeted selection of individuals with pre-symptomatic Alzheimer's disease to allow early implementation of therapeutic strategies to modify the course of this common and burdensome disease.

Nicholas I. Bradfield is a basic physician trainee at St Vincent's Hospital, Melbourne, Australia and is a clinical neuropsychologist in private practice in Melbourne, Australia. **David Ames** is Emeritus Professor in the University of Melbourne Academic Unit for Psychiatry of Old Age, St George's Hospital, Kew, Australia, a consultant psychiatrist with Melbourne Heath, Parkville, Australia, and director of the National Ageing Research Institute, Parkville, Australia.

As interest in psychedelic research continues to increase, it is clear that a new conceptual framework is needed to investigate phenomena associated with altered states of consciousness. While research has focused primarily on their psychotherapeutic and entheogenic uses, few studies have dared to consider psychedelics as potent tools for enhancing cognition, conducting conceptual research and improving complex problem-solving. Sensing an opportunity to kick-start an intellectual revolution, Roberts introduces ‘multistate theory’ as a potential framework to guide new exploration of altered states of consciousness.

A core tenant of multistate theory is the rejection of the ‘singlestate fallacy’, which Roberts defines as the erroneous assumption that all worthwhile skills, abilities and knowledge reside in our default waking state. He argues that our default state is simply one of many possible states of consciousness (or ‘mindbody states’) that the mind can produce and operationalise. Directly criticising mainstream science and philosophy’s understanding of intelligence and consciousness, Roberts provides ample evidence that cognitive processes qualifying as intelligence reside in other mindbody states.

MindApps explores a simple analogy – as apps are to smart devices, ‘mindapps’ are to the brain–mind complex. Therefore, any agent of psychological change (both drug and non-drug) that produces a mindbody state can be considered a mindapp. Different kinds of mindapp, of which psychedelics are perhaps the most potent, ultimately produce disparate mindbody states. Consequently, Roberts challenges the reader to consider a new age of ‘mind design’, where mindapps are used in combinations to investigate mindbody states, create new ones and uncover the full extent of the human mind. As transhumanist and transpersonal perspectives begin to intersect, could it be possible to design minds that far surpass the functions and capabilities of our current ones?

Multistate theory is a novel conceptual framework that sits at the crossroads of science, philosophy, spirituality, humanities and the arts. Considering the evidence illustrating the efficacy of psychedelics and other mindapps as catalysts for substantive psychological change, multistate theory can serve as a guide not only for systematically investigating mindapps and the cognitive processes that characterise mindbody states, but also for conducting conceptual research.

While he is clearly optimistic about the future, Roberts is quick to highlight that *MindApps* is merely the start of a new conversation about what it means to have a mind. However, given his contributions to psychedelic research and education over the past 30 years, Roberts’s conclusions are deserving of a wider audience. As we shift from the age of information to the age of experience, his clarion call for bold innovation should be heard by all who wish to pioneer the development of new research questions, creative methodologies and engaging education for future generations of mind-designers.

Abstract

A growing body of research has focused on understanding what may contribute to cessation of self-injury. Although these efforts are of value, cessation represents just one component of self-injury recovery. Exclusive or primary focus on cessation may foster unrealistic expectations for those with lived experience of non-suicidal self-injury (NSSI). Accordingly, this commentary discusses the importance of expanding the concept of NSSI recovery beyond cessation in both research and clinical domains. We conclude by presenting a person-centred and non-stigmatising conceptual reframing of recovery.

Contents

- *Rethinking self-injury recovery: a commentary and conceptual reframing*
 - *Recent trends in NSSI recovery research*
 - *Moving beyond cessation*
 - *Reframing recovery*
 - *Summary*

Non-suicidal self-injury (NSSI), deliberate damage to one's body tissue in the absence of conscious suicidal intent,¹ is a behaviour that is most often used to regulate intense or unwanted emotions.^{2,3} In community samples, 18% of adolescents, 13% of young adults and 5% of adults (aged 25+) report a history of NSSI,⁴ with approximately one-third persisting with the behaviour for longer than 1 year.⁵ Associated with psychological distress, mental health difficulties (e.g. depression, anxiety, eating disorders),^{2,3} interpersonal difficulties^{2,3} and subsequent suicide risk,⁶ NSSI can also leave physical scars that can represent both resilience and a source of shame for people who have self-injured.⁷

Given its many adverse consequences, researchers have recently focused on identifying factors that facilitate cessation of NSSI. In particular, researchers have sought to delineate individuals who currently engage in NSSI and those who report having stopped, with the aim of identifying targets for intervention.^{5,8-12} Clearly, there is merit in these efforts. Yet, this approach may inadvertently emphasise NSSI cessation, without equal attention to the many concerns those with lived NSSI experience report in the broader context of recovery. In keeping with a recent trend in the NSSI literature to offer more person-centred views of NSSI,¹³⁻¹⁵ the present commentary discusses issues inherent in limiting focus to NSSI cessation and offers a person-centred, non-stigmatising framing of recovery.

Recent trends in NSSI recovery research

Notwithstanding the value of examining NSSI recovery, focus is often circumscribed to desistance of the behaviour. Indeed, this is typically the primary outcome measure in research.^{5,8-12} From a theoretical standpoint, NSSI has been situated within the context of recovery-based models in which desistance of a behaviour is the primary aim.¹⁶ For example, NSSI has been viewed in the context of the transtheoretical stages of change model, which considers individuals as 'recovered' (from the target behaviour) following a 6-month period of abstinence from that behaviour.¹⁶⁻¹⁸

In contrast to these views are those of individuals with lived NSSI experience, who have expressed concern that salient NSSI experiences may be neglected if the primary focus is on the behaviour.¹⁹ Indeed, individuals discuss a range of concerns (e.g. scarring, disclosure, coping) that extend well beyond NSSI disengagement.^{6,7,20-23} Taken together, the

totality of experiences expressed by individuals with lived experience of NSSI may not consistently be represented in the extant literature. Moreover, emphasis on cessation of behaviour may inadvertently place NSSI in disease-based conceptualisations of ‘illness’. In particular, there has been a recent and growing movement away from pathologising behaviour, including NSSI.²⁴ Notwithstanding the psychological and medical consequences of NSSI (e.g. distress, scarring), using disease-based language to describe NSSI can conflate illness with a behaviour, and exacerbate the already strong stigma associated with NSSI.¹⁴ Specifically, the tendency to conceptualise NSSI within models of infectious disease, including borrowing language from this domain (e.g. contagion), can have an ‘othering’ effect in distancing people who self-injure from those who are not ‘diseased’.¹⁴ This is reflected in recent research eliciting views from individuals with lived NSSI experience.¹⁹ Consistent with an emerging trend in the field, researchers and clinicians may find it more helpful to adopt a strengths-based and person-centred (rather than deficit- or disease-based) conceptualisation of NSSI and recovery.

Moving beyond cessation

Cessation of NSSI represents just one element of an ongoing and multifaceted recovery process. Although many would not disagree that recovery is broader in scope, researchers typically focus on cessation of the behaviour,^{5,9–12} with the implicit argument that this is the desired outcome of any intervention effort. However, it is not uncommon for people with lived NSSI experience to mention ongoing NSSI thoughts or urges,^{7,20} learning new ways to cope with difficult emotions,^{8,20,23} disclosure-related concerns²² and coming to terms with scarring^{7,21} – even long after ceasing to self-injure.

Attenuated focus on complete NSSI cessation may result in people perceiving their own recovery as all-or-nothing. As ongoing NSSI thoughts and urges are common, beliefs that people can be ‘cured’ or fully removed from NSSI are unrealistic. Likewise, equating recovery with a single outcome and viewing cessation as the sole indication of success are unhelpful. Ultimately, considering cessation as ‘successful recovery’ detracts from the multifarious paths people inevitably have. Left with the impression that recovery is a linear path to cessation, individuals are prone to become discouraged (even when progress is made) or may view their own efforts as futile.

A more realistic expectation would be that many individuals *will* continue to experience thoughts and even urges to self-injure in the future. However, over time, these occurrences will abate in magnitude and frequency. Moreover, as individuals begin to find and utilise alternative strategies in lieu of NSSI, the pairing of NSSI with painful emotions should correspondingly dissipate. By acknowledging and ultimately adopting more realistic and holistic expectations, individuals are apt to feel encouraged over the course of their NSSI journeys.

Reframing recovery

Following the above, we would encourage researchers and clinicians to adopt a broad, multipronged conception of recovery to account for a range of variables, including but not limited to NSSI cessation. Hence, we propose that consideration be given to how: people respond to difficult emotions and thoughts of NSSI (including coping responses); individuals adapt to and live with having NSSI scars; the process is non-linear and may involve setbacks (e.g. instances of NSSI); recovery may be an enduring (at times life-long) process; and other factors (e.g. disclosure, future coping, mental health difficulties) are germane. By virtue of expanding beyond NSSI cessation, more realistic expectations can be fostered. This not only acknowledges the multitude of experiences people may have but stands to foster more resilience.

In keeping with the above, when working with people with lived NSSI experience, it might be more helpful for researchers and clinicians to strive to adopt and reflect back the precise language these individuals use when referring to recovery. As the lexis of recovery is commonplace in NSSI discourses,^{17,18,25} the term ‘recovery’ is bound to be used. Yet, alternative referents (e.g. journey, overcoming self-injury) may also be employed. Some people may even be resistant to using the term ‘recovery’ as it may position NSSI within disease-based (as opposed to behavioural) frameworks. As noted above, such framings have been rendered stigmatising by those with lived experience.¹⁹ Others may view the term recovery as conceptually ill-suited, as recovery is defined as a return to a normal or healthy state.²⁶ Indeed, individuals may not view their experience as a return but more an experience in which they view themselves in a new light

(e.g. more resilient);^{7,23} additionally, some may view this definition as inferring that people who self-injure are somehow ‘abnormal’. Ultimately, by using individuals’ own language researchers and clinicians can avoid unnecessarily ‘correcting’ those who are arguably experts in *their* experience; further, this approach coheres with recommendations for discussing NSSI in assessment and related contexts.^{3,27}

Nevertheless, irrespective of the phrasings used, it would be helpful if conversations could underscore and foster realistic expectations extending beyond NSSI cessation. This may necessitate ascertaining what individuals mean by the particular term they use. Doing so can help determine whether an individual’s primary focus is on desistance of NSSI. Although desistance may have value for some people (e.g. acknowledging progress by the time elapsed since they last self-injured), it would be important to ensure that individuals view their trajectory realistically, cognisant of the manifold complexion of recovery (e.g. persistent urges, set-backs).

Summary

Recent trends in the NSSI literature have seen the emergence of research on NSSI recovery, with a particular focus on factors related to cessation of the behaviour. Hopefully, it is apparent from our commentary that a primary focus on cessation in the context of self-injury could detract from the myriad experiences people have and may inadvertently lead to a sense of failure, as thoughts and urges (among other features) are apt to continue long after a person no longer self-injures. Instead, we call on researchers and clinicians to focus on how people respond to intense or unwanted emotions and whether the chosen strategies are meeting the desired aims. In this way, focus centres on individuals and their experiences, with realistic expectations about their own progress, while allowing the requisite space to adopt alternative strategies that will best serve the functions needed.

- *Innate*
- *Psychiatric genomics*
- *Towards a unifying theory for neuroscience*

Professor Kevin Mitchell has a few pet peeves with the way neuroscience is represented in the media. To start, he highlights the siren call of fMRI scans that often adorn any remotely psychological article: ‘People demonstrably find that same article more convincing if it has a glowing brain in one corner of it than if it doesn’t. So people are a bit susceptible, I think, to what we affectionately term “neuro-bollocks”’.

Mitchell is Associate Professor in Developmental Neurobiology and Genetics at Trinity College Dublin, where he is also Dean of Undergraduate Studies. His mission is to make complex neuroscience more accessible while resisting the temptations of neuro-reductionism. In his blog ‘Wiring the Brain’ (www.wiringthebrain.com), he writes spirited and forensic take-downs of overly hyped neuroscience research, as well as thoughtful philosophical explorations of the nature of the brain and mind. Blog titles include: ‘Is your future income written in your DNA?’ and ‘The murderous brain – can neuroimaging really distinguish murderers?’.

In 2018 he published *Innate*, an engaging popular science book exploring ‘how the wiring of our brains shapes who we are’, which has been praised by Stephen Pinker as a ‘new landmark’ in the old nature versus nurture debate.

Any other neuromyths he’d like to bust? He laughs, ‘There are so many!’. He is a critic of ‘blobology’ generally (the tendency to use blurry pictures of the brain to illustrate articles of little scientific value, such as ‘Your brain reacts to love like cocaine’), in part because it reflects a modular understanding of the way the brain works that bears no resemblance to reality.

One of his key messages is that nature is not obliged to make biology simple enough for us to understand. He does, though, think that public engagement by neuroscientists is vital, as ‘we see the effects of scientific illiteracy in lots of public policy’. He has several popular public talks on YouTube (including a TED talk titled ‘Who’s in charge? You or your brain?’).

Mitchell fizzes with infectious enthusiasm for his subject. Two and a half hours later we’re still talking and I feel I’ve just skimmed the surface. The themes of outdated traditions in neuroscience that try to localise brain functions (telling us nothing about the connectivity of the brain) and the lack of an underpinning philosophy of neuroscience are ones he continually comes back to. The way that neuroscience is taught explains the appeal of things like the decorative fMRI to professionals and public alike, he thinks. He emphasises that these scans are very indirect measures of neural activity on a background of constant endogenous activity. There is also the intuitive appeal of finding a ‘biomarker’ for mental illness.

Biomarker research

Mitchell dismisses the idea that we have biomarkers for any neurodevelopmental or psychiatric conditions: ‘All that literature [on biomarkers] is polluted with false positives’. Small samples, lack of replication, statistical ‘fishing’ in an exploratory fashion are all major problems that undermine the validity of biomarker research. And, he says, ‘it gets worse if you add in the dimension of genomics to that, because now you have the enormous genomics space in which to search for covariates of neural activity or structure’.

So, no scans as diagnostic tests for mental illnesses then? He is bracingly sceptical: “‘There’s not going to be a blood test. There’s not going to be a brain scan. There’s not going to be any other biomarker that captures those things, because they’re looking at the wrong level. [Those conditions] are defined at the level of human behaviour [...] Even if there’s a dynamic neural state that underpins some aspect of psychosis that we both share, the way that that state looks in your brain may be very different from the way it looks in my brain because our brains are not the same. So I don’t hold out much hope for, you know, getting to diagnostic biomarkers from that kind of imaging.’”

The neuro-hype of epigenetics

We turn next to epigenetics, a mechanism in molecular biology by which genes are ‘switched’ on and off and which is at risk of becoming ‘neuro-hype’. Epigenetics as a mode of intergenerational trauma transmission is very much a buzzword at present. Mitchell cautions against invoking sciency-sounding mechanisms to lend credibility to ‘nurture’ as a cause of psychological distress: ‘So people look at two fields – neuroplasticity/brain plasticity and now epigenetics – as some kind of a “get out of genetics free card”. I think people don’t like the idea, some people anyway, that we are born with certain predispositions that are hard to change’.

Mitchell finds the concept of trauma transmission through epigenetic mechanisms implausible primarily because it suggests an overly simplistic relationship between genes and our psychological traits. Our experiences, he says, are expressed through changes in our neuroanatomy, not in our patterns of gene expression.

He sees in such flimsy claims a cautionary tale about the need for a different approach in science publishing: ‘There is a hype industry around science, which I think is corrosive. And I think scientists are willing participants in it in a way that I find more and more distasteful the older I get, because it does a massive disservice cumulatively to how science is understood by the general public because we have this constant hype’. He thinks his cynicism reflects a growing awareness in the research community of the need to focus on replicability and reproducibility and is hopeful things are changing for the better.

‘Biology is not just complicated physics’

Mitchell is most passionate when discussing the need to bring about a sea-change in the way neuroscience is taught and thought about. At this stage in his career he sees this as the biggest contribution he can make to his field.

By and large, he says, biological research is conducted in a theoretical vacuum, which means that a mechanistic understanding of how brains and minds work has become entrenched. Much neuroscience research is, he feels, linear and reductionist as a result: “‘We have one theory, which is the theory of evolution, which is great. And it does underpin everything. But it doesn’t really explain how biological systems work and what they do [...] There are lots of engineering principles and dynamic systems principles that we could be applying from those fields [from engineering and physics] that most biologists don’t think about. It’s just not the way that we approach things.’”

He emphasises the need to get away from a modular understanding of how the brain works – the old ‘find the lesion’ trope – which works in neurology but not in psychiatry. ‘The connectivity across circuits is what’s really important’, he says.

He thinks an understanding of neuroscience *is* important for psychiatrists but needs to be taught alongside complexity theory (understanding the dynamics of change in systems) so that we don’t see brains as ‘passive stimulus–response machines’. He has a gift for the memorable tagline: ‘Biology is not just complicated physics!’, he quips.

Undergraduates

Mitchell’s genetics background influences his approach to his role as undergraduate dean. He says, ‘IQ scores, for example, are I think a measure not of potential but of achievement’. So two people with the same biological potential will perform differently depending on whether their environment allows them to thrive. He talks about the so-called ‘Matthew effect’ – the positive feedback loop between socioeconomic privilege, exam success and later career success that gets amplified across generations. Trinity College Dublin has pioneered novel approaches to making admissions criteria more equitable by accounting for social factors that affect a student’s exam grades.

He is critical of commentators in the British press who use the partial heritability of intelligence to suggest that we live in a meritocracy and even to lend credence to eugenics: ‘It’s a very Ayn Randian kind of idea that. Most of the people who’ve done well may have had some genetic capital in terms of talents and natural abilities but, of course, many of them also had lots of social capital and cultural capital’.

Innate

In his book *Innate*, Mitchell argues strongly against the idea of the mind as a *tabula rasa* but he distinguishes his book from the work of people such as Robert Plomin, who also writes about the influence of DNA on our psychological traits. He agrees with Plomin that our traits are partly heritable but differs in how predictive he thinks that is.

He explains that the precise statistical meaning of ‘heritability’ is commonly misunderstood. It refers to the variance in a particular trait being due to genetic differences. This variance or ‘heritability’ is meaningful at a population level, but less useful when it comes to individuals. If, for example, intelligence is 50% heritable, it does not mean that 50% of your intelligence comes from your genes.

He is sceptical of the idea that genomic analysis or ‘polygenic risk scores’ in individuals can be used as a prediction of, for example, how intelligent that person will be, because of the massive spread in distribution of a particular trait across people with the same polygenic score.

Polygenic scores also have poor predictive value because of the nature of genetic variation. They capture a background of common mutations, each with a tiny effect on a trait, which account for about half of genetic effects, but ‘the rest will be from really rare newer mutations that have bigger effects but that kind of wink in and out of existence in a population because they get selected against’.

Another key theme in his work is that our DNA has distal and very indirect effects on the development of our brain. It is the multitudinous ‘noisy’ developmental processes between the transcription of the program encoded in our genome and the ‘wiring’ of our brain that are responsible for much of the variation in our traits. He says: “‘So one of the main points, I guess, of *Innate* that I was trying to make was that there’s this source of variation in our psychological make-up that has gone largely unappreciated. It’s not just genes and environment. There’s this third source, third component of variation, this developmental variation that isn’t due either to genetics or to environment. It’s just the way that the development plays out during embryogenesis, during gestation and the way that it continues to play out over life.’”

Psychiatric genomics

All of this ‘noise’ in developmental variation is one of the reasons that Mitchell is guarded about the potential for genomics research to directly influence psychiatry. He points out that schizophrenia risk is only about 50% heritable but that doesn’t necessarily mean that the other 50% of the variation is environmental: ‘A lot of the outcome may just be the random chance actually during development’.

Mitchell mistrusts much of the early work in psychiatric genetics, in particular the candidate gene association studies, in which researchers studied one or two genes at a time. He describes the statistical acrobatics in data analysis and publication bias towards positive results that threw up spurious associations between individual genes and psychological distress. Genome-wide association studies (GWAS) have shown candidate gene studies to be unreliable. The effects of genes implicated in the development of mental illness are mediated by the sum of interactions between probably thousands of different genes with different biochemical pathways.

So, has genetic research added to our understanding of the causes of mental illness? Mitchell thinks it has, but not in the way we’d hoped for. He cites the example that 80–90% of the variance in who develops autism is down to genetics, but most of the contributing variants are not inherited – so-called *de novo* variants.

Another key finding is that genetic risk factors overlap and are shared between multiple psychiatric and neurodevelopmental morbidities: ‘One of the things we’ve learned is that those sorts of [*de novo*] mutations can give rise in different people to autism or ADHD or epilepsy or intellectual disability or schizophrenia or bipolar disorder, depression or a whole range of things. So, they don’t respect the diagnostic boundaries that we have’.

He feels that genetics research adds weight to the need to think about psychiatric disorders in dimensional terms but also in developmental terms: ‘You have two identical twins. As their brain is developing, what is the trajectory that leads one to develop schizophrenia and the other not? We can’t just look at the genes and say these are genes for psychosis because that’s not what the genes are doing’.

So far, so gloomy for a brave new world of psychiatric genomics leading to personalised medicine and new therapeutic targets. Genetics research will be useful for psychiatry in a probabilistic kind of way but he finds it difficult to see how it could be used to predict outcomes or therapies with certainty in individuals.

Towards a unifying theory for neuroscience

Where then does the future lie for genetics research into psychiatric disorders? Mitchell stresses that genes are algorithms for making proteins. Human behaviour is not directly resultant from the activities of proteins; instead we perceive and think and feel with our neural circuits: ‘So, the way the neural circuits are organised is, for me, the proximal biological underpinning of the conditions. The genetic variations that led to those things being organised in that way are extremely distal causes [...] So I think what we need to do is hand off to the neuroscientists’. Basically, he sees the biological causes of psychiatric disorders as a neuroscience problem: ‘I’m more optimistic about the idea of using genetic findings as a starting point to get at the neuroscience’.

He is particularly excited by the new field of optogenetics to help us study how discrete neural circuits work to influence animal behaviour in real time. He also hopes that the field of computational psychiatry will develop ‘so that we can develop a kind of a mature theory of what these circuits are doing in a complex dynamical systems kind of framework’.

He seems to bristle slightly at my suggestion that his approach to understanding the mind could be criticised as epiphenomenalism, and the associated problems with rooting thoughts, feelings and behaviours in biology. He appeals to holism: ‘I wouldn’t use the word epiphenomena because that sounds a bit dismissive actually, but I would say emergent phenomena’. He emphasises that our cognitive and social development are crucial in understanding these phenomena: ‘We shouldn’t think of nature and nurture as independent from each other, but highly interactive’.

He thinks neuroscience may be in the midst of a paradigm shift due to new technologies and mathematical tools that let us model the brain in a way that reflects its complexity.

So, I ask him, how long before the fruits of this new approach to neuroscience will benefit patients in psychiatry clinics? ‘Maybe if you ask me again in 5 years I’d be giving you, I think, a much more positive view of the importance of that. And if you ask me in 10 years, I’d be, I hope, pointing to areas where that understanding has led to some difference in the clinic’. He pauses. ‘Maybe 10 years is still too optimistic. Give me 20 years. Give us 20 years’. Not quite a headline that plays well to the gallery but a tonic in our era of spin.

1.3.5 Basic safety first: trauma-informed care in a hostile environment

Abstract

This editorial introduces and reflects on a Praxis article in the trainees' section of this issue. The article, 'Assessing asylum seekers, refugees and undocumented migrants' by Waterman *et al*, begins with a clinical scenario describing an emergency presentation at a 'place of safety'. The authors are to be congratulated for navigating a compassionate path through the complexities of law, health and new diagnostic categories. The resources found in the article, drawing on the principles of trauma-informed care and the work of Judith Herman, can help trainees to be more confident in promoting the basic rights of survivors of trauma, which might form a first step in the re-establishment of trust and empowerment.

Contents

- *Basic safety first: trauma-informed care in a hostile environment*

 - *Trauma-informed and human rights-based care*

There has never been a more timely moment to highlight the needs and rights of asylum seekers and refugees, as so comprehensively described in this month's Praxis article 'Assessing asylum seekers, refugees and undocumented migrants', by Waterman *et al*.¹ This population and those who care for them face many challenges. Not least of these is the ongoing hostile environment. In the UK, immigration checks are embedded in everyday interactions and accessing healthcare may result in sharing of personal data with the Home Office, leading to deportation or detention.² Frequently changing funding arrangements related to Brexit threaten numerous charities that support migrants.³ However, Waterman *et al*'s article can empower us to be hopeful and compassionate and, importantly, well-versed in relevant law. In so doing it embraces some of the core values of a psychiatrist as outlined by the Royal College of Psychiatrists, including advocacy, empowerment and a person-centred biopsychosocial approach.⁴

The article introduces a fictitious but sadly all too familiar case, which begins with a presentation in crisis at an inner-city 'place of safety'. What I have learned in reviewing this article has already helped me to advocate for two patients under my care to receive National Health Service (NHS) treatment and eligibility for housing that was called into question owing to legal uncertainties. Both had been the victims of torture and were at varying stages in asylum claims. The securing of such basic rights is the first step for survivors of trauma beginning to find safety and regain control over their lives, what Judith Herman describes as a primary stage in her book *Trauma and Recovery* (p. 326).⁵ However, it would seem that I was not alone in my ignorance of the complexities of law. A recent survey of a 514 health professionals found that only 26% were aware that all migrants were entitled to free general practitioner (GP) services.⁶ Just 39% were able to identify which groups of migrants were entitled to non-emergency NHS care.⁶

Individual and societal responses to trauma

In words that still hold true today, Herman wrote in the introduction to her powerful work: 'The ordinary response to atrocities is to banish them from consciousness'.⁵ Psychiatry and trauma have a long and complicated relationship. Trauma has had an often 'underground' history, resurfacing and then disappearing at various points depending on the sociopolitical climate.⁷ As far back as 1919 Janet recognised that the survivors of trauma 'are unable to make the recital which we call narrative memory, and yet they remain confronted by [the] difficult situation' (Janet 1919: see van der Kolk *et al*⁸). Years later Kardiner built on Janet's studies of 'hysteria' in women to formulate the outlines of traumatic syndromes in male combat veterans (Kardiner 1941: see van der Kolk *et al*⁸). Contemporary psychiatrists such as Herman and van der Kolk have formulated and communicated clearly and conclusively how traumatic life experiences have far-reaching effects on the mind and body. This has paved the way for an understanding of the neurobiological effects of trauma on the brain, endocrine and immune systems, including dysregulation of the hypothalamic–pituitary–adrenal axis and sympathetic nervous hyperarousal.⁹ Thanks to Felitti and colleagues' large and important study on adverse childhood experiences (ACEs), there are now robust and undeniable links between exposure to trauma and cardiovas-

cular and respiratory disease, cancer, obesity, chronic pain and gastrointestinal illness.^{9,10} The intergenerational effects of trauma are also being increasingly understood. It has recently been found that the children of mothers who were Holocaust survivors and suffered post-traumatic stress disorder (PTSD) have increased glucocorticoid sensitivity.¹¹

Herman, more than 20 years ago, identified the syndrome of complex post-traumatic stress disorder (CPTSD).¹² Yet it has taken tireless work and campaigning from clinicians, researchers and people with lived experience for it to now be included in ICD-11.¹³ The operationalisation and recognition of the diagnosis is a significant step towards research and treatments which acknowledge that prolonged and repeated trauma profoundly affects the sense of self, affective stability and relationships. Indeed, some studies have shown that CPTSD may be even more common than PTSD,¹³ and deserves specialist attention, both within services and also in the educational curricula for future psychiatrists.

Facing a culture of disbelief

The article by Waterman and colleagues avoids the scapegoating of refugees¹⁴ and the ‘denial, repression and dissociation’ of trauma that Herman identified operating on both societal and individual levels.⁵ Refugees and asylum seekers who are survivors of trauma encounter multiple challenges, which are described in the article. First, there is the trauma itself, which is known to cause ‘disintegration of experience’ and loss of narrative.⁸ Echoing Janet’s work, Herman describes how ‘people who have survived atrocities often tell their stories in a highly emotional, contradictory and fragmented manner’.⁵ Yet the processes of accessing healthcare or asylum demand that survivors tell their story repeatedly, and they are received by a ‘culture of disbelief’ and face both testimonial and hermeneutical injustice.^{2,15} Individuals who are already hypervigilant to threat must navigate health services that may share information with the Home Office, mistakenly charge them for treatment and inadvertently re-victimise them with unjust, uneducated and sometimes perverse decisions.² Psychiatrist Sandra Bloom states: ‘because of complex interactions between traumatized clients, stressed staff, pressured organizations, and a social and economic environment that is frequently hostile to the aims of recovery, our systems frequently recapitulate the very experiences that have proven to be so toxic for the people we are supposed to treat’.¹⁶

Trauma-informed and human rights-based care

Trauma-informed care can provide some framework for individuals and health services and is premised on a fundamental shift from thinking ‘What’s wrong with you?’ to ‘What happened to you?’.¹⁷ Such approaches seek to rebuild trust, create safe environments, empower and to avoid re-traumatisation.¹⁷

After reading this Praxis article I would urge trainees to familiarise themselves with the principles of trauma-informed care and to think how these might be applied in their organisations. Sweeney and colleagues’ article in *BJPsych Advances* is an extremely helpful summary.¹⁷ We must also remember that trauma does not occur only in wars or in other countries; experiences of torture and childhood adversity are all too common, as highlighted by the original study of ACEs in the USA.¹⁰ Research in the UK has found a similarly high frequency, with 47% of almost 4000 participants reporting having experienced at least one ACE.¹⁸ The pivotal works of Herman⁵ and van der Kolk¹⁹ provide a compelling, compassionate and eloquent narrative on a subject that is so often unspeakable. Practical resources and links to specialist agencies for asylum seekers and refugees can be found as an online supplement to the Praxis article.¹ Trainees may be interested to explore the various communities of healthcare professionals who advocate for human rights-based approaches to healthcare such as Medact (www.medact.org/project/migration-health), Docs Not Cops (www.docsnotcops.co.uk) and the Twitter hashtag #patientsnotpassports. Poetry and storytelling can also communicate and transform, with the potential to both educate and liberate from shame and secrecy.

British-Somali poet Warsan Shire writes in her poem ‘Home’: ‘no one leaves home unless home is the mouth of a shark. You only run for the border when you see the whole city running as well.’²⁰ I hope that Waterman and colleagues’ article offers trainees a framework for thinking about providing safe and compassionate care to asylum seekers, refugees and undocumented migrants. I thank the authors for their perseverance in bringing together complex legislation and issues of mental and physical healthcare in such a fine example of what we are seeking in Praxis articles. The article and the work of Herman, van der Kolk and the principles of trauma-informed care demand us as clinicians, as fellow humans, to bear witness and to empower survivors. We must strive to avoid re-traumatisation and rejection, despite the current hostile environment in which we live and practice.

Cate Bailey, MBBS, MRCPsych, MRes, is a Fellow in Medical Education at East London NHS Foundation Trust; an honorary clinical lecturer at Barts and the London School of Medicine; Trainees' Section Editor of the *BJPsych Bulletin*; and Co-chair of the Older Adults Section of the Association for Psychoanalytic Psychotherapy in the NHS, UK.

1.3.6 Online psychotherapy: trailblazing digital healthcare

Annabel McDonald Jessica A. Eccles Sanaz Fallahkhair Hugo D. Critchley¹

Correspondence

Abstract

Advances in digital technology have a profound impact on conventional healthcare systems. We examine the trailblazing use of online interventions to enable autonomous psychological care which can greatly enhance individual- and population-level access to services. There is strong evidence supporting online cognitive-behavioural therapy and more engaging programmes are now appearing so as to reduce user 'attrition'. The next generation of autonomous psychotherapy programmes will implement adaptive and personalised responses, moving beyond impersonalised advice on cognitive and behavioural techniques. This will be a more authentic form of psychotherapy that integrates therapy with the actual relationship experiences of the individual user.

As in many other countries, the UK is looking to expand digital technology to control burgeoning healthcare costs. These plans are articulated in recent government publications such as *The NHS Long Term Plan*.¹ The top level of this ambitious scheme refers to a system that might offer seamless care across all aspects of the National Health Service (NHS) and associated services. A second level proposes enhancing access to clinicians through digital platforms such as video conferencing channels. A third level is the ambition for broad implementation of technological monitoring services for patients in their homes, enhancing care in the community through high-quality information. However, this long-term plan also illustrates that, particularly in general medicine, the implementation of autonomous computerised treatment remains a distant goal. In mental health, by way of contrast, psychotherapy is trailblazing this field. The recent Royal College of Psychiatry recommendations accompanying the NHS long-term plan² recognise the value of extending therapist-led psychotherapies through technology, for instance by using avatars to explore client identity. However, even here there is limited recognition of progress toward autonomous psychotherapy treatments where digital treatment programmes are established NHS-approved referral options. Examples of such programmes include *FearFighter* (UK),³ *MoodGYM* (Australia; <https://moodgym.com.au/>) and *SPARX* (New Zealand; <https://www.sparx.org.nz/>). We refer to these programmes in our appraisal of current digital psychotherapy services, which we then compare with the next generation of autonomous therapies that will offer a truly individualised form of therapy, informed by the user's personal profile and experience.

Advantages associated with an online medium for psychotherapy

Online therapy offers a number of potential advantages compared with other therapies. Perhaps the most obvious are broad accessibility and low treatment cost; however therapists also refer to the fact that patients often find it a less inhibiting medium, enabling greater disclosure and interaction.⁴ There is, in addition, a belief that young patients are generally more willing to engage with digital interfaces, as explicitly noted by the team working on a gaming application in New Zealand (*SPARX*).

Accessibility

Specific groups may particularly benefit from the improved accessibility of psychotherapy when offered through an online medium. These include those in low- and middle-income countries, the financially disadvantaged individuals without access to a free health service, full-time employees, people who cannot physically visit therapists and those who are not deemed 'ill enough' to meet a threshold to be offered services. Nevertheless, accessibility would not be augmented for those who are unable to engage with a digital service due to a lack of equipment, physical constraints or poor online confidence. Such individuals are over-represented in psychologically vulnerable groups.

In low- to middle-income countries, the responses to psychotherapy for depression are high, and there does not appear to be a requirement for the therapy to be adapted to local situations.⁵ These effects appear larger than in the high-income countries; this may partly reflect less-efficacious 'standard treatments', resulting in limited improvement in comparison control groups. There is ample scope to access the online-therapy format as ownership of mobile phones has high priority in these communities: 67% of African people owned a mobile phone in 2018.⁶

In high-income countries, free provision of psychotherapy is by no means universal. Psychotherapy is a relatively expensive service, often provided on an individual basis in predefined sessions typically totalling 6–20 h. Financial costs limit access to those who can afford treatment but, even where free-to-user services exist, access tends to be rationed according to symptom severity and degree of functional impact. Thus, individuals who are functioning reasonably well, in particular those who are working, are rarely eligible for psychotherapy even if quality of life is low. An online service could reach many of those individuals who cannot afford high therapy costs, and those individuals judged to be below the arbitrary threshold of clinical severity for access to standard delivery of psychotherapy.

Physical constraints compromise engagement with multisession therapies and may have medical, social or psychological origins (e.g. physical disability, imprisonment or agoraphobia). Among mental health symptoms, Community

Mental Health Teams in the UK recognise agoraphobia and social anxiety as a common barrier to accessing and delivering therapy. However, community patients can also struggle to access psychotherapy if they are perceived as having anger problems and are implicitly judged a risk as emotionally challenging issues are explored during therapy. Large geographical areas with sparse populations can limit access to specialised psychotherapy. In Australia and New Zealand, geographical access has motivated the priority development of online psychotherapy.

Financial costs

Online psychotherapy encompasses multiple modalities and approaches, including online contact – either through a video service or texting – with a therapist. Clearly the cost of this type of treatment is broadly comparable to face-to-face therapy in well-populated areas where travel is not a major factor but it can support service access. There are also systems that offer a limited amount of personal contact with a guiding therapist while the patient works through online modules. This can take the form of ‘check-up’ phone calls through to full therapy sessions interspersed between the computerised modules. However, ‘unguided’ therapy, where the patient uses a programme autonomously without any direct or personalised therapist support, has the most potential to save significant costs. Autonomous digital psychotherapy can nevertheless incorporate automated text messages and even user forums, while retaining minimal therapist costs. This type of therapy may represent a viable ‘first-level’ care strategy, with patients progressing to therapy with personal contact if required thereafter.³ Many programmes have been shown to be effective; however sustaining patient engagement in the therapy, which can be as low as 20% by the end of a treatment programme,⁷ remains a problem. However, because such a large number of people could be treated very cheaply, the potential gain in care is still enormous, provided the online therapy does not discourage or prejudice the efficacy of any future personalised therapy.

Current online therapies

The aim of early pioneering work on online therapy was to overcome access problems caused by population dispersal. Leading developments have thus originated in Australia (e.g. *MoodGYM* and *BluePages* [<https://bluepages.anu.edu.au/>]). Similarly, in New Zealand the development of *SPARX* was driven by poor mental health across widely dispersed young people. These therapies are offered on three financial bases: charged, access paid by health services and free to access. Australian services approve the use of *MoodGYM* (free) and *MyCompass*.⁸ New Zealand nationals can use *SPARX* for free. The UK’s NHS partly funds the use of two computerised cognitive–behavioural therapy (CBT) programmes, *Beating the Blues* (<http://www.beatingtheblues.co.uk/>) and *FearFighter* (<https://magellanascent.com/Content/View/2526>), as part of their ‘stepped model’ of treatment for depression and anxiety, respectively.³

The evolution of online psychotherapy is shown in *Fig. 1*. The earliest autonomous treatments, primarily based on CBT, are interactive programmes where users complete questionnaires and white-space areas with their own information so as to develop their insight and encourage internal reflection about habitual behaviour. This is combined with examples of characters with extreme forms of behaviour to help the user recognise their own thinking and behaviour patterns. *MoodGYM* is an illustrative example of this form of online therapy. Extensive evaluation suggests *MoodGYM* promotes significant improvements in users’ mental states.^{9–13} *MoodGYM* and related programmes generally consist of five to ten CBT modules that consider key aspects such as negative thinking and activation. The path through the programme is not modified according to earlier information provided by the user. This genre has now been extended to programmes that engage the user in mindfulness and meditation. *Headspace* (<https://www.headspace.com/>) is a well-known commercial example. Here the user participates in meditation exercises, including breathing and focusing, accompanied by calming graphics. Programmes within this general category, including those based on both CBT and mindfulness, may send automated texts to the user, often as reminders to engage with the programme. There is also a subgenre that combines online therapy with intermittent therapist contact through the use of phone calls, messages or emails. *Fig. 1* Evolution of online autonomous psychotherapy (may include access to a user forum). a. https://business.talkspace.com/?_ga=2.6168373.769027487.1553093877-2135218530.1553093877 b. <https://www.helloself.com/> c. <https://www.italk.org.uk/1-2-1-treatments-groups/computerised-therapy-c-cbt/> d. https://www.online-therapy.com/about_us.php e. <https://moodgym.com.au/> f. <https://www.headspace.com/> g. <http://ccbmain.cbtprogram.com/products/fearfighter/> h. <https://www.sparx.org.nz/> i. <http://www.celestegame.com/> j. <https://www.wysa.io/meet-wysa> k. <https://www.youper.ai/about-us> CBT, cognitive–behavioural therapy.

These early forms of online psychotherapy treatment require a high level of motivation that may be challenging for people with mental health problems. Concerns about engagement have prompted the introduction of ‘gamified’ CBT resources such as *SPARX* and *Celeste* (<http://www.celestegame.com/>), where CBT techniques are embedded within an intrinsically entertaining experience. *SPARX* offers self-help for young New Zealanders by being set within such a video-gaming framework. The user selects an avatar to fulfil a number of tasks, which include challenges such as bursting floating bubbles called GNATS (gloomy negative automatic thoughts) with a staff, while receiving CBT-based wisdom from a guiding character who draws links to behaviour in the user’s own life. *Celeste* is an even more traditional game which has drawn acclaim from video-game forums. *Celeste* centres on a nervous character who ‘learns’ to modify anxiety through CBT techniques that include breathing- and meditation-style tasks. These programmes may herald a new genre in which online virtual worlds combine gaming with the mutual support of internet forums.¹⁴ *Autcraft* (<https://www.autcraft.com/>) is another notable example of an early development of this format; it is packaged as a ‘limited edition’ of Minecraft which offers a kinder and more protected environment for autistic users to build confidence and practice social interaction. There is, however, a tension within such gamified applications in balancing the need to provide therapy while maintaining the unbroken flow of a game.

Not unrelated to interactive gamified therapy is the increasing presence of ‘chatbot’ forms of therapy. The programme is set within a machine-messaging environment and so is able to ‘chat’ to the user. These programmes, of which *Wysa* (<https://www.wysa.io/meet-wysa>) is a very good example, tend to deliver CBT, mindfulness and meditation. User are free to move between the encouraging and supportive online machine ‘conversations’ and subunits engaging them in direct psychotherapy. These programmes store information about the user, including their current state of mind, and use this information within the ongoing conversation. An example of this would be a comment such as ‘You said that you felt low yesterday, are you feeling a bit better today?’

The next stage in the evolution of autonomous online therapy is likely to involve a significant extension of the collection of user information and increased ‘tailoring’ of programme responses to the user’s behaviour and relationship experiences (*Fig. 1*). This would move online care beyond CBT-style interventions and start to offer a relational form of therapy, through which the user can develop a deeper insight into his/her own relationship styles, their aetiology and potential means of escaping negative patterns of behaviour.

Existing internet forums can offer mutual support for those with psychological distress or more specific mental health problems. They are sometimes suggested or offered as adjuncts to the types of digital therapy programmes described above. The use of such forums may or may not be free and are generally moderated. Examples include *Mood Garden* (<http://www.moodgarden.org/>) and *Big White Wall* (<https://www.bigwhitewall.com/v2/Home.aspx?ReturnUrl=%2f>), the latter of which has trained staff online on a 24-h basis.

Evidence base for online therapies

Research into online therapies reveals two important aspects: (1) improvement of psychological state, and (2) the degree of engagement demonstrated by users (Supplementary Table 1 available at <https://doi.org/10.1192/bjb.2019.66>). Perhaps unsurprisingly in view of the heterogeneity of studies, a wide range of results are shown for both of these measures across the different online programmes. The selection of participants is also a factor, which may depend upon unsolicited clicks on a website through to targeted selection of a specific patient group. Many studies include brief phone or text contact to encourage engagement.

Online CBT programmes have been the main source of evidence for efficacy of digital therapies. However, examination of bias-modification programmes for anxiety reveals weak effects of borderline significance (observed effect sizes, 0.07–0.42).⁸ In contrast, for a mindfulness programme aimed at patients with established bipolar disorder, a significant change is observed with an effect size of 0.52 on an intention-to-treat basis. Nevertheless, the attrition rate was 38%.¹⁵

There is a paucity of published evidence on those users who begin online CBT therapy independently through search engines or clinical recommendations. One informative exception is data on the use of the modular CBT programme *MoodGYM*. Only around 25% of arrivals proceeded from the initial introductory module through to a second module. Moreover, the maximum observed pre-post effect size was 0.4.^{7,9} Notably, around 50% of those enrolling on such programmes fulfil clinical criteria for depression.

Thus the majority of research into effectiveness examines the effects of CBT programmes on preselected clinical populations. Here, the typical pre-post effect size is 0.5–0.8^{8,13,16,17} with variation between individual studies. The effect size drops when a comparison group – typically a treatment-as-usual or waiting-list group – is included, negating statistical group differences in a subset of studies. On average, the effect size is typically reduced to around 0.4,^{13,17,18} which represents a low to moderate treatment effect. This suggests that part of the pre-post effect is a natural recovery cycle from psychological distress, a view also supported by mixed findings as to whether recovery is enhanced by an increased engagement with the digital programme. No association was found between reliable clinical improvement and either the (extended) duration of engagement with an online programme¹⁸ or the number of therapy modules offered,⁷ although other studies do report increasing therapeutic benefit in association with longer therapy engagement.¹⁹

Engagement is generally poor, with high rates of attrition among user of online therapies. A true meta-analysis of these data is impossible given the range of measures across studies (including full programme completion, minimum ‘adequate’ number of therapy sessions, average percentage of completed modules, percentage of participants progressing to second module or percentage completing half of the modules). However, data for full completion or adequate engagement show a wide range, e.g. 16–82% for completion. A ‘typical’ value appears to be around 50% for the completion of half of the modules.^{12,13,17,18,20–25}

The degree of engagement with online therapy is likely to reflect the variety of programmes, the range of indications or whether users were contacted (e.g. brief emails or text) to encourage adherence. Some of the factors that affect therapy engagement have been studied; for example observed higher levels of therapy adherence are reported in people with lower baseline symptoms.¹⁹ Although other studies have not found associations between engagement and symptom severity or improvement.¹⁸ Among social factors, adherence is reported to be higher among users who are white and older.²³ A meta-analysis also found engagement is better in females, individuals with higher educational attainment and in older users. Comorbid anxiety symptoms appear to introduce an additional challenge to adherence.²⁶

Forms of additional support for online therapy

A number of ‘add-ons’ have been introduced to stand-alone online therapy programmes, generally with the aim of reducing attrition. These include brief contact with therapists or allied health staff by phone or text. The use of weekly phone calls seems to be a particularly popular approach during treatment trials with the aim of increasing engagement. The number of therapy modules, out of ten, that were completed increases from when a user has no contact, to a weekly email to a weekly phone call (3.7, 5.5 and 7.3 modules, respectively).²⁴ A related approach is the use of automated reminder emails. Interestingly, better results appear to be achieved when the automated email informs the user about new site content, rather than simply reminding them to return to the programme. Moreover, email reminders are more effective when sent after 2 weeks of absence than when the user had been absent for 4 or 6 weeks.²⁷

An alternative add-on is membership of a social forum with other users, noted above to be a potentially valuable adjunct to a bipolar disorder mindfulness programme.¹⁵ Although the addition of a forum generally requires staffing in the form of moderation, peer support can improve adherence to psychoeducation modules.²⁸ Forum membership is reported to provide an impetus to ‘keep going’ in a qualitative study of a CBT sleep improvement programme. Here, users offered each other support during difficult parts of the programme.²⁹ Reported reasons for involvement with the forum were a desire to connect with peers, receive personalised advice, curiosity, being invited and wanting to use all sleep improvement tools. Reasons given for not joining the forum include design problems, negative self-comparisons, excessive time commitment, data privacy concerns and the uncertain quality of user-generated content. A user forum linked to an online CBT programme for individuals receiving prostate cancer treatment failed to show any improvement in CBT programme completion.³⁰

Online therapy: strengths, weaknesses and potential concerns

As previously discussed, there are concerns about the high attrition rate in the use of online therapy programmes and the small-to-moderate effect size when compared with other groups such as those on the waiting list or receiving treatment as usual. Expectation management should thus form an integral part of such programmes.³¹ One potentially compensating effect at the service level is the low cost of massive open online interventions. When the cost of minor improvement is minimal and the number of patients receiving treatment is so large, there is a large resulting gain in psychological health. Related to this is the advantage, highlighted above, afforded by an increased accessibility of treatments that no longer need to be time limited.

Online therapy is likely to be most appropriate as an early phase in a stepped treatment plan.^{3,13} A potentially worrying aspect of online therapy is whether it might have a negative impact on acceptance/receptivity to face-to-face therapy. Interestingly, enthusiasm for personal CBT may be increased among individuals receiving online treatment when compared with the provision of only psychoeducational information about depression,³² or there may be no observable effect on face-to-face treatment.³³ Some users of course may become ‘well enough’ that they do not feel in need of the further improvement that could occur through subsequent face-to-face therapy.³⁴ This is an odd reversal of the potential gain of online therapy improving the condition of those not considered ill enough to require face-to-face therapy.

It is also important to consider whether other harmful effects might result from engaging in online psychotherapy. Higher rates of clinical deterioration occur in patients receiving watchful waiting (7.2%) than those receiving online CBT (5.8%).³⁵ Feedback from those who completed a mindfulness programme saw 15 users denying any issues whereas 1 had been uncomfortable during a 30-min exercise (body scan) as it reawakened a traumatic memory.¹⁵ This potentially supports the concern that re-traumatisation might occur with increased vulnerability due to the reduction of psychological defences. A less direct form of harm to a user might occur if online responses could be subject to subpoena.³⁴

There are potential concerns that high-risk individuals may not be identified during online therapy. Questions have been raised as to whether it should be possible, or ethical, to trace individuals directly if worrying information is declared while using the programme. Coupled telephone help services are provided for users of some programmes such as *SPARX*. Other programmes rely on the presentation of emergency contact details in a more generic form, for example advising users to contact local mental health services or helplines. Similar issues have long been recognised with respect to self-help manuals, whether they are presented as literature or online. Online therapies have more opportunity to provide support through ‘help’ buttons or facilities to put the user in immediate contact with personal support by phone, email or messaging. An as-yet-unresolved issue relates to the international nature of the internet that makes it difficult to establish the jurisdiction under which the programme is being operated,³⁴ and consequently how users might seek redress for grievances.

The next generation

All of the psychotherapy programmes discussed above share a critical limitation. They do not adapt to the behaviour and relationship styles of the individual user. They set out to treat a ‘typical psychology patient’ and supply information that is known to be widely helpful in developing a healthier self-narrative. Thus *MoodGYM* encourages the user to understand the concept of ‘warpy thoughts’, which are related to automatic negative assumptions. *MoodGYM* illustrates this principal with tales of the experiences of programme characters with varying mental states. The user is then invited to reflect on circumstances in their own life when they react in this automatic negative manner. There is no feedback or onward development of these personal experiences by the programme. Similarly, *SPARX* encourages the user’s avatar to destroy pictorial bubbles or GNATs, then further expands on how these types of thoughts are expressed in ‘real life’. But again, the information is not specific to the user’s experiences in any manner. The chatbot programmes provide generic information for problems suggested during the chat conversation.

The limited dynamic personalisation makes it very difficult to move beyond meditation- and CBT-type programmes toward more relational forms of psychotherapy that are critically dependent on personal interactions both inside and outside the therapy room. Nevertheless, there is no inherent reason why such relationships cannot be explored online with personalised responses. The programming of such a functionality within a digital therapy is inherently more complex, requiring a wider range of outcomes, depending on the user’s inputs. The implementation of such levels

of complexity within online psychotherapy programmes is ongoing and is anticipated to lead to truly personalised therapies. This key development will presage the arrival of the next generation of autonomous online psychotherapy programmes.

Future directions

We are at an exciting phase in the development of autonomous online psychotherapy services. Increasingly, programmes are aiming to move from being informative to entertaining. The advent of programmes such as *SPARX* and *Celeste* as well as the protected virtual reality of *Autcraft* show how developers now attempt to offer integral enjoyment to facilitate the therapeutic process. This is a promising solution to the problem of high attrition observed in today's more 'instructional' programmes, despite their excellent therapeutic value for those individuals motivated enough to work through the programme. We now anticipate another generation of autonomous online psychotherapy where programmes will become responsive to the circumstances of the individual user and offer an agile, adaptive environment in which the user should feel more personally engaged with the process.

It might be intuitively strange to think about psychotherapy, a highly relational form of medical treatment, being in the forefront of autonomous digital care. Perhaps this can be explained by the fact that we are often seeking to treat the unfortunate effects of earlier interactions with others. Themed interaction with another's mind, through an internet programme, offers a fresh framework through which earlier negative experiences might be reconsidered, reappraised and restructured for future well-being. Ultimately, the future of autonomous digital psychotherapy is not about communication with a computer, but with the body of knowledge established through evidence-based practice and its dynamic tailoring to personal need.

Abstract

Identifying the causes of psychiatric and physical symptoms in asylum seekers, refugees and other migrants and making definitive diagnoses can be challenging. Ethical and legal challenges in the UK include the likely deterrent effects of upfront charging for National Health Service (NHS) services. This paper focuses on the fictitious case of an asylum seeker presenting to a mental health service in England, highlighting some of the difficulties in assessing and treating this patient group and providing advice to clinicians on clinical and practical management. Current NHS entitlements for migrants are summarised and a list is presented in the online supplement of non-governmental organisations that can provide further support.

Clinical scenario

You are a psychiatry trainee at an inner-city ‘place of safety’ unit in England. You have been called to see Mr S.T., a 30-year-old Tamil asylum seeker from Sri Lanka, who has been brought in at 22.00 h by police. He is reported to be ‘responding to voices’ and to have collapsed twice, apparently losing consciousness. S.T. speaks minimal English and the Tamil telephone interpreter does not appear to be translating everything he is saying. Furthermore, S.T.’s ability to use the telephone service is limited owing to his distractibility and apparent guardedness towards the interpreter.

S.T. had claimed asylum on arrival at the UK border in 2015. He describes having fled Sri Lanka, where he had been detained and tortured for many months. However, his asylum claim was refused a month ago because of inconsistencies in his account. He was then evicted from accommodation provided by the Home Office and has since been street homeless. The timeline is difficult to establish and his story is not fully coherent.

S.T. states that since his traumatic experiences he has been experiencing frequent visual and auditory hallucinations, mood swings and ‘jumpiness’ whenever there is a loud noise. He avoids being close to anyone wearing a uniform and prefers being alone. He has not had a physical health check since arrival in the UK 4 years ago. He explains that initially he was unaware of how the medical services worked or what he was entitled to. Since his asylum refusal he has been feeling intermittently dizzy and has experienced several episodes of collapse, about which he can remember little. He recently tried to register with a general practitioner (GP); however, the GP practice refused to take him on because he had no proof of address. S.T. stopped trying as he became fearful that the GP would forward his whereabouts to the Home Office and that he would then be sent back to Sri Lanka, where he believes his life would be in danger.

After carrying out an initial assessment, you are uncertain whether there might be an underlying organic cause to S.T.’s presentation, as he has not had any previous medical investigations in the UK. You also feel that he would benefit from a period of in-patient assessment to further clarify the diagnosis and risk. Furthermore, because he is street homeless there is no safe place to discharge him to. He is consenting to in-patient admission but has no funds to pay for National Health Service (NHS) secondary care and you are unsure what NHS care he would be eligible for. The key questions raised by this case are presented in *Box 1*. **Box 1** Key questions •What is this person’s most likely diagnosis?•What are the possible causes of his physical symptoms?•What NHS treatment is he eligible for?•What management would you provide?•What political and social issues may you need to consider?

Assessment, differential diagnosis and formulation

Could there be a non-psychiatric cause for S.T.’s physical symptoms?

Many migrants are not registered with a GP, for reasons described below. It is therefore common to encounter someone such as S.T. who, despite being at high risk for physical and mental illness, has not previously accessed healthcare since arrival in the UK and may have multiple undiagnosed and untreated illnesses. This adds significant complexity to the diagnostic assessment as, although asylum seekers are more likely to have physical symptoms as a result of psychological trauma, they may also have undiagnosed physical illnesses and physical injuries as a result of torture. It is therefore vital to complete a full physical health workup, including screening for tuberculosis and sexually transmitted infections where indicated, in order to identify and treat medical conditions. Extra care should be taken during physical examinations to avoid retraumatizing the patient.

Dizziness and collapse are important features of S.T.’s presentation. Not only does he find these episodes distressing but his lack of awareness during the episodes renders him vulnerable to injury, exploitation and violence. When assessing patients who are in severe distress it is important to be mindful of the potential for diagnostic overshadowing and vital to identify possible medical causes for these episodes. These could include epilepsy, non-epileptic attack disorder, hypoglycaemia, dehydration and vasovagal syncope (fainting), and potentially substance misuse. If a neurological cause is suspected, referral to neurology may be indicated. Epilepsy is often difficult to distinguish from non-epileptic seizures and the two may both occur in the same individual. Important causes of non-epileptic seizures (particularly in people who have been severely traumatised) include panic attacks and dissociative episodes.¹ Panic attacks are usually rapid but not immediate in onset and are associated with prominent autonomic symptoms such as palpitations, shortness of breath and tingling in the extremities. Dissociation is a psychological defence mechanism manifested as a perceived detachment of the mind from the emotional state and the body. It often occurs in the aftermath of severe trauma and

may be triggered by reminders of the trauma. In our clinical experience, episodes of dissociative ‘unconsciousness’ are particularly common in people who have been subjected to sexual trauma and who have an overwhelming sense of shame and revulsion about what has been done to them.

A detailed history, including a collateral history (where possible), neurological examination and simple investigations (such as blood sugar and blood pressure, both during and after the episode) can be helpful to distinguish between these causes.

Psychotic phenomena in PTSD: a diagnostic challenge

S.T. was reported to be ‘responding to voices’. This might initially be thought to indicate a primary psychotic illness such as schizophrenia. However, it is also important to consider whether the voices might be a manifestation of post-traumatic stress disorder (PTSD). In PTSD, individuals may hear voices as part of a flashback to past traumatic events. Flashbacks may be triggered by reminders of the trauma or stressful situations and could therefore be intensified when the person encounters uniformed officers or is placed in a confined space (such as in hospital). Victims may find it difficult to distinguish these vivid phenomena from reality and may respond to them.

Ways in which flashbacks can be differentiated from primary psychotic experiences include: by their close relationship to the past traumatic experiences; by their transience; and by the preservation of some degree of insight. However, many experts believe that some people with PTSD also have more generalised psychotic experiences which are best understood as part of the PTSD process. This has been termed ‘PTSD with secondary psychotic features’.² A history of trauma is also common in people with psychosis. Therefore, it can be challenging to make a differential diagnosis of a psychotic illness in someone with comorbid symptoms of PTSD and it is common for clinicians to disagree on the primary diagnosis.

Distinguishing complex PTSD from PTSD and emotionally unstable personality disorder

Complex post-traumatic stress disorder (complex PTSD) is a new diagnosis included in the forthcoming ICD-11.³ Complex PTSD is more likely to develop following exposure to prolonged or repeated traumatic events from which escape is difficult (such as torture, slavery, human trafficking, prolonged domestic violence and repeated childhood abuse), whereas PTSD tends to develop following isolated traumatic events.⁴ Complex PTSD is also more likely to develop following interpersonal trauma than following events such as a road-traffic accident.⁴ Complex PTSD shares the same core features of PTSD (exposure to a threatening or horrific event, re-experiencing of the traumatic event, avoidance of traumatic reminders, sense of current threat and interference with functioning) but includes three additional features, all of which must be present for the diagnosis to be made. These are: interpersonal disturbances, affect dysregulation and a persistent negative self-concept. These additional features are believed to result from the degradation of the person’s self-identity and autonomy. Functional impairment tends to be worse in complex PTSD than in PTSD, and standard PTSD treatment may be less effective.⁴

It can sometimes be challenging to distinguish between complex PTSD and PTSD with comorbid emotionally unstable personality disorder (EUPD), since complex PTSD and EUPD may both stem from trauma in early life and share disturbances in affect regulation, self-image and interpersonal relationships. Although a pertinent feature of personality disorders is that, by definition, they develop in childhood, it can be particularly difficult to differentiate the disorders in someone who has experienced traumas at an early age or for whom we know little about their premorbid personality, like our patient S.T. However, there are some key differences: in EUPD, the person’s self-image and interpersonal relationships tend to be unstable, whereas in complex PTSD the person is more likely to avoid relationships and have a persistently negative self-image.⁵

Cultural idioms of distress

It is important to consider cultural idioms of distress when assessing patients from different backgrounds. For example, perceptual disturbances such as hearing voices might have a different significance or meaning to that assumed in a Western medical model. As with any symptom, asking the patient what it means to them is often illuminating. The section on cultural formulation in DSM-5 has some useful questions in this regard.⁶

A challenge for assessment: memory deficits are common following trauma

Trauma and its associated disorders, including PTSD and depression, are associated with relative deficits in autobiographical memory retrieval,^{7,8} and there is evidence that other aspects of memory may also be affected.⁹ As a result, asylum seekers who have experienced trauma may tell a story that is convoluted and has an inconsistent timeline, which can make eliciting a clear history challenging. It is often helpful to check back frequently with the patient to make sure that you have understood correctly and to reflect with the patient on elements of the account that you find inconsistent or incomprehensible. The process of recounting may be distressing for the patient; thus, breaks may need to be taken and it is often not feasible to elicit a full account in a single session.

Of note, it is therefore possible that S.T.'s poor memory had affected his asylum claim, since an inconsistent story or inability to recall specific memories is often considered by immigration systems to indicate poor credibility, despite this link between trauma and memory deficit.¹⁰

Decompensation since refusal of the asylum claim

S.T.'s mental health worsened following the refusal of his asylum claim. This is not surprising, since such refusals are often associated with being discredited and disbelieved and with the threat of imminent removal to a place where the individual believes themselves to be unsafe. Refusal of an asylum claim is also often associated with loss of accommodation and financial support. Even for those who are currently awaiting a decision, the research evidence indicates that prolonged immigration uncertainty is associated with a deterioration in mental health.¹¹

Many asylum seekers' claims are refused because of inadequate legal representation and/or lack of evidence to support their claim. These individuals may present in crisis and healthcare professionals are often unsure how to help people with such a precarious socio-legal situation. A number of useful charities that provide psychological, social and/or legal support are listed in online supplement 1 (available at <https://doi.org/10.1192/bjb.2019.67>).

Eligibility for treatment from NHS primary care, in-patient and community mental health services, and common access barriers

Is it important to note that it is not your job as a clinician to make decisions about who should receive NHS treatment free of charge. This responsibility lies with the NHS trust. According to General Medical Council guidance, the clinician's primary duty is to treat the patient. However, you may be asked by your NHS trust about the clinical urgency of providing treatment for patients who the trust has deemed otherwise 'ineligible' for free treatment (as highlighted below). Additionally, it is important to be aware of the eligibility for NHS services of different migrant groups so that, in making your management plan, you have an idea of potential barriers to access for these patients and can advocate for them as necessary.

Access and barriers to treatment in general practice

Eligibility for primary healthcare

According to guidance issued by NHS England in November 2015, anyone in England can register with a GP and receive GP services without charge and ‘GP practices are not required to request any proof of identity or of immigration status from patients wishing to register’.¹²

Barriers to registering with a GP

GP practices often mistakenly believe that prospective patients need to provide proof of address and residency, even though that is not legally required. This can result in vulnerable migrants being turned away. For example, of 1717 migrants who approached a charity following difficulties registering with a GP, 20% were still wrongly refused GP access even when supported by a charity case worker.¹³ Some GP practices register migrants as temporary patients,¹⁴ even though they are eligible to be registered as permanent. Migrants such as S.T. may not have a fixed address or may not have access to identity documents or proof of address.

Data protection and confidentiality issues

An additional barrier is that refused asylum seekers and undocumented migrants may be afraid to give personal details to a GP practice in case these details are accessed by the Home Office, which could in turn lead them to be arrested, detained and/or deported. Some try to get around this by registering using an alias.¹⁵ Their fears are well-founded. Non-clinical information about patients may be disclosed to the Home Office by NHS services in certain situations, such as if a patient who is ineligible for free treatment does not pay their treatment bill within 2 months. Their debt to the NHS may also affect their future immigration applications.¹² Previously, a memorandum of understanding (MoU) stated that NHS Digital could also disclose confidential patient information to the Home Office for the purpose of assisting immigration enforcement.¹⁶ However, this MoU was withdrawn for amendment in May 2018 and it has not yet been re-released.¹² At the time of writing, it is unclear how confidential information will be shared with the Home Office in the near future.

Access and barriers to treatment in secondary care (including community mental healthcare) and in-patient services

Asylum seekers, refugees and victims of torture are exempt from NHS charges across all services

All NHS services in England are currently free of charge for asylum seekers (those who have claimed asylum in the UK and are awaiting a decision from the Home Office), those with a rejected asylum/human rights application but who have officially appealed their rejected claim, refugees (those whose asylum claim has been approved) and suspected victims of human trafficking, among a number of other categories.¹² Also, refused asylum seekers can continue, free of charge, with any course of treatment already underway before their application was refused.¹² Additionally, a category of NHS services that is currently free of charge irrespective of immigration status is ‘services for the treatment of a physical or mental condition caused by torture, female genital mutilation, domestic violence, or sexual violence’,¹² which would apply to S.T., whose reported history of undergoing torture may have contributed to his current illness.

However, for those belonging to these exempt categories, the lack of clarity and misinformation about who is eligible for free care has had a deterrent effect and made many vulnerable individuals reluctant to present to services. These individuals often have complex legal situations or are unable to provide the documents requested. Furthermore, administrative staff rarely receive sufficient training in immigration law to adequately determine eligibility for care.¹⁷

New upfront eligibility checks and upfront charging regulations

Following new government regulations introduced in October 2017, all hospital departments in England are legally required to check patients' eligibility for free NHS healthcare. If a patient is unable to prove that they are exempt from charges, they are required to pay upfront in full before receiving any treatment.¹⁸ This requirement has now been extended to all NHS community health organisations, including community mental health services.¹⁹ If a patient cannot prove that they are entitled to free care, they have to pay the estimated price for their treatment upfront, unless it is considered 'urgent' or 'immediately necessary'. Doctors will have to review each case to decide whether care is 'immediately necessary' or 'urgent': if it is deemed immediately necessary/urgent, treatment can be offered and the patient will be charged later; however, any treatment deemed non-urgent can be refused until the patient is able to pay upfront.²⁰ However, this does not apply to GP care, which is currently free to all, as described above.

The effects of upfront charging

Even though the treatment needed is often deemed immediately necessary or urgent, the worry about being charged upfront can deter vulnerable patients from seeking help. A recent analysis of case notes from a Doctors of the World clinic found that 46 patients (over a third of all chargeable cases) had delayed seeking necessary healthcare owing to concerns related to charging, including concerns that their information would be shared with the Home Office.²⁰ A number of the UK's medical Royal Colleges have released statements about the upfront charging policy, warning of its risks.²¹

What is 'urgent' or 'immediately necessary' treatment?

There is a lack of clarity from NHS England about what constitutes 'immediately necessary' or 'urgent' treatment, resulting in confusion and inconsistency between and within services. 'Immediately necessary' is usually taken to signify treatment that is life-saving or is needed immediately to prevent a condition from becoming either damaging to the person or life-threatening. Urgent treatment is usually taken to signify treatment that, owing to pain, disability or the risk of the condition worsening without treatment, cannot wait until the person returns to their country of residence (it is usually expected that an undocumented migrant will not return to their home country for at least 6 months).²² Treatment is deemed 'non-urgent' if 'it can wait until the patient can reasonably be expected to return to their country of residence'.¹² Many clinicians and healthcare providers believe that the vast majority of healthcare treatment can be legitimately considered to be at least 'urgent', given that most physical and mental health conditions could deteriorate without timely treatment.

Treatment under the Mental Health Act and Mental Capacity Act

Those who are detained and/or treated under the Mental Health Act 1983 or Mental Capacity Act 2005 are also exempt from charges for treatment.¹² Therefore, S.T. would not be charged for his treatment if we decide to detain him.

What treatment would S.T. be eligible for without charge?

S.T. is consenting to an informal admission and would not be appropriate for community treatment (as he is street homeless). However, would he be eligible for an informal in-patient admission without charge?

S.T. is not currently legally classified as an asylum seeker as his asylum claim has been rejected and he has not yet launched an appeal. However, it could be argued that he still would be eligible for free voluntary psychiatric treatment, both as an in-patient and in the community, as a victim of torture.

Regardless, he should be eligible for voluntary psychiatric treatment (as an in-patient and in the community) without being charged upfront, on the grounds that the medical team consider his treatment to be 'immediately necessary' or 'urgent'. If he does receive treatment on this basis, it is important to note that he would still get a bill for this after his

treatment and, if he is unable to pay that bill, his details could be shared with the Home Office, putting him at risk of being detained or deported.

It is vital that this eligibility is clearly explained to him so that he does not become confused and frightened when the hospital conducts its compulsory eligibility checks.

How about if he were in Scotland, Wales or Northern Ireland?

The above guidelines only apply to NHS England. Separate guidelines apply to Scotland²³, Wales²⁴ and Northern Ireland.²⁵ In Northern Ireland, the eligibility guidelines are similar to in the UK. Key differences are that in Northern Ireland not all migrants are eligible for free GP care, and refused asylum seekers who have had their asylum claim refused since 2015 have the same entitlements as any other ordinary resident. Undocumented migrants (who do not meet the other exception criteria, such as being a victim of human trafficking) are liable to be charged for GP, inpatient and secondary care, but are not charged for A&E treatment, compulsory detention in hospital or treatment for some infectious diseases and HIV.²⁵ In Scotland and Wales, asylum seekers and refused asylum seekers are entitled to free primary and secondary healthcare on the same terms as any other ordinary resident.^{23,24} Please see the relevant guidance for further information.

Management of S.T.'s case

Which treatments are effective for someone in such a precarious social situation?

In an acute situation such as S.T.'s, the priority should be to allow the patient to feel as safe and comfortable as possible. Measures should be taken to provide a quiet and private space in which to talk to the patient. Short-term use of benzodiazepines should be (cautiously) considered if the patient is acutely agitated or anxious. If in-patient admission is thought to be indicated, clinicians should be mindful of how an acute in-patient psychiatric ward could be distressing for someone with a history of trauma.

Regarding longer-term management options for S.T., psychological treatments appear to have the greatest benefit in reducing PTSD symptoms.²⁶ For example, there is robust evidence supporting the use of narrative exposure therapy (NET).²⁷ Although a sense of safety is often considered to be a prerequisite for psychological therapies to be effective, NET (which was developed for use in conflict zones) may be beneficial even for patients whose immigration status and social circumstances remain unstable. The humanising effect of having someone trusted to talk to regularly, in a safe space and without judgement, can be an especially helpful aspect of talking therapies. There is emerging evidence to suggest that arts-based therapies can be effective for those who find it more difficult to express themselves verbally about their trauma.²⁸

Psychotropic medication can also be used to treat PTSD-related symptoms. Antidepressants can be helpful in treating depressive symptoms in people who have been severely traumatised: mirtazapine is often used because of its hypnotic effect. Antipsychotic medication (such as quetiapine, which is widely used) can be of benefit, particularly in the context of vivid flashbacks or hallucinations or in the management of persistent anxiety and agitation.²⁹

Practicalities and primary needs

S.T. has been made street homeless since the refusal of his asylum claim. This will also have implications for discharge planning if he is admitted to a psychiatric hospital for treatment. It is important to carry out a comprehensive needs and risks assessment as soon as possible and to generate a care plan in which these needs are prioritised appropriately.

If S.T. launches an appeal against his asylum application rejection, he would become eligible for support such as accommodation and certain other benefits; therefore, providing him with information on non-governmental organisations (NGOs) that provide legal advice may be a priority. A number of NGOs also support asylum seekers by providing therapeutic services, English language courses, social inclusion projects, housing and general ad-

vice. For example, NACCOM provides a useful list of charities/services that help destitute migrants across the UK (<https://naccom.org.uk/projects/>). Further information on some of these NGOs is given in online supplement 1.

Online supplement 2 gives advice on working with and assessing capacity via interpreters, which might help in further assessment of S.T.

It is also important to consider that, even if S.T. has a telephone, he might not have credit with which to make outgoing calls.

Suggested management plan for S.T.

- Informal psychiatric admission for further assessment and formulation
- Obtain collateral history from friends or relatives if possible (and if S.T. consents to this)
- Thorough physical assessment to identify and treat any non-psychiatric illnesses
- Early and proactive assessment of spectrum of needs: including prioritising housing, finances and referral to relevant charities for psychosocial and legal support
- Consideration of short-term use of benzodiazepines if highly agitated
- Consideration of anti-depressant and/or antipsychotic medication
- Referral for talking therapy with a trauma focus (if available locally or via a charity)

Conclusions

Diagnosing the causes of psychiatric and physical symptoms in asylum seekers and torture victims and making definitive diagnoses can be challenging. It is often difficult to determine whether psychotic symptoms in this group of patients relate to a primary psychotic disorder or to PTSD; and a new diagnosis of complex PTSD in ICD-11 adds to the pool of diagnostic options. Psychological distress is a common aetiological factor in physical symptoms such as dizziness and chronic pain. However, medical causes should not be excluded without sufficient physical health assessment as migrants may also have undiagnosed and untreated physical illness because of difficulty in accessing medical care.

S.T., the patient discussed in this paper, is fictitious and his case study was constructed to depict a realistic scenario based on our clinical experience of working with refugees and asylum seekers. Although his case may appear to be a particularly complex one, it is very common for migrants to encounter many of the barriers to accessing healthcare highlighted here. This can be very stressful for the healthcare team involved, especially if they are unclear about the frequently changing healthcare access requirements. Charities such as the Health Foundation, Doctors of the World, Medical Justice, Freedom from Torture, Medact and the Helen Bamber Foundation regularly release updated guidance that can be helpful.

There remain many ethical and legal issues that need addressing nationally, including the sharing of patient data between NHS services and the Home Office and the likely deterrent effects of upfront charging for NHS services. An urgent assessment is needed into the impact on vulnerable groups of extending charging into NHS community services. There is often confusion for both patients and healthcare staff about eligibility for free NHS care. This can result in patients who are eligible for free healthcare being denied this care, disengaging from healthcare services or not seeking care in the first place.

We thank R.M., our patient contributor, for her useful reflections on this case. She particularly emphasised how difficult it is for asylum seekers to tell an autobiographical story and the effects of prolonged immigration uncertainty on mental health.

1.3.8 The clinical fellows project: emergence of the FY3 year?

Anirban Raha Robert Heminway

date

2020-04

Contents

- *The clinical fellows project: emergence of the FY3 year?*

Since August 2017, Sheffield Health and Social Care have begun providing a new non-training post in psychiatry. This was done with multiple aims, including attempting to increase the uptake of core psychiatry training jobs in South Yorkshire by giving a positive experience of working in a psychiatric setting and improving local clinical care with an increase in the number of doctors working at SHO/CT1 level. The non-training posts were described as clinical fellowships and were open to doctors who had not yet undertaken higher training in psychiatry.

We, Drs Raha and Heminway, were among the first people to take up these clinical fellowship posts and were therefore in a prime position to review how the project is being received and some of its outcomes. Since August 2017, 15 clinical fellows have been recruited, largely in the 'FY3 gap' but with some coming from general practitioner (GP) training. Dr Raha entered after having been a GP trainee and Dr Heminway from a post-foundation training break.

The clinical fellowship consists of a non-training junior doctor post, working at FY2/CT1-equivalent level in psychiatry. A number of rotational placements were created, including those based in general adult, older adult and addiction psychiatry, across both community and in-patient settings. A key benefit that was felt by the clinical fellows was that there were additional training opportunities given – a split of 80% clinical to 20% non-clinical time allowance, access to weekly continuing professional development (CPD) sessions, weekly supervision with a consultant psychiatrist and attending the core psychiatry training course for MRCPsych examinations. Clinical fellows have also since set up their own peer group to improve CPD and training opportunities for future clinical fellows.

The experience has been invaluable, not just for ourselves but also for other clinical fellows involved in the project; this has been borne out by the increasing uptake of core psychiatry training posts by the clinical fellows. Of the 2017–2018 cohort, half entered core psychiatry training, one entered GP training and one left owing to long-term sickness. Half the 2018–2019 cohort were also considering entering psychiatric training at the end of the clinical fellowship posting.

The culmination of this experience was the opportunity to present this project at the Choose Psychiatry meeting of the Royal College of Psychiatrists earlier this year. It was well received, owing to the fact that it was both improving access to psychiatry and improving junior doctors' opinion of psychiatric training and work (including those leaving the post to take up GP jobs). It was also highlighted that many junior doctors are no longer entering core training directly after foundation training. This clinical fellowship has therefore been an excellent way to accommodate this trend and provide a springboard for increasing access to and awareness of psychiatric training.

1.3.9 Authors' reply

Rachel Gibbons Fiona Brand Anne Carbonnier Alison Croft Karen Lascelles Gislene Wolfart Keith Hawton

date

2020-04

Contents

- *Authors' reply*

Authors' reply: We are grateful for Professor Morgan's engagement with our paper,¹ and that we have stimulated debate in this important area. We do, however, feel it necessary to respond to two fundamental misinterpretations of our discussion about the predictability and preventability of suicide.

First, the letter states that we were asserting there is 'no evidence that suicide risk assessment in clinical practice can usefully guide clinical decision-making', whereas we actually said that our ability to predict patients at the highest level of risk is limited and that despite the ubiquity of advice to use suicide risk assessment in clinical practice, the positive predictive value is low and there is no evidence that these assessments can usefully guide decision-making.

Second, Prof. Morgan asserts that we were advocating 'ignoring the value of suicide ideation', which was not indicated at any point in the paper.

Suicidal thoughts are very common; however, completed suicide is rare. The process that leads any individual to take their life is often poorly understood. Given this, identifying the specific individuals most likely to die by suicide is a very a challenging task. An overly high personal and systemic expectation of a clinician's capacity to predict suicide in any individual case is unreasonable and can lead to increased feelings of distress and blame following a death. The distorted focus on psychiatrists' role to prevent suicide obfuscates their important role in working to alleviate mental pain, encourage recovery and improve quality of life.

We strongly advocate dynamic formulation of risk as part of clinical care but question an over-reliance on risk assessment tools that have little or no face validity. There is now a general consensus^{3,4,5} that these tools do not predict likelihood of suicide. Indeed, the National Institute for Health and Care Excellence guideline on self-harm from 2011, based on reviewing evidence, states: 'Do not use risk assessment tools and scales to predict future suicide or repetition of self-harm', nor 'to determine who should and should not be offered treatment or who should be discharged'.⁶

We agree with Prof. Morgan that there is much to affirm the important role of assessing suicidal ideation in guiding clinical decision-making. Suicidal ideation is important not only as an indicator of potential suicide but also as a clear sign of mental distress. Self-destructive thoughts are a key symptom in various types of mental disorder, including depression and personality disorders. These thoughts need to be assessed in the context of other factors, as recommended by various agencies, including the National Confidential Inquiry into Suicide and Homicide,⁷ such as previous self-harm, social circumstances, patients' relationship with their mental health team, access to means and early follow-up. We also endorse the current move away from primarily focusing on trying to identify patients at most risk to individualised safety planning for all patients.

We thank Dr Calcia for her supportive letter.⁸ We particularly agree with her focus on the need to prepare trainees for the experience of a patient death by suicide. In this respect, we include the following quotes from psychiatrists in our survey.

‘Start training the trainees early on suicide and suicide prevention. Do not neglect the impact it will have on level of functioning and on career choices. Building resilience is essential to help doctors sustain the possibly repeated events of patient suicide.’

‘I think the training on this subject should be part of core and higher training and higher trainees should have some mentoring and exposure to this process.’

While the above comments may seem counter to the current focus on a zero suicide policy, in our opinion they do reflect the reality of psychiatric practice. Preparation for this often painful event is likely to decrease personal trauma and reduce the risk of losing valuable staff from our profession.

1.3.10 A brief history of the evolution of the Parliamentary Scholar Scheme

Keir Jones Asit Biswas

date

2020-04

Contents

- *A brief history of the evolution of the Parliamentary Scholar Scheme*

We were really pleased to read about the Parliamentary Scholar Scheme and how successful it has become – thank you for your thorough overview of this invaluable opportunity for speciality trainees in psychiatry.¹ The scheme can trace its origins back to a pilot scheme set up by Baroness Hollins in 2012, when KJ was one of three trainees at higher speciality trainee level in Psychiatry of Intellectual Disability or Child and Adolescent Psychiatry. He joined her team at the House of Lords one day a week for four months as a special interest session in Parliamentary affairs.

Similar to the current scheme, the role was to assist in the research and preparation of Parliamentary business, including speeches and written questions delivered by Baroness Hollins in the House of Lords. A wide range of new skills were developed by trainees, including understanding Parliamentary processes; developing communication skills beyond the usual boundaries of medicine; and making alliances with individuals and organisations from different professional and lay backgrounds in order to accomplish shared goals for the benefit of the vulnerable groups we support.

The work Baroness Hollins and her team did to represent the voice of people with an intellectual disability and/or mental illness at a Parliamentary level was truly inspiring, and the opportunity to be part of this team, advocating for our patient groups at a national level, was extremely rewarding and a great privilege. As you mentioned in your article, the opportunity opened our eyes to the substantial influence that medically trained professionals can have in contributing to political and managerial discourse and decision-making, in the widest sense.

AB, who was the Speciality Advisory Committee Chair, Intellectual Disability Faculty, Royal College of Psychiatrists, at the time, believes that this unparalleled and unique training opportunity and experience had a long-lasting effect on

the careers and overall personal development of trainees who were successful in the selection process and then went on to train, refine their skills, and learn about Parliamentary processes and how to influence policy-making, supervised by Baroness Hollins.

KJ feels it has influenced his subsequent decisions to pursue dual training in Intellectual Disability (after a first CCT in Child and Adolescent Psychiatry), act as trainee representative in the Royal College Faculty Executive and more recently join the Royal College of Psychiatrists Leadership and Management Scheme. Another colleague from this early form of the scheme went on to join the Royal College of Psychiatrists Westminster Parliamentary Committee.

We would like to take this opportunity to sincerely thank Baroness Hollins for setting up this scheme and encourage all trainees with an interest in this area to consider the scheme as a unique and invaluable opportunity. We believe this pioneering scheme in all its iterations has already left an important legacy within our generation of psychiatrists and beyond.

1.3.11 The place of free will and agency in psychiatric practice

: Commentary on ... William James and British thought: then and now

Steve Pearce¹

Correspondence

Dr Steve Pearce

(steve.pearce@psych.ox.ac.uk)²

date

2020-04

Abstract

In psychiatric practice, professionals tend to split patients into those who are responsible for their actions, and those who are not. This approach does a disservice to both groups. Patients assumed to retain agency may be blamed, and those assumed to lack agency are disempowered. Professionals should adopt a more nuanced approach to agency and control, recognising that it is impaired in most psychiatric disorders, but absent in very few. This is possible without making stigma worse.

William James' views on free will

The article by Leary¹ encourages a reappraisal of William James's contribution to the early study of psychology. He is best known for his interest in, and lectures on, the psychology of religious experience,² but Leary notes another central interest, in free will. He notes James's doubts in his early writings that even 'a wiggle of the will' is possible. James writes, for example, that addicts ('dipsomaniacs') experience a compulsion³ unlike anything experienced by other people, an impulse that is irresistible (James 1890, quoted in Pickard³). The presence or absence of responsible agency, meaning the ability to make choices and act upon them (thus an expression of free will), is central to modern psychiatric practice, and one of the ways in which James' interests continue to be relevant.

Agency as an all-or-nothing concept

Interest in agency by mental health professionals has fluctuated. Ideas such as locus of control and generalised self-efficacy have been the subject of research, but refer to the person's beliefs about their ability to choose and act, rather than their ability to make choices and carry through the actions associated with them (agency). In psychiatry, agency itself has been neglected as a subject for study,⁴ although in practice it is generally assumed either to be present or absent. In other words mental health workers, like their peers in the rest of society, have a tendency to split patients into those who have agency – who have the freedom to choose to act differently – and those who do not, and are powerless to control their behaviour.

The tendency to dichotomise agency in this way is not restricted to psychiatry. The legal system treats people as either responsible for their actions (having *mens rea*) or not, a dichotomy echoed in the choice between two possible verdicts.⁵ Addiction provides a recent example of the way agency is dichotomised in mental health. Before the 20th century addictions were generally considered character flaws, consisting of unwise choices freely made. The adoption of the illness model of addiction (a movement with a long history of which James was a part, crystallising in 1939 with the birth of Alcoholics Anonymous⁶) alters the formulation to that of someone who is unable to resist their impulses to use, latterly formulated as owing to changes in brain chemistry.⁷ Thus agency is either retained, along with fault, or lost, which allows for compassionate treatment. For a discussion of the debate as it pertains to addictions, see Pickard³ and Pickard and Pearce.⁸

3

The term compulsion is used here in its general usage, meaning that a person is compelled to act, having no freedom to do otherwise. In psychiatric use, such as in obsessive-compulsive disorder, a compulsion can sometimes be resisted.

Agency in psychiatry

The tendency to dichotomise agency in psychiatry leads to patients being split into two groups. One consists of those who are thought to lack agency (at least when suffering from an episode of illness), who cannot recover by their own efforts, and who are unlikely to be able to contribute significantly to their recovery. The other contains those who retain agency, could act differently, but choose not to. For example, patients with personality disorder are usually thought to retain agency (they could choose to do things differently), whereas those ill with affective disorders and psychoses are thought not to. Although, if asked, mental health professionals may agree that the situation is more nuanced, this 'rule of thumb' approach is widespread, and has negative consequences. Control, or agency, when assumed to be fully present, can make it difficult for professionals not to blame patients, since if you are responsible for your actions, and some of those actions harm yourself or others, you deserve to be blamed. This can lead to poor treatment and stigma from the belief that the unpleasant and harmful behaviours by the patient are a conscious choice. **Box 1** Dichotomising agency in the clinical situation Helen has a family history of depression and self-harm. She has become more suicidal following the break-up of her marriage. She disclosed to her care coordinator that she had a rope and is intending to kill herself on her wedding anniversary. She is diagnosed with an exacerbation of chronic treatment resistant depression. She is admitted and placed on general observations. Over the course of the next few weeks she ties ligatures around her neck and cuts herself with smuggled razors. As the perceived riskiness of her behaviour escalates, her level of observations are gradually increased. Staff find it difficult to tolerate her levels of distress and aggression. Staff become split. Some feel she is severely depressed, and that she cannot help acting in this way. They spend increasing amounts of time with her. Others feel her problems are 'behavioural', by which they mean they are under her control; they wonder if she has a personality disorder, and advocate discharge.

The place of agency in recovery

An all-or-nothing approach to agency also has an adverse effect on those deemed unable to exercise choice and control. The assumption is that change is beyond the power of the patient, and is in the hands of professionals, or in some cases down to chance. But symptoms (when they are behaviours, as they often are in psychiatry) and maintaining factors of a range of common psychiatric conditions include actions and omissions. Examples include addictions, eating disorders, depression and anxiety disorders, and the list could be expanded to include all conditions for which there is treatment which requires concordance as, if the patient decides not to take their medication, say, the omission will affect their condition and act as a maintaining factor. Actions and omissions that are either core features or maintaining factors of psychiatric disorders involve a degree of control, and thus recovery from these conditions requires the patient to have the motivation and will to change their behavior.⁹ An anxious patient who finds it difficult to leave the house may eventually recover simply by taking a selective serotonin reuptake inhibitor, but at some point they will have to take the difficult decision to go out of the front door, and the sooner they do (for example, as part of a treatment programme) the sooner they will recover. Telling a patient, or implying, that they have no control over their behaviours undermines their contribution to their recovery, and, if they conclude from this that they should cease their own efforts, may prevent recovery altogether.

The wedge model of responsible agency

What is the alternative to the idea that patients are either subject to compulsion, and therefore entirely lacking in agency, or easily able to change their behaviours, but refusing to do so? It is the idea that control comes in degrees. This is a concept with which we are familiar when applied to ourselves, but have a tendency to forget in the clinical situation. Thus we find it easier not to shout at the kids when we are well rested and happy, more difficult when tired and stressed. The ability to exercise control (responsible agency) may be reduced by physical states like fatigue and pain, and emotional states like fear, anger and anxiety. In other words, it bears some relation to motivational and epistemic context;⁸ the ability to exercise control may vary with motivation, and with one's understanding of the situation and consequences – a smoker may stop when she becomes pregnant despite having previously attempted to do so without success.

Agency might also be impaired, to an extent, in a range of psychiatric disorders. Henderson lists ways in which this

might happen ‘through a defect in consciousness, a change in mood, in perception, in the ability to think or the content of thought’.⁴ It may be more difficult for an agoraphobic to leave their house than it would be for you or me, for these reasons, but the impairment is one of degree, and although leaving the house may be difficult, it is not impossible. This understanding forms the basis of the behavioural treatment of agoraphobia.

The tendency to think of behaviour in some psychiatric disorders as compulsive (wholly without choice) is unsustainable also in view of the way people suffering from these disorders behave in practice. People with these problems quite commonly do change their behaviour. Some interventions bolster the ability to choose; for example, buprenorphine reduces the euphoric effects of opiates, and behavioural experimentation improves the ability to tolerate phobic stimuli. Psychiatric treatments change behaviours across a range of disorders and interventions.^{10,11}

It also appears to be the case that behavioural changes become progressively easier as agency gradually increases. For example, the theory of behavioural activation for depression suggests that completing easier tasks leads to an improved ability to undertake more difficult tasks, possibly related to the impact of increasing self-efficacy on agency. This rationale is also seen in the graded exposure hierarchies used in the behavioural treatment of anxiety. In addition, experiments indicate that effortful practice appears to bolster willpower, the so-called ‘muscle model’ of the will.¹²

Could retaining the idea of agency, and thus choice, invite stigma?

It is possible that widening the arena in which choice is considered a factor could subject those who suffer conditions that may be less subject to agency-related stigma, such as depression, to the additional stigma that those suffering disorders thought to be more choice-based, such as personality disorder, are subject to. Might professionals, and the public, have more difficulty feeling compassion if we reconsider the contribution made to mental disorders from patient choices?

This is possible, but is not a reason to retain an inaccurate approach to agency. Maintaining that a person has no control over a situation, when they appear to in fact retain some control, is not a viable solution to stigma, and the folk are probably not convinced by this anyway. Although people are generally willing to allow some slack to people who are ill, they are also sensitive to when the sick person appears to be ‘overstepping the mark’.¹³

Ways of avoiding stigma when a degree of agency is retained

How might we mitigate any negative effect of acknowledging the place of will in the maintenance of mental disorder? ‘Responsibility without blame’ is a concept observed by a philosopher when visiting democratic therapeutic communities.¹⁴ Blame used in this context refers to affective blame, the negative feelings and attitudes that arise in another when someone is responsible for an action with a negative consequence. Pickard noticed that the staff of the therapeutic communities were able to retain the idea that patients with personality disorder were responsible for their decisions and actions – that they retained agency – while not engaging in blaming behaviours, or adopting a blaming attitude, that would be normal when those decisions and actions have negative consequences. She concluded that responsibility and blame can be separated, and should be for the purposes of good clinical care. Blame is usually countertherapeutic, and makes providing compassionate care more difficult, whereas the attribution of responsibility is essential both in motivating change, and in maintaining a mutually respectful therapeutic relationship (if your patient is not responsible for their apparent choices, you should treat them not as an equal moral being, but more like a child). Pickard thought that paying attention to the patient’s personal history was one of the elements that make it possible to avoid blame, as this evokes compassion and empathy, which make affective blame less likely.

The acknowledgement of choice and control should not be allowed to affect treatment. This is already a problem, for example, when patients who have self-harmed are treated poorly in emergency departments.¹⁵ The solution to this is not to maintain the fiction that such behaviours are outside the patient’s control, but to train professionals to act with compassion and care no matter the cause of the patient’s distress.

What are the practical implications of this approach?

If the exercise of free will is essential to recovery from mental disorders, we should treat people in such a way as to encourage the development of agency, to improve their capacity for control. It is possible to support patients through the difficult process of change, without moving to a paternalistic position in which change and recovery depends on us rather than the patient.⁹ Our approach to patients should thus be to acknowledge and bolster their power and agency in relation to their condition. In practical terms, when a patient tells us they cannot exercise control, such as to get out of bed when feeling depressed, it is helpful to regard them as able to exercise control, but to explore with them the degree to which this may be reduced, and the reasons for this. We should also work to avoid demoralising self-blame; for example, by emphasising that it is common for someone in their position to have these problems, that there are strategies for addressing it, and that it is okay to find it hard. It will be important to be circumspect in how this conceptualisation is used with regard to carers and relatives; the public is no less likely to dichotomise agency than professionals, and may react to the idea that agency is retained to a degree, by assuming that the patient is acting this way 'on purpose', a perennial problem in psychiatric disorder.

There is an additional point to note. As conditions such as obesity and addiction increasingly come to be seen as illnesses, or even diseases, people see themselves as less responsible and less able to change, with consequent increasing reliance on the efforts of professionals rather than themselves.

Conclusion

Most mental disorders probably affect agency, making it more difficult to implement good choices. The extent to which this affects the patient will depend on both the nature and the severity of the disorder. Although it is probably true that people with even severe personality disorders retain agency much of the time to a greater degree than people with severe affective and psychotic disorders, agency is likely to be retained to some degree in all but a small proportion of patients with psychiatric disorders. Most psychiatric patients are able to contribute to their recovery through the exercise of their will. For this reason, treatment should emphasise the bolstering of control and willpower, which should include working to improve patients' understanding of their problems, and morale. In this way, we can avoid the twin mistakes of disempowering the patient by assuming they have no meaningful power to make choices that affect the course of their illness, and adopting a blaming attitude, which can allow the correct attribution of agency to detract from compassionate and energetic care.

Thank you to Richard Gipps for very helpful comments on the draft of this paper.

Abstract**Aims and method**

True Colours is an automated symptom monitoring programme used by National Health Service psychiatric services. This study explored whether patients with unipolar treatment-resistant depression (TRD) found this a useful addition to their treatment regimes. Semi-structured qualitative interviews were conducted with 21 patients with TRD, who had engaged in True Colours monitoring as part of the Lithium versus Quetiapine in Depression study. A thematic analysis was used to assess participant experiences of the system.

Results

Six main themes emerged from the data, the most notable indicating that mood monitoring increased patients' insight into their disorder, but that subsequent behaviour change was absent.

Clinical implications

Patients with TRD can benefit from mood monitoring via True Colours, making it a worthwhile addition to treatment. Further development of such systems and additional support may be required for patients with TRD to experience further benefits as reported by other patient groups.

Patients with treatment-resistant depression (TRD) can experience a more chronic and severe course of illness.¹ These outcomes could be improved by online mood monitoring to facilitate treatment personalisation, and the evaluation of

treatment efficacy.²⁻⁴ True Colours is an automated monitoring system developed by clinicians and currently used by psychiatric services in Oxford Health National Health Service (NHS) Foundation Trust, as well as by clinical trials across the country. Patients in Oxford Health are provided with access to True Colours by their clinical team at their or their clinicians request, whereas clinical trial teams can use the system to monitor participants and collect relevant outcome data. True Colours is also available via the Bipolar Disorder Research Network to patients with a diagnosis of bipolar disorder living in the UK.⁵ The system allows patients to self-monitor and self-manage symptoms⁶ by prompting them to complete personalised questionnaire assessments according to the time, frequency and mode of interaction selected. Patient responses are stored and displayed graphically through the interface, and are also made available to the patient's clinician or research team.

Adherence rates in patients with bipolar disorder are between 75 and 100%,^{7,8} and qualitative assessments indicated that patients with bipolar disorder find the system easy to use and a positive contributor to their clinical care and self-management.⁹ Comments on the flexibility of the system led to the development of a personalised questionnaire feature, which allows patients to add questions to their schedule.¹⁰ However, although the system is routinely used by patients with unipolar TRD, it is not clear whether they similarly benefit. Establishing the experience of this patient group is essential to maximising the clinical utility of this and other mood monitoring systems. This study aimed to qualitatively assess the perspectives of patients with unipolar TRD who used True Colours as part of the Lithium versus Quetiapine in Depression (LQD) study.¹¹

Method

Ethical approval was obtained from Cambridge South Research Ethics Committee (approval number 16/EE/0318). All participants provided written informed consent. This study has been carried out in accordance with the Declaration of Helsinki.

Participants

LQD participants were invited to take part in this study between March 2017 and March 2018. This was a convenience sample, meaning that LQD participants attending an 8, 26 or 52 week follow-up assessment in that period were given the opportunity to participate in this additional study at the relevant follow-up assessment, conducted at a clinical research facility. Repeat interviews were not conducted. The full methodology of LQD has been reported.¹¹ In brief, adult patients meeting the criteria for TRD were randomised to receive lithium or quetiapine augmentation and followed up over 12 months. As part of the study, participants were asked to complete two questionnaires weekly via True Colours to collect primary outcome data: the Quick Inventory of Depressive Symptomatology (QIDS-SR)¹² and Work and Social Adjustment Scale (WSAS).¹³ Study-specific questions regarding medication were included to track dosage and adherence.

Interview procedures

Participants took part in semi-structured interviews conducted by a researcher (full interview schedule is in the supplementary material, available at <https://doi.org/10.1192/bjb.2019.92>). Researchers were predominantly female and held a relevant undergraduate or master's degree. L.M. conducted training with all interviewers. Typically, the researchers had an existing relationship with the interviewees having conducted their prior LQD assessments. Interviews ceased once data saturation was reached, meaning no new emergent themes were being identified by the collection of additional data.¹⁴

Data analysis

Interviews were audio-recorded, transcribed verbatim and checked by another researcher. All identifiable information was removed, and participants were assigned a code for reference.

A thematic analysis was conducted – a widely used method for identifying, analysing and reporting patterns within data – with steps recommended by Braun and Clarke.¹⁵ This included actively reading the entire data-set several times, systematically identifying and coding for key features, analysing codes and combining them to form broader themes. Themes were then reviewed and refined to ensure that they were appropriate in relation to the coded extracts, as well as the entire data-set. This led to the removal of some themes (e.g. owing to lack of supporting data), and the collapsing of others into one, with additional subthemes. Finally, themes were appropriately named, and evidence included for each in the present report. This approach is inductive (bottom-up), meaning the themes identified were data driven.¹⁶ Two researchers (E.I. and B.V.) conducted analyses independently, and discrepancies in the identified themes were discussed with L.M. and R.W.T. until resolved by consensus. The second rater (B.V.) did not conduct any qualitative interviews, minimising any potential bias.

Results

A total of 26 individuals were invited to take part; 21 participated and five declined, primarily owing to fatigue (see *Tables 1* and *2* for demographics and clinical characteristics). We generated 81 initial codes from the qualitative data and combined them to form six themes (see *Table 3*). Duration of interviews ranged from 3 to 17 min (mean 6.9 ± 3.3). *Table 1* Demographic characteristics of participants ($n = 21$)

Insight

Anticipated insight (before using True Colours)

Participants frequently described how True Colours enabled greater understanding of illness. This outcome was anticipated by almost half of the participants upon hearing about the system. “I thought that, you know, it would give us something to go by, some kind of guideline, on, you know, where I am with my moods, or my behaviour and my sleeping and so forth’ (P6). ‘I had an expectation that it may be useful that you would have some form of er. . . information that you know, whether you’re progressing or whether you’re not in relation to your treatment, and in relation to how your illness is affecting you’ (P7).”

Experienced insight

Regardless of whether it had been anticipated, 18 participants found that symptom monitoring enabled reflection. For some, viewing changes over time helped put their mood into perspective, particularly when feeling low. The process of completing questionnaire(s) appeared to play a key role in increasing awareness, and how mood linked to symptoms such as increased weight. Although many participants viewed this awareness positively, and one person reported a positive effect on their mood, a small number did not find it beneficial. “It’s allowed me to monitor things ‘cause obviously certain weeks can be worse than others or better than others. . . so yeah it’s been quite useful’ (P1) ‘Rather than thinking “I’m really depressed, I’m really depressed, I’m really depressed”, I’m able to kind of say “the score’s the same” and actually, it’s. . . your mood is the same. . . it’s, you know, in your head that things are worse’ (P10). ‘You’re looking at that [graphs] saying “Eee God I’m depressed” and it makes you feel even worse’ (P7).”

Envisioned insight

This subtheme refers to insight that could be gained through continued use of True Colours. Six participants felt this could be possible, several of whom had not experienced significant mood fluctuations when using True Colours, but felt the graphs could help detect future changes. Others, who had not used the graphs discussed how they could offer future insight into mood patterns. “I would have thought that if I did use it [graphs], yes it would be useful. . .” cause it would, you know, be able to tell me where the fluctuations are. With this said, I will make, um. . . endeavour to have a look in the next couple of weeks’ (P6). ‘I don’t think it was originally that it would be particularly useful until I actually see how the changes are mapped on the graphs and stuff like that. So, the more interested I am, I think the more useful it’ll be’ (P8). ‘I mean its early days but umm. . . but I think it [the graphs] will be useful in the future’ (P20).”

Absence of behaviour change

True Colours did not appear to affect the way in which most participants ($n = 19$) managed their depression. Because of the lack of changes reported, no subthemes were identified for this category. Participants recognised that the system could provide them with information, but did not see how this could translate to illness management. “Probably er. . . not err. . . not as much as manage it but be aware of it’ (P21). ‘No. Just. . . just it’s informative. It doesn’t change my lifestyle’ (P18).”

Improved clinical care

Using feedback during clinical appointments

Seven participants suggested the feedback provided via True Colours (i.e. graphs) could improve the efficiency of time spent with healthcare providers. “‘True Colours would be a way of keeping track of everything and also it would give me a visual representation to show medical professionals as opposed to just going well... I had a bad week 2 weeks ago. I can actually show them what happened as opposed to trying to remember it’ (P1). ‘I think for a professional that is dealing with your, or supporting you, I think that information I think may be useful’ (P7).”

Valuing access to human support

For four participants, the awareness that they could be monitored by a professional who would understand their difficulties was a source of reassurance. “‘When I had a bad week then I emailed Tr...the...the link on True Colours...to say look, this is happening and...and it did help to know that somebody else understood what I was going through rather than me saying to somebody I’m feeling a bit...crap this week and they’re just - oh...pooh poohing it really’ (P4). ‘Knowing that there is somebody out there that’s monitoring me... which is nice’ (P3).”

Prioritisation

Organising time

Seven participants admitted that they struggled to schedule time for True Colours and often forgot to complete questionnaires. “‘There just isn’t enough time in my day to do it’ (P5). ‘Sometimes I’ll be working or something and I’ll forget to do it’ (P1). ‘The only times I’ve kind of not done it is when I’ve kind of been really busy throughout the day’ (P10).”

Motivation

Even setting aside the issue of time, over half of participants indicated that because of a lack of interest, not prioritising or viewing True Colours as useful and/or an inertia (related to their illness), it was difficult to engage consistently. “‘It depends where I am mentally on that particular day. Um... sometimes, do you know, I won’t, I won’t, won’t be able to get out of bed to brush my teeth. And to be able, do you know, look onto your phone and fill out questionnaires, it’s nigh on impossible’ (P6). ‘While I was sat there trying to psychoanalyse myself through True Colours I feel as though I could be doing something, achieving something that will possibly help me through this journey I am on’ (P5). ‘I think that you can spend too much time thinking about like erm being depressed, or the causes of depression, or how you’re feeling, rather than living your life’ (P8).”

Categorisation concerns

Discrepancy between experience and questionnaire response options

Seven participants raised concerns regarding their ability to accurately summarise symptoms over the past week when there had been significant variability. They also felt there were not sufficient options to express experiences. “‘I couldn’t categorise myself because my days are so... at the moment so mixed up’ (P5). ‘Umm... sometimes it’s hard to put how you’ve been feeling or... kind of... getting an average... having a discrete box can be hard when you kind of want to do “well it’s that point 5 or...”... ideally I’d say “it’s just one between two points” rather than... a specific number’ (P15).”

Ambiguity and repetitiveness of questions

Comments were also made regarding the wording of some questions, and how they were either difficult to understand, or similar to others. This left a small number of participants feeling unsure about how to respond. “‘There was one question on there which... um... seemed a bit... could be misconstrued’ (P2). ‘Yeah, yeah, like it’s sometimes you feel it’s getting rep... uh... repeating itself all the time’ (P3).”

Interface features

Positive experiences

Positive features relating to the interface were identified. Just over half of participants described the ease of logging on and completing questionnaire(s), and five participants commented on the usefulness of personalised weekly prompts. “‘Yeah... it’s really easy... it’s all... it’s all laid out there for you so you just umm you know... tick whatever it is’ (P20). ‘I’ve had experienced nothing technical wise about it, nah, it’s always been quite problem free’ (P7). ‘I think like it’s good that there’s a reminder... and that I could choose when it was. Umm... because it’s like quite a convenient time for me just like in the evening to go on my phone, and it’s quite quick to do the questionnaires... and like you can choose when that comes which I think’s really good’ (P19).”

Challenges

A variety of challenges relating to True Colours were similarly identified. Although participants were aware they could access response graphs, not all were using this feature. Four found the graphs difficult to interpret, and therefore not useful, and one commented on the lack of graphs for personalised questions. Further, 13 participants reported technical and interface issues, which affected their ability to complete questionnaire(s) and/or access feedback. “‘Like the symptom graph I don’t quite get, and I don’t quite understand how it works... erm... ’cause I just see it as a load of blobs’ (P10). ‘I’d added like other questions just like for myself on there, but I wasn’t able to see those on the graph, I could only see the study ones’ (P19). ‘It’s not as good on the phone ’cause you can’t see it as properly as well as you can on the computer’ (P3). ‘I can’t log in, I don’t try anymore’ (P14).”

Finally, two participants felt that human contact, rather than a technology-based approach, would more likely facilitate an open and honest sharing of information and aid recovery. “‘I think the only way you get to know things is by talking... I know that’s not um... possible... but for people like me with my problem at my age we are not used to... um... baring our soul on a computer’ (P5). ‘I could fill a questionnaire and I could lie through my teeth, but I think you soon get caught out if you’re sitting with a human being’ (P8).”

Suggestions for improvement

Six participants volunteered information about ways in which the interface could be improved, including simplification of the questionnaire(s), and further personalisation options such as adding notes to questionnaire responses. “‘I still feel it can be simplified, to make it, make it a bit more user friendly. Realising that, you know, people using it may have various mental health issues, that might require, a bit more basis yes or no’ (P7). ‘Maybe if you could like... I don’t know, like write notes at bottom or something, or like just for your own reference’ (P20). ‘Perhaps some way of changing the size of the text very easily would help, especially for people who aren’t very computer literate’ (P15).”

Discussion

This study explored whether patients with unipolar TRD found True Colours, an online mood monitoring system used by NHS services, a useful addition to their treatment regimens. Our key findings were that mood monitoring enabled participants to feel that they had greater insight into their disorder, regardless of whether this was anticipated before use, but participants felt that their use of True Colours did not result in behaviour change. Many participants viewed their increased insight positively; but for some, spending time evaluating their symptoms was thought to contribute to a deterioration in mood. This aligns with the suggestion that the ability to identify and characterise one's mood state can predict positive affect, but a tendency to frequently scrutinise one's mood can predict negative affect and rumination.¹⁷

For most participants the perceived increase in insight was not associated with subsequent behaviour change. Neither completing the questionnaire(s) nor viewing the online graphs, which depicted their responses over time, led participants to make connections between patterns in their illness and their lifestyle choices. This is in contrast with research in patients with bipolar disorder, whereby monitoring via True Colours and other automated systems was associated with change in behaviour/improved self-management.^{8,9} This may be owing to the differing nature of TRD, which is not characterised by the same cyclic mood changes, and patients with unipolar TRD may require additional support for mood monitoring to inform behaviour change. It may be that patients with TRD who are undertaking therapies such as behavioural activation could benefit in this regard. The potentially unique needs of this patient group highlighted here would clearly benefit from further qualitative and quantitative research to fully understand how patients with TRD can benefit from this and other mood monitoring systems.

Although participants did not use True Colours for self-management, their responses suggested confidence that the system could improve clinical care by reducing reliance on their ability to accurately recall symptoms over time. The prospect of obtaining more contemporaneous data via this and other mood monitoring systems may improve our understanding of the course of major depressive disorder/TRD, and support the improvement of outcomes. Another key contributor to the enhanced clinical care theme was the belief that True Colours would give patients access to human support. This perception appeared to provide participants with a sense of support and reassurance, although this may have been inflated because of participants' awareness that their adherence was monitored by the LQD study team. However, True Colours does facilitate real-time data sharing with clinicians in standard clinical practice, although this may not be the case with other mood monitoring systems, and whether or not data is monitored by a clinician should therefore be made clear to those who use any online mood monitoring platform.

Three key barriers to mood monitoring via True Colours were identified. First, participants indicated that it was difficult to find the time and/or motivation to engage consistently with the system. However, as discussed, LQD participants were required to complete two questionnaires each week as well as study-specific questions.¹¹ In standard clinical practice, a manageable amount and frequency of use could be agreed between patient and clinician. Balancing the need to collect sufficient data while minimising the burden placed on patients is an important consideration and likely to be relevant to other online platforms.

Second, participants raised concerns about their ability to categorise experiences on standardised questionnaire(s). For some, there were clear discrepancies between what they had experienced and available response options. Others felt uncertain about question wording, reporting that they were difficult to understand or repetitive. Although these difficulties relate to the QIDS-SR and WSAS, and not the monitoring system itself, they indicate a need for the continued development of simplified self-report questionnaires to maximise the utility of online mood monitoring systems while maintaining the validity and reliability of assessments.

Finally, although participants had a positive experience with features of the interface (e.g. weekly prompts), a variety of issues were reported. Several participants chose not to view the graphs, and the majority of those who did had difficulty accessing or interpreting feedback. In addition, technical issues limited the ability of some to interact with the system. Although these graphical and technical concerns can be addressed, the finding that a small number of participants simply preferred human contact indicates that applications such as True Colours will not be acceptable to all, as is the case with any intervention.

There are limitations to this study. Convenience sampling was used, and although this is a widely used method of sampling in qualitative work, it may limit the transferability of the results to other settings, particularly as all participants were selected from a single clinical trial.¹⁸ Participants also varied in how long and to what extent they had used True Colours, making it difficult for some to comment on certain features (e.g. the graphs). The content and frequency of

questionnaires was also protocolised according to the design of the wider clinical trial, although patients did have the flexibility to add additional questionnaires to their schedule. Therefore the experience of participants in the present study may therefore differ from those of patients using the system to support their usual care, and future investigation of online mood monitoring in a purely clinical setting would be of benefit. However, it is noted that the protocolised questionnaires included in this study are routinely used in clinical practice.

To our knowledge, this is the first study to explore the experiences of patients with TRD who use the True Colours mood monitoring system. Our findings are encouraging and suggest the system is reasonably well adhered to and provides an effective way of capturing outcomes. However further development is needed to improve the participant–system interface, and maximise the clinical utility of True Colours for this group. Another important step should be the examination of True Colours use in relation to treatment outcomes, to assess not only whether patients perceive the system to be beneficial, but also whether this translates to an improvement in empirical outcomes.

Although this qualitative study was conducted in a single sample taken from a clinical trial, the differences between the experiences of patients with unipolar TRD reported here and those of patients with bipolar disorder⁹ may have wider implications across settings and mood monitoring platforms. It is clear that online tools developed to support patient care are not ‘one size fits all’, and the experiences and preferences of individual patient groups must be accounted for during development if such tools are to provide the benefits intended.

We would like to thank Vanashree Wadekar for programming and setting up the LQD study questionnaires on the True Colours system, Valeria De Angel and Emanuella Oprea for their contribution to data collection, and Sarah Mather, Jake Hutchinson and Kimberly Nortey for transcribing interviews and data collection. We also thank all of the participants for their valued contribution.

date

2020-04

Abstract

The American psychologist and philosopher William James drew inspiration from British evolutionary theory, neurology, psychiatry, psychology and philosophy. Trained in anatomy, physiology and medicine, he developed a physiological psychology that offered acute analyses of consciousness and of the relations between mind and brain, habit and thought, cognition and emotion and other aspects of psychology. One of his insights, regarding the relation between attention and will, was based upon his own experience of panic anxiety, which was resolved through his reading of several British authors. The story of his psychiatric experience, practical response and later theoretical conclusion offers a potential contribution to contemporary therapeutic practice.

Contents

- *William James and British thought: then and now*

William James (1842–1910) was and remains one of the leading academic and public intellectuals in American history. A founder of modern scientific psychology, he was also instrumental in orienting contemporary clinical psychology. While establishing the pragmatic tradition in American philosophy, he became an inspiring and popular public lecturer, addressing topics like the will to believe and what makes life worth living. Although a psychologist and philosopher, he had a much broader background that included other fields in the sciences and humanities, but for all of that, the only degree he ever received was an MD from Harvard Medical School. His first job at Harvard, before transferring to its Department of Philosophy, was as an Instructor of Anatomy and Physiology.

James's significant contributions to the history of psychology and philosophy depended upon his knowledge of German philosophy and experimental psychology as well as his familiarity with French philosophy and clinical psychiatry, but just as important was his intimate connection with British philosophy and psychology, and his earlier study of British physiology, medical psychology and psychiatry. Beyond that, Charles Darwin provided the larger conceptual framework for his work, British neurologists helped him understand the workings of the brain and many other British thinkers, including literary authors, contributed insights that he integrated into his monumental *Principles of Psychology* (1890)¹ as well as into his later philosophical work. Indeed, he explicitly stated that his psychology represented a continuation, albeit with important revisions, of the tradition that began with John Locke's empirical psychology, and he dedicated his ground-breaking philosophical work, *Pragmatism* (1907),² to 'the Memory of John Stuart Mill', from whom he had learned 'pragmatic openness of mind'.

It was from Britain, too, that James received an invitation to deliver lectures, in Edinburgh, that led to his *Varieties*

¹

of *Religious Experience* (1902),³ which is still the starting point for empirical studies of the subjective aspects of religious belief, feeling and action. And just a few years later, Oxford invited him to deliver the lectures on *A Pluralistic Universe* (1909)⁴ in which he called for respectful awareness and acceptance of the diverse array of people, phenomena, perspectives and persuasions that compose this world of ours. (He had earlier denounced ‘blindness’ to the valuable distinctiveness of those unlike ourselves, citing Robert Louis Stevenson as well as Wordsworth to bolster his argument.)

Bringing together German, French and British sources was not the only act of integration that made James’s *Principles of Psychology* such a landmark achievement. He also joined the scientific with the humanistic dimensions of psychology. His central argument was that the human mind depends upon, but is not reducible to, its physiological and neurological conditions. To the contrary, it is an essential factor in the evolution and operation of those conditions, a proposition that is once again being entertained by many, after decades of neglect. Ironically, James’s conjoining of physiology and neurology with a careful and precise phenomenology of consciousness drew innumerable readers to his work, but also set the scene for the future dismemberment of what he had brought together. For he was so successful in drawing attention to the significance of the nervous system for an understanding of psychological phenomena that he helped to generate a thriving tradition of neuropsychological research that, until recently, overlooked the reciprocal influence of consciousness on the human organism, which was equally important to James. Similarly, James’s acute analysis of habit helped to inspire generations of behaviourists who proceeded, until the past quarter-century, to ignore the essential role of thought in the development and modification of habits, which James had strongly emphasised. And, on the other side of the coin, those who loved his masterful descriptions of consciousness, thinking, emotion and self came to neglect topics, this time neurophysiology and habituation, which James had shown to be intimately related to them. In addition, with ever-increasing specialisation within psychology, researchers came to ignore the relations among consciousness, thinking, emotion and self, which James had highlighted. As a result, it is only in the past few decades, with the advent of ‘interdisciplinary studies’, that cognition and emotion have been studied once again in terms of their significant overlap, as they were by James more than 100 years ago. And after a similarly long lapse, the role of attention is again a vital topic of research, even leading to explorations of its relation to will, which was a central interest of James.

In this context, returning to James’s work can yield dividends, for there are many other insights that James has to offer; this is also true with regard to James’s philosophical work, but that is beyond the scope of this essay. Because those insights often entail connections between different subfields of psychology, my own recent book on James’s *Principles of Psychology* focused intentionally on some of the more important relations within his thought: between his treatments of mind and body, habit and thought, perception and conception, imagination and memory, cognition and emotion, consciousness and subconsciousness, attention and will, and self and others, not to mention psychology and philosophy, all of which make his work so timely to explore.

The revisions James made in traditional empirical psychology involved changing the Lockean model of the mind from the passive mode, as exemplified in Herbert Spencer’s work, to the active mode, as accomplished by the introduction of subjective interest and individual choice into psychological dynamics, a crucial addition that James traced to insights from the British philosopher Shadworth Hodgson as well as to his own American mentor Chauncey Wright. James’s subsequent radical empiricism, which included subjective experience as its leavening element, placed James at odds with the kind of mechanistic psychology that was later advanced by John B. Watson and all those who banished subjectivity from psychology.

With this in mind, we can consider one possible contribution that James’s non-mechanistic psychology could make to current understanding of the relations between psychiatric conditions – in particular, depression, anxiety and panic of the sort suffered by James himself in a critical period of his life – and consciousness. To do so, we need to be aware of some additional facts, the relevant episode in James’s life and the role played by two additional British people, the 17th century writer John Bunyan and the mid-19th century physiologist William B. Carpenter. Bunyan, as we shall see, suggested to James a practice that changed his life for the better – in fact, a practice that saved his life, as far as he was concerned – and Carpenter proposed an idea that helped James explain the efficacy of that practice, thus influencing his construction of a psychology that began with a focus on brain processes but ended with an affirmation of consciousness, indeterminacy and free will: not a radically free will independent of natural conditions, but a will possessing sufficient personal agency to make life worth living, for James and many others. James’s notion of will, of voluntarism, of being able to make a difference in the world by virtue of his own capacities for resistance, participation and collaborative creation, was grounded upon his conviction that we live in a moral universe in which human action, however limited and pressed upon, can still have some sway, with each of us potentially ‘in the game’, as he put it. For

if human life is truly the struggle that it feels like, as James remarked, it is vitally important for us to believe that the results of that struggle are not foreordained. The difference each of us makes may be small, but it nonetheless makes all the difference for us.

James struggled in his 20s and 30s with poor health, depression, neurasthenia, suicidal thoughts and other related conditions, both before and during the first years of his commitment to the development of psychology. His reading of the French philosopher Charles Renouvier, along with his reading of Wordsworth and Browning, helped him survive and intermittently to emerge from his depressive state. (Less well known, but also significant, is the role that his meditations on Shakespeare's *Hamlet* played in the alleviation of his condition.) Not surprisingly, the variety of causes that fed his depression and ill health are somewhat less understood. He himself feared that inherited physiological factors were at the root of his problems. This generated an understandably fatalistic anxiety, exacerbated by his inclination to accept the deterministic assumptions that undergirded modern science. This nexus of anxiety and supposition led him to the unhappy conclusion that 'we are nature through and through' and that 'not even a wiggle of our will' occurs without some cause outside of our control. This threw into jeopardy his earlier hope to 'leave a trace' in human history, one that only he (through his own self-determination) could leave. And it made him question the very possibility of what he called 'the moral business' by which he had hoped to make his 'nick', thereby contributing his small but real 'mite' to the common good. As he agonised about all of this, he realised that what was at stake was the thought of 'my having a will'. Renouvier had offered an argument, effective for James only on an off-and-on-again basis, that no one can prove or disprove free will, but if free will does exist, its verification would lie in the personal act of freely willing to believe in it. Knowing that he was miserable when he did not believe in it, James committed himself to believe for a year and observe whether that belief made a positive difference in his life.

This is all background to an experience of massive anxiety and panic that was a turning point in James's life, almost certainly in 1870. This momentous incident was described, as if drawn from someone else's experience, in his *Varieties of Religious Experience*. It occurred, according to this 'anonymous report', during a period of 'the worst kind of melancholy' that took 'the form of panic fear'. It consisted of 'a horrible fear of my own existence' that 'came out of the darkness', accompanied by 'the image of an epileptic patient whom I had seen in the asylum, a black-haired youth with greenish skin, entirely idiotic, who used to sit all day on one of the benches... with his knees drawn up against his chin', moving 'nothing but his black eyes and looking absolutely non-human'. And here was the barb at the centre of his panic: 'This image and my fear entered into a species of combination with each other. *That shape am I*, I felt, potentially. Nothing that I possess can defend me against that fate, if the hour for it should strike for me as it struck for him'. The horror of him and the fear for himself – and the sense of his own 'merely momentary discrepancy from him' – left James 'a mass of quivering fear... with a horrible dread at the pit of my stomach' that he managed to escape only by clinging to scripture texts like 'The eternal God is my refuge', 'Come unto me, all ye that labor and are heavy-laden', 'I am the resurrection and the life', and so forth. At the end of his description of this harrowing incident, James asserted: 'Without clinging to these phrases rather than submit to the image of the idiotic patient, I think I should have grown really insane'.

I have written two articles about this episode, one providing new information about its immediately precipitating cause (namely, James's reading of the philosophy of Arthur Schopenhauer, with its pessimistic message about the illusion of individual personhood and of the associated belief in the indeterminacy of individual will) and the other identifying the source of its resolution. How James came to this resolution and how he came to understand and integrate its significance into his psychology is an interesting and relevant story.

In the months preceding the probable date of his fearful encounter with the idiotic, green-skinned phantom, James was not only depressed, but also reading John Bunyan's *Pilgrim's Progress* (1678–1684).⁵ As discovered fairly recently, his mother had given him a copy of this book (in a revised and simplified edition) in late January 1870. She did so purposefully, one assumes, since James was then in the midst of the same bout of suffering that eventually led to his 'touching bottom' during his hallucinatory panic attack. But in any case, James had clearly read the chapter entitled 'The Fight' in this revised version of Bunyan's work, as evinced by a dog-eared page within an extended passage that begins with Christian being 'full of fear' as he is confronted by the 'foul fiend' Apollyon, and then suffers even greater fear as he approaches the Valley of the Shadow of Death. At this point, Christian has a dream, not unlike James's own apparition, in which he comes to the edge of the 'dark as pitch' Shadow of Death. There he sees 'ghosts and imps and fiends of the pit', and hears 'howls and yells as of men in great pain, who sat bound in woe and chains'. Despite his terror, Christian trudges on, seeing and hearing 'dread things' until 'at last' he hears 'a band of fiends' coming to torment him. In trembling fear, he considers 'what he had best do'. And here, on that dog-eared page in James's

recently discovered personal copy, is where Christian's tale touches James's life: "At times he had half a thought he would go back; but then he knew that he might be half way through the vale. He thought, too, of all that he had gone through, and that it might be worse to go back than to go on. So he made up his mind to go on, but the fiends drew near. But when they had come at him, as it were, he cried out with all his might, 'I will walk in the strength of the Lord God'. (pp. 94–95)"

Then, as Christian went on with his mind riveted on the strength of God, he was comforted by a voice saying, 'Though I walk through the Valley-of-the-Shadow-of-Death, I will fear no ill, for thou art with me'. And with that, shrouded by these protective verses from Psalms 71 and 23, Christian 'came to the end of the vale'.

It is not difficult to connect Christian's experience with James's. Similarly full of fear, James confronted his own nightmarish apparition and escaped his own spectre of damnation through the recitation of biblical verses, just like Christian. Although his fear of impending insanity was different from Christian's fear of punishment by 'fiends of the pit', the analogy is easy to see. And James himself, always a perceptive and thoughtful reader, would have seen it. Indeed, in a letter to his brother Henry on 7 May 1870, he wrote that 'I have I think at last begun to rise out of the slough of the past 3 months'. Slough is, of course, a clear reference to the 'Slough of Despond' in *The Pilgrim's Progress*.

We can now consider how James translated this experience into a usable psychological proposition: how, in psychological terms, repeating biblical phrases helped James endure his journey through the Valley of the Shadow of Death without utterly breaking down. This is where the work of William B. Carpenter enters the story. Four years after his devastating experience, as he was beginning to formulate his own psychology, James read Carpenter's *Principles of Mental Physiology* (1874).⁶ In a published review, he specifically noted Carpenter's notion of 'ideo-motor action', which applied to some 'curiosities of our mental life', instances in which a dominating (we would say obsessive) idea gives rise to repetitive motor (behavioural) actions. What James came to realise was that ideo-motor action is, in fact, a more general principle of mental life, not confined to idiosyncratic clinical cases. Indeed, he concluded that the evolutionary function of all ideas is precisely to serve as intermediaries between sensory stimulation and behavioural movement, all of which occur without the intervention of the will. Ideas are naturally 'impulsive', as James put it. So the question is not why ideas lead to action (sensation-ideation-action being the normal course of events), but rather, why some ideas do not.

This is where James's Bunyan-related experience melded with his Carpenter-inspired realisation. Why had the image of the idiotic patient not led to a breakdown in his sanity as James had fully expected? He came to believe that the impulsive efficacy of the image was thwarted when his mind was distracted by more powerful ideas: when images associated with the biblical phrases became more dominant in his consciousness by means of his wilfully attending (or 'clinging') to them. James was well aware that the mind sometimes entertains multiple ideas, with the strongest taking precedence over the weaker ones. Now he added that selective attention could change the relative strength of an idea, bringing it to greater intensity in the centre of consciousness, while other ideas recede as a consequence to the margins of awareness. In short, James made Carpenter's observation about occasional ideo-motor action into a full-blown ideo-motor theory, with an important codicil about how ideas come to be, or not to be, in the centre of one's consciousness. This is precisely where subjective interest and wilful attention come into play, James concluded. Will, in this rendition, is equivalent to enhanced selective attention, which is directed by our interests. (James later clarified that our interests can be aesthetic and moral as well as intellectual and practical.) Will creates nothing; it does not directly affect action, it can only do so indirectly by increasing the prominence of one idea over others, thereby 'loading the dice' for one action over others. (Another way to say this is that we cannot will a movement independently of thinking about it.) In this way only do dominant ideas bring about 'voluntary action' as opposed to involuntary, instinctive or habituated responses.

This psychological explanation, giving a restricted yet significant role to personal interest and selective attention, provides the essential framework for James's chapter on 'The Will' in his *Principles of Psychology*. In that chapter, he explains and defends his ideo-motor theory and outlines 'Five Types of Decision' according to the prominence, conflict or absence of competing ideas. He also discusses extreme cases of 'The Explosive Will,' in which the impulsive power of ideas is not sufficiently repressed by countervailing ideas, and 'The Obstructed Will,' in which the repression of ideas is excessive. Clearly, what James offered was primarily a phenomenological description of the experience of will. Simple though it is, it bears consideration as contemporary research re-opens the matter of selective attention and its relation to will or willpower. The proof of its theoretical adequacy will depend, of course, upon the accumulation of scientific evidence, but its practical utility will be judged best by psychotherapeutic outcomes. Can a focus

on certain ideas or images facilitate behavioural change, whether immediately or after repeated occurrence, whatever might be going on ‘behind the scenes’ in terms of biochemical transformations and neurological processes? Research on meditation suggests that it can. What about therapeutic success? More should be made of this, especially among those who typically emphasise biomedical factors in treatment settings. More particularly, it might be useful to explore James’s claim that, although individuals cannot directly will a change in their psychiatric condition, they can and should maintain a focus on the idea of an alternative, keeping that idea forcefully in mind during the course of whatever kind of therapy might be taking place. It cannot hurt, and it might well prove to be beneficial. A good deal of research, after all, has shown that the mind is much more powerful, in a variety of ways, than was once assumed.

This is all reminiscent of Viktor Frankl’s comment, very possibly made with James’s views in mind, that even when all other means of changing a situation are blocked, as in a concentration camp or a severe psychiatric condition, one can at least posit one’s own attitude toward what is happening in one’s life.⁷ That attitude, expressing a firmly held idea or wish for another state of affairs, may well contribute, along with other remedies, to a positive change. William James, the grateful recipient of many British ideas, certainly thought so.

Interested persons can find additional information about James and his work, relevant to this essay, in references⁸⁻⁹⁻¹⁰⁻¹¹. The title of the last reference, ‘A moralist in an age of scientific analysis and skepticism’, is used to describe James, but it comes, in fact, from James’s own description of the British novelist George Eliot, indicating yet another link between James and British authors.

David E. Leary is University Professor Emeritus at the School of Arts and Sciences, University of Richmond, USA.

One of the most difficult things about writing a book for general readers on mental health (and, more particularly, psychiatry) is knowing how to structure it – and where to begin. The authors of this very comprehensive book, a liaison psychiatrist (Ellen) and a writer–comedian (Deveny), have both experienced depression and they share their tales with considerable frankness and humility. However, instead of beginning with these engaging stories, they choose to start with a section on diagnosis and classification – which might unfortunately deter some from continuing.

There are really useful sections on how to talk to friends who you think might need help and what happens when you go to see a mental health professional. However, my particular favourite has to be ‘clues your shrink is a dud’, which warns against those who claim excessive certainty, have a guru mentality and are excessively expensive. And therein lie clues that this book doesn’t originate in the UK, but hails instead from Australia. The text has clearly been edited for the UK edition, with reference to clinical commissioning groups, mental health trusts and a list of UK organisations from which further help can be sought. However, there is, for example, no reference to the problems faced by those from UK ethnic minorities, the section on drugs mentions neither ‘skunk’ or ‘legal highs’ and the classification system is, of course, DSM.

Readers of this book would learn a great deal about mental health and illness from a biopsychosocial perspective. They might, however, be left with an idea that there is considerably more choice of professional and therapist in the National Health Service than in reality – although this may of course be true if they can pay. Personally, I don’t see any problem in asking your GP if they are good at mental health, and I wish it was easier to ask for second opinions. The authors tell us ‘remember you are in charge!’ but for many people seeking help it rarely feels that way.

2020-04

Contents

- *Hanafy Ahmed Youssef, DM, MRCS, FRCPsych*

Formerly Consultant Psychiatrist, St Davnet's Hospital, Monaghan, Ireland

Hanafy Youssef, who died at the age of 80 on 21 January 2019, was a leading figure in Irish psychiatry. With his colleague John Owens, he set up the first community-based psychiatric service in Ireland. He was able to show that this pattern of service led to better outcomes for patients and their families. As a result, a number of other community-based services in Ireland and the UK were established.

Over a 20-year period in the 1980s and 1990s, he developed a highly productive research relationship with Professor John Waddington of the Royal College of Surgeons, Ireland. Together they published many papers on aspects of psychotic illness occurring in patients referred to the Cavan/Monaghan psychiatric services. Hanafy Youssef contributed to over 60 publications in the fields of psychotic illness, neurodevelopmental psychiatry and psychopharmacology. The relationship between the Cavan/Monaghan psychiatric services and the Department of Psychopharmacology at the Royal College of Surgeons, Ireland, continues to this day.

Hanafy had a strong interest in postgraduate psychiatric education. He was clinical tutor at St Davnet's Hospital and a member of the Irish Psychiatric Training Committee. He had a great capacity for explaining difficult concepts to medical and nursing staff. Indeed, as an educator, he was at the forefront of psychiatric education in Ireland. He was also a mentor to many overseas doctors who worked with him. He was an inspiration to them as they saw him become a leader in his specialty. He was a particularly strong supporter of women in medicine at a time when women doctors were still finding it difficult to climb the career ladder.

He had a great interest in the development of psychiatric services in less economically developed countries. In the 1970s he spent time in Zambia, developing clinics in rural areas and helping to confront the stigma often attached to psychiatric illnesses. From 1994, he spent 2 years in a professorial post in Trinidad and Tobago, where he helped improve the quality and prominence of undergraduate psychiatry training. He felt this was crucial if the finest doctors were to be recruited into the specialty. He then returned to take up a consultant post in liaison and general psychiatry at Addenbrooke's, a teaching hospital within Cambridge University Hospitals NHS Foundation Trust. In addition, he carried out voluntary work with charities in Yemen and Libya, providing both general medical and psychiatric care in areas where there was a shortage of doctors.

Hanafy was also a philanthropist, fiercely passionate about social justice, who took seriously the welfare of the less privileged. Together with his siblings he established Latifa's Orphanage House and a mosque in the suburbs of Alexandria. He worked tirelessly for the underprivileged and would offer free medical care to any in need.

Whether they spoke to him in person, heard him speak at international conferences or were his patients, Hanafy Youssef left a lasting impression on all he met. His knowledge, dedication to his field and commitment to his patients were widely appreciated.

He came from humble beginnings. He was born on 14 January 1939 in Alexandria, Egypt, to Ahmed Mahmoud and Latifa (née Taher). His father ran a hunting and tackle store there. Hanafy studied medicine at Alexandria University and undertook postgraduate training in the Department of Psychiatry at the University of Cairo. At university, he led an extremely active life, both in cultural pursuits and in sport. He authored several published novellas in Arabic, won a national poetry award and was the arts reviewer for the university paper. At the same time, he was a member of the university football and wrestling teams. He took an interest in science and politics, and became multilingual, adding French and Russian to the Arabic and English he spoke before entering university. After qualifying as a doctor, he spent 2 years as a medical officer in the Egyptian Army, including service during the Arab–Israeli Six-Day War.

He moved to Derry in 1971 to obtain further training in psychiatry and fell in love with Ireland and its people. This is where he met his wife Ann. He obtained a consultant psychiatrist's post at St Davnet's Hospital, Monaghan, in 1975 and spent most of his career there.

Hanafy retired in 2001 and enjoyed his retirement years in Armagh. He remained highly active, interested in medicine and writing about and closely following the struggle of his Egyptian compatriots for freedom and progress. He published several papers on the history of psychiatry, reviewed books on psychiatry and had several letters published in national broadsheets on a wide range of subjects. He was very proud of his family and their achievements.

He passed away peacefully surrounded by his family. He leaves Ann, his wife of 46 years, five children (Emma, Mahmoud, Latifa, Zahra and Omar) and three grandchildren.

date

2020-12

Abstract

Despite the increasingly widespread use of video consultations, there are very few documented descriptions of how to set up and implement video consultations in real-time practice. This step-by-step guide will describe the set-up process based on the authors' experience of two real-time National Health Service (NHS) examples: a single health board use (delivered in normal time), and an All-Wales National Video Consultation Service roll-out (delivered during an emergency pandemic as part of the COVID-19 response). This paper provides a simple visual step-by-step guide for using telepsychiatry via the remote use of video consultations in mental health services, and outlines the mandatory steps to achieving a safe, successful and sustainable use of video consultations in the NHS by ensuring that video consultations fit into existing and new NHS workflow systems and adhere to legal and ethical guidelines.

There is a large and growing evidence base of published data that demonstrates an overall consensus of suitability, acceptability and satisfaction regarding the use of digital technology,¹⁻⁶ particularly video consultations for the purpose of remote assessments and appointments in mental health, known as ‘telepsychiatry’.⁷⁻¹⁵ Telepsychiatry is widely reported to be at least as efficient and effective as traditional face-to-face care, providing improved clinical and quality of life outcomes across a wide range of population groups and settings.⁷⁻²⁰ Studies have compared video consultations with standard in-person care and concluded that video consultations might be superior to in-person consultations for some forms of treatment and population groups.^{2,7} The evidence base for telepsychiatry remains strong and consistent across mental health studies for both adult and child services.⁷⁻²⁰ It is commonly argued that mental health and psychiatry are particularly well suited to video consultations and that the psychiatric interaction translates exceptionally well to the technological world. This is because many treatments are based on interpersonal ‘talking therapies’ and medication management, which typically do not require any other medical devices for clinical use, perhaps in contrast to other specialties.²¹ Video consultations have the potential to offer many additional benefits to patients, families and clinicians besides treatment. They are reported to improve and widen patient and family access to healthcare, support co-production and self-management, increase efficiency and improve clinical outcomes, as well as significantly reducing clinical time and patient and family travel.^{2,22,23}

Local evidence to support this step-by-step guide

The CWTCH quality improvement project

In 2019, the Health Foundation²⁴ funded Aneurin Bevan University Health Board (ABUHB) for 1 year to establish a telepsychiatry programme with the objective of providing mental health appointments to children and adolescents within Gwent mental health services. This ABUHB programme is called Connecting with Telehealth to Children in Hospital and Healthcare (CWTCH). It is a National Health Service (NHS) quality improvement project that provides faster and more efficient appointments in child and adolescent mental health services (CAMHS) using a communication platform called Attend Anywhere (<https://www.attendanywhere.com>). The programme tested the suitability and acceptability of telepsychiatry and measured satisfaction across a wide range of settings and uses, including paediatric wards for emergency assessments, out-patient appointments, medication reviews, autism assessments, school post-vention clinics for pupil suicides, virtual groups and more. It demonstrated that telepsychiatry in CAMHS is a highly suitable adjunct to routine ways of working; once people became familiar with this way of holding appointments, it was rated as acceptable and satisfactory by patients, families and clinicians.^{25,26}

Rebranding of CWTCH and Royal College of Psychiatry endorsement

CWTCH has now been rebranded and is called CWTCH Cymru. It has received local and national recognition for its success and is now considered an exemplar of good practice across Wales. CWTCH Cymru and its guiding principles²⁶ have also been endorsed by the Welsh Royal College of Psychiatrists.²⁷

Partnership and development of the national roll-out of video consultations

In March 2020, in response to the COVID-19 emergency, CWTCH Cymru went into partnership with Technology Enabled Care (TEC; <https://digitalhealth.wales/tec-cymru>) and the Welsh Government to form a National Video Consultation Service.²⁸ This service is currently rapidly scaling up the routine use of video consultations across Wales, using the Attend Anywhere communication platform, to all appropriate primary, secondary and community care services, including mental healthcare for all ages. The National Video Consultation Service has a fully resourced website, with helpful guides, videos and toolkits, which can be accessed and used in addition to this paper.^{28,29}

Video consultation experience and lessons learned

The experience gained from working on two very different sized projects (small versus large scale) and in two very different contexts (normal versus pandemic) has demonstrated that regardless of the scale and rate of adoption, there are distinct challenges in introducing video consultations as a new way of working in the NHS for clinicians. Clinician acceptance and use of video as an accepted alternative to established ways of working were found to be rate-limiting factors with respect to adoption and spread. This challenge is defined by the authors as ‘clinician need versus clinical need’. This definition suggests that video consultations are more likely to be adopted and accepted as a feasible approach to healthcare delivery when the ‘need’ for this way of working is defined and accepted by the clinician or service, compared with when they are defined and accepted as a clinical need. In other words, video consultations are generally more successful and sustainable when a clinician or service perceives the need themselves and requests the service, rather when they are motivated by the projection of need or want from their patient population. It is therefore essential to establish and define this ‘need’ within a service, seeing clinician/service ‘pull’ for video consultation as an essential criterion for successful adoption. When the perceived need for video consultations by clinicians and services increased in the pandemic context, there was greater willingness to test new ways of working and overcome perceived or internal barriers to change. This has significant implications for how video consultations should be introduced into services and organisations, highlighting the need to focus on both the technical and the cultural aspects of the adoption process. These findings mirror the work of Greenhalgh et al and their ‘NASSS’ (non-adoption, abandonment and barriers to spread, scale-up and sustainability) framework.³⁰

Rationale and objectives

Despite the increasingly widespread use of video consultations, there are very few visual and fully documented descriptions of how to set up and implement such consultations in real-time practice with specific attention to features such as fitting into existing systems and the legal and ethical requirements of video consultations. This step-by-step guide will describe the process based on two examples: a single health board project (delivered in normal time), and an All-Wales National Video Consultation service roll-out (delivered during the COVID-19 pandemic emergency).

Methods

This paper was designed to be a simple and visual step-by-step guide describing how to set up and use video consultations for mental health services, including a range of ‘technical’ skills and knowledge that clinicians and services may find helpful for the adoption of video consultations. This paper will describe the various steps that have been taken by the authors in their real-time experience to initiate and implement a new video consultation programme in an existing NHS systems. The visuals used on the TEC website and in this paper are adaptations and syntheses of work from other recent video consultation reports in the UK.³¹⁻³³ Note that the visual diagrams and infographics used in this paper are examples based on the communication platform Attend Anywhere (<https://www.attendanywhere.com>); therefore, descriptions and instructions may differ slightly depending on the type of platform used in your health service.

Ethical approval was obtained from all seven Welsh research and development departments. Consent was obtained from all participants in both CWTCH and the National Video Consulting Service.

Results

Step-by-step guide

This section of the paper will provide a step-by-step guide that is divided up into three distinct sections. The first section demonstrates how to set up video consultations in an existing healthcare workflow. The second section provides the appropriate steps regarding ethical and legal principles. The third section discusses how to use video consultations in a secondary care health service, with the help of an infographic diagram.

A guide to setting up video consultations in existing systems

Managing the video consultation service

Within your healthcare service, you will need to identify a lead clinician who will decide how best to set up, use and manage the video consultations (*Fig. 1*). This person will be the ‘point of call’ for your service and its use of video consultations. *Fig. 1* Workflow visual guide. Diagram from the Welsh National Video Consultation Service Toolkit.²⁹

Setting clinical criteria

Your healthcare service will need to define and agree on clinical criteria for video consultations and the suitability and appropriateness of appointment types. Following this agreement, a template for triage or suitability would need to be developed and provided to the person(s) in charge of making video appointments, e.g. a receptionist.

Making and managing appointments:

Your service will need to identify how video consultations will be made, and who will make and deliver these appointments. Your service will also need to identify how appointment links and information will be sent to patients – for example, via a letter, verbally or via an SMS text or email – and how appointment slots will be offered, documented and given to the delivering clinician. In addition, your service will need to decide how the video consultation will be managed, how clinical templates and coding will be used for video consultations, and how these will be matched to existing systems. Your service will need to have a contingency plan for possible scenarios or problems (for both technical and clinical possibilities). Finally, your service will need to consider how clinical information is later documented, for example, similarly to the hand-written notes used in usual practice.

Setting up the clinical space

Your health service will need to identify how video consultations will be set up. For example, you will need to think about factors such as the room layout, e.g. whether it is well-lit and well-positioned, confidentiality issues and clinical appropriateness. More about this can be found in the following sections.

Additional considerations

Your service will need to decide how to deal with providing additional information; for instance, if the picture definition obtained via a video consultation is not good enough to allow accurate visualisation and identification of skin lesions, your service needs to decide how to obtain this additional information. It is important that patients are able to receive patient information leaflets as they would in a standard consultation. Your service needs to decide the best mechanism for communicating this information to them. For example, you could email them. Your service would also need to consider additional plans for in-person contact, such as for collection of prescriptions.

A guide to risk, safeguarding and ethical guidelines

Key considerations in the use of video consultations include legal and ethical issues, such as defining and documenting patient suitability and the role of the clinician, risk assessments and contingency planning, privacy, confidentiality, security and consent (*Fig. 2*). Appropriate strategies covering ethical issues will be necessary, such as taking informed consent and ensuring confidentiality and security while using technology, and procedures for conducting risk assessments. *Fig. 2* Legal and ethical visual guide. Diagram from the Welsh National Video Consultation Service Toolkit.²⁹ VC, video consultation.

Define and document clinical suitability and appropriateness

Your healthcare service will need to define and agree to clinical criteria for video consultations and the suitability and appropriateness of appointment types. This defining and documentation process would need to include the roles and responsibilities of clinical staff.

Risk, safeguarding and ethical considerations

All types of mental health services using video consultations, regardless of their level of risk, should consider conducting risk assessments, and abide by safeguarding principles and ethical guidelines.

To start thinking about the population your service will deliver a video consultation to, and the risk exposure that may arise, it is advised to conduct an initial ‘process mapping’ of your service. Process mapping will help your team to define video consultations in the context of your service, understand who is responsible for what and where, and to flag up any potential concerns or risk exposures. Process mapping and risk assessment will help your service to start thinking about and understanding what types of risks may arise in specific situations, and possibly how to avoid them.

You would need to think about the following. •Would using video consultations instead of in-person care increase risk in any way?•If so, what are these risks, and can they be resolved?•Is the risk of using video consultations greater than not seeing the patient at all?•Would these risks be the same if the service was delivered in person?•What other types of risks might there be – such as the setting, environment and clinical outcome?

On completion of process mapping and initial risk assessments, the next step would be to start thinking about – and formally agreeing to and documenting – clear and concise safeguarding contingency plans for your video consultation service. This would involve a ‘what to do’ plan in the event of an emergency or concern arising during a virtual appointment. It is advised to list a wide range of scenarios, ranging from low- to high-risk possibilities. Make it as specific to your service as possible, to make potential scenarios relatable to your staff. When developing the contingency plan, think about who is best suited to develop it and who will be following it, and consider a wide range of opinions and possibilities. Develop a list of all possible scenarios and all levels of risk exposure, and make them specific, applicable and relatable to your service.

Ethical guidelines

Video consultations, like any other form of healthcare delivery, will need to be treated exactly the same way as in-person care with regards to ethical guidelines and procedures. However, owing to the obvious remoteness of a virtual appointment, there are additional ethical considerations which need to be considered and applied, such as confidentiality, privacy and security issues.

It is essential that a video consultation service replicates an in-person appointment or assessment as much as possible. For example, the setting of an appointment room would ideally need to be the same as an in-person appointment room, e.g. if your service would normally use a private room for an in-person appointment, then a virtual appointment would also need this. It is also important to ensure that the platform used for video consultations is safe and secure, and that it meets your existing health systems standards, including software encryption. Many popular video chat platforms such as FaceTime and WhatsApp are not compliant with healthcare standards; therefore, you would need to seek out a safe and secure platform such as Attend Anywhere (<https://www.attendanywhere.com>).

Informed consent is the process of seeking agreement from a person before taking a course of action that requires consent. Informed consent is required from any person who is receiving a video consultation. There are two types of consent. •Implied consent (or tacit consent), which is signalled by the behaviour of an informed person in agreement. This type of consent is typically used in the delivery of ‘in-person’ healthcare.•Explicit consent is when a person actively agrees, either verbally or in writing. This type of consent is highly recommended for video consultations, as signalled (implied) behaviour may be more difficult to capture remotely.

To obtain consent, the person giving it would need to be considered to fully understand the process and to have full capacity to do so. A person with incapacity, such as a child or vulnerable adult, may not be able to give informed consent; therefore, parental or guardian consent (known as assent) would be required.

A guide to conducting the video consultation

The final step of this guide describes how to use video consultations in a secondary healthcare service (*Fig. 3*). *Fig. 3* How to use video consultations visual guide. Diagram from the Welsh National Video Consultation Service Toolkit.²⁹

Define and document clinical suitability and appropriateness

As shown in the above *Figs 1* and *2*, your healthcare service will need to define and agree to clinical criteria and patient suitability for video consultations. This is considered the most important step for video consultations.

Contact the patient and send instructions and video call link

Depending on the type of communication platform (e.g. Attend Anywhere) you will be using, the patient will need to be offered the video appointment; they will then need to agree to it, after which they will need to be sent the patient information sheet and URL link to access the video call.

Set up video call and start consultation

Again, depending on the type of communication platform you will be using, there will need to be clear steps set out to determine how best to use video consultations in your service.

Evaluation component

To ensure that the use of video consultations is properly integrated into your health service, it is important to capture feedback on use, acceptability, suitability and satisfaction. It is therefore advisable to establish an evaluation framework to capture this. An example of this may include attaching a basic satisfaction survey to the end of the video consultation, asking a few ‘how did it go’ questions.

For additional information, please see the TEC website (<https://digitalhealth.wales/tec-cymru>), which provides a detailed step-by-step guide on setting up a video consultation (*Fig. 4*), healthcare-specific toolkits, including examples of information sheets, suggested scripting for clinicians, technical guides to the Attend Anywhere communication platform and much more. *Fig. 4* Infographic visual guide: video consultations in secondary care. Diagram from the Welsh National Video Consultation Service Toolkit.²⁹

Conclusions

This paper outlines a simple visual step-by-step guide to help clinicians to set up and use video consultations in mental health services. This resource has been used to support clinicians to gain the technical skills and knowledge required to routinely use video consultations in practice. In addition, we found that there is an important ‘cultural’ aspect to successful adoption of video consultations, where the rate-limiting factor for successful adoption is the ‘need’ and ‘pull’ for this way of working to be defined and accepted by the clinician or service.

When the perceived need for video consultations by clinicians and services increased in the pandemic context, there was greater willingness to test new ways of working and overcome perceived or internal barriers to change. It will be interesting to see whether having made the change to this new way working in the pandemic context, clinicians and services actively choose to maintain these newly gained technical skills – and also whether patients and carers, having experienced video consultations for the first time, increase their demand for this to become a new ‘routine’ way of working. As use of video consultations increases, we will also undoubtedly learn how to titrate this offer according to need, circumstance and demographics, and discover which healthcare treatments can best be deployed or augmented through the use of video consultations.

This paper provides a guide to using video consultations in the NHS, based on personal experience of the authors and feedback from their evaluation. However, it is still early days for video consultations in Wales, and more research is needed to understand more about their use, particularly what can and can't be done using video consultation, as this is still unspeculative and unproven.

Gemma Johns is Research & Evaluation Lead of CWTCH and TEC Cymru ABUHB, Wales, UK. Gemma worked on both the CWTCH and National Video Consultation project and led the evaluation for both. **Jacinta Tan** is a Child and Adolescent Mental Health Consultant Psychiatrist and Project Manager of CWTCH, ABUHB. **Anna Burhouse** is the Health Foundation QI Adviser for CWTCH and supported the evaluation of the National VC programme, Northumbria Healthcare NHS Foundation Trust. **Mike Ogonovsky** is Assistant Director of Informatics ABUHB and Senior Responsible Officer of TEC Cymru. **Catrin Rees** is at Life Sciences Hub, Welsh Government, and is a Graphics & Web Designer for TEC Cymru. **Alka Ahuja** is a Child and Adolescent Mental Health Consultant Psychiatrist, Clinical Lead for TEC Cymru, Chief Investigator for CWTCH.

G.J. contributed to the main write up and development of the paper; she developed the manuscript draft, designed the template of the visual and infographics, and was involved in the overall structure and design, and in making amendments to the final manuscript. J.T. helped structure the manuscript and contributed clinical understanding to the guidelines, visuals and infographics. A.B. contributed some of the written text in the paper and wrote up the conclusion, and also helped structure the final manuscript and helped with amendments. M.O. contributed to the development, structure and reading of the manuscript (draft and final), and provided a technical and overall National Programme perspective on the paper and its guidelines. C.R. redesigned the draft templates into the final graphics for this paper, including the four visuals and the infographic, and also contributed to the structure and reading of the manuscript. A.A. was responsible for overseeing the entire development of the paper, helped structure the manuscript (draft and final), developed and shaped the clinical and technical perspective on the clinical guidelines provided in the paper, and helped develop the visuals and infographic.

The CWTCH project was funded by the Health Foundation as a quality improvement project in Aneurin Bevan University Health Board in Wales. The National Video Consultation Programme is currently being funded by the Welsh Government to test video consultation across all of Wales.

1.3.16 Defining what a ‘carer’ is and the role they play in in-patient mental health-care: A focus group study with patients, carers and clinicians

Aysegul Dirik Justina Kaselionyte Domenico Giacco Stefan Priebe **Correspondence:** Aysegul Dirik. Email: a.dirik@qmul.ac.uk

date

2020-09

Abstract

Background

The value of carer involvement has been extensively researched and promoted. However, the field lacks exploration of conceptual issues, which might help to explain why there are widespread difficulties in putting policy into practice in this area, as implementation rates remain low internationally.

Aims

This qualitative study explored patients’, carers’ and clinicians’ perspectives on the role of carers in mental healthcare, particularly with regards to in-patient settings.

Method

Sixteen focus groups were conducted with patients, carers and clinicians who have current or previous experience of in-patient settings. A thematic analysis was conducted on the transcripts, exploring two key domains: (a) what a ‘carer’ is, and (b) how the ‘carer’ role is described within the context of the hospital environment.

Results

Participants diverged in their opinions of what the ‘carer’ role entails, and the perceived helpfulness of it. Issues unique to the in-patient setting were identified, such as the role of the hospital environment in enabling or being a barrier to carer involvement. These differing perspectives and contextual factors had an impact on the position of carers in the hospital setting, as they could be viewed as helpful, a hindrance or as passive visitors, depending on the perspectives of clinicians.

Conclusions

More clarity and agreement is needed between patients, carers and clinicians in terms of how the ‘carer’ role is defined. This has the potential to improve carers’ experience of involvement in hospital settings.

Background

In the field of mental healthcare, the involvement of family and friends, often referred to as ‘caregivers’ or ‘carers’, has been demonstrated to be useful for a variety of outcomes for patients. This includes a decrease in relapse and rates of readmission to hospital.¹ The efficacy and implementation of carer involvement has therefore received much attention in research and carer involvement policies and guidelines are widely promoted in mental healthcare internationally (for example from the UK National Collaborating Centre for Mental Health² and UK Department of Health and Social Care³). However, the literature lacks an examination of fundamental conceptual issues,⁴ the exploration of which might help us to better understand why carer involvement is so widely promoted in theory yet so poorly or inconsistently implemented in practice, both in the UK and internationally.^{5,6}

‘Carer’ is a policy-derived term, which aims to value the contribution that family members and friends make to patients’ care. However, there is a need to explore how the ‘carer’ role is actually understood by patients, their family members and friends and front-line clinicians. This is especially pertinent in hospital settings, as patients may be admitted to hospital following the deterioration of relationships or as a result of a breakdown in their usual social support networks.⁷ There is therefore value in exploring this topic to better understand how ‘carers’ are viewed in the context of mental healthcare, and how this might have an impact on the nature of their involvement in patients’ care.

Research question

How do patients, carers and clinicians conceptualise the role of carers in the context of mental healthcare and in-patient settings?

Method

Design

Focus groups were conducted with patients, carers and clinicians to explore their opinions and experiences of carer involvement in in-patient mental healthcare. The groups were conducted as part of a larger study of stakeholders' views on what carer involvement in in-patient mental healthcare should entail, and the methodology is described in further detail in a separate article.⁸ For the present part of the study, the topic guide contained questions and prompts pertaining to participants' conceptualisations of what the carer role entails, and the use of the term 'carer'.

Participants

Purposive sampling was used to recruit patients and carers through the East London NHS Foundation Trust in-patient and out-patient mental health services as well as local service user and carer organisations located in the London Boroughs of Hackney, Newham and Tower Hamlets. Advertisements were put on social media (Twitter and Facebook). All clinicians who participated in the study worked in in-patient services at the East London NHS Foundation Trust.

Maximum variation sampling was used to ensure a diverse sample of participants across mental health settings (acute in-patient units, triage wards, community settings), local boroughs and, in the case of staff, job positions. Patient and carer participants were recruited both from settings where a patient was currently in hospital, and from those who had been admitted to hospital within the past 5 years. Additionally, carers were recruited from both settings where an individual might already self-identify as a 'carer' (for example carer organisations) and settings where they might not do so (for example by being approached by a clinician when they visit a relative in hospital). Carers could also self-refer by responding to adverts shared widely via email lists, Twitter and bulletin boards. The advert did not use the word 'carer' but instead asked 'have you or someone you support ever been admitted to hospital for mental health reasons?'. This was to attract participants with potentially wide-ranging views on the 'carer' role, as well as those who were not familiar with the term 'carer'.

Sample size was initially planned on the basis of aiming for 6–8 participants per focus group, and 6–12 groups in total, as recommended by Finch, Lewis & Turley (cited in Ritchie et al).⁹ This was envisaged to allow for active participation for all members while giving individuals opportunities for more detailed discussion. However, adjustments were made for each group type, for example carers and clinicians were invited in higher numbers, to allow for the possibility that a proportion would cancel because of caring or working responsibilities.

Patients over 18 years old who were able to provide informed consent, had experience of admission to psychiatric hospital (within 5 years) and sufficient command of English were eligible for the study. Carers were eligible if they were over 18 years old, had experience of supporting someone who was admitted to psychiatric hospital (within 5 years) and sufficient command of English. Clinicians had to have current experience of working in acute in-patient settings.

Potentially eligible patients who were identified by clinicians were asked permission to receive further information from researchers about the study. Patients, carers and clinicians who self-referred were also given the opportunity to discuss details of the study with the researcher, before arranging to attend a focus group.

Ethics statement

All procedures contributing to this work comply with the ethical standards of the relevant national and institutional committees and with the Helsinki Declaration of 1975, as revised in 2008. Ethical and institutional approvals were provided by the East London NHS Foundation Trust and the East of England – Essex NHS Research Ethics Committee (ref:15/EE/0456). All participants provided their written informed consent to take part in the study, as well as providing verbal consent to begin recording.

Procedures

Focus groups were facilitated by two researchers, with at least one clinically experienced and able to provide support if any of the participants became distressed or agitated. Except for one mixed patient–carer group, separate focus groups were conducted with carers, patients and clinicians to account for possible counterproductive dynamics between the groups and ensure that each group could express their views freely. Although up to ten participants were sought for most of the focus groups, smaller groups of three to five participants were arranged with patients who were currently in hospital, to minimise overstimulation and allow each participant to share their opinions comfortably.

A topic guide was developed based on guidance in Ritchie et al⁹ and was designed to facilitate up to 90 minutes of discussion. Each of the three participant groups had a slightly amended version of the same topic guide, so that the questions were relevant to them as patients, carers or clinicians. The initial aim of the guide was to gather opinions to develop a carer involvement intervention to be used in in-patient settings. After introductions and ground-rule setting, two main topics were introduced, each with a set of questions, probes and prompts to encourage active participation of all members. The discussion topics began (a) generally, asking participants about their views on carer involvement in mental healthcare, and (b) developed into specific questions about how to involve carers in hospital settings, including a discussion of barriers and facilitators to involvement in different clinical procedures. The topic guide was amended after five focus groups, as the questions on hospital procedures and potential interventions were refined following discussions in the initial groups.

The guide was applied flexibly to enable open discussions within each group. Consequently, although the whole topic guide was covered in each group, different groups discussed some topics more in-depth than others. Participants were asked open-ended questions to stimulate discussions, and all questions were posed as neutrally as possible to encourage them to express their honest opinions. For example, they were asked what they think about the term ‘carer’ and following this, they were asked to discuss what the helpful and unhelpful aspects might be of involving carers in in-patient treatment.

Analysis

The focus groups were audio recorded and transcribed using intelligent verbatim and omission of identifiable information, such as names. The analysis was conducted independently of the linked study,⁸ which had focused on the practicalities of barriers and facilitators to carer involvement in in-patient treatment. NVivo software was used for coding and organising data during the analysis. Interim analysis was conducted by J.K. and A.D. after nine focus groups and a decision was made to continue with recruitment. After 16 focus groups, J.K., A.D. and D.G. had a reflective discussion about whether saturation of themes had been reached, and it was decided to cease recruitment.

Inductive thematic analysis¹⁰ was used to analyse the transcripts. This involved looking for common themes and exploring whether there are any similarities and differences between the participant groups. The stages included initial familiarisation with the data corpus by reading all transcripts. Initial coding of the transcripts was then conducted for all transcripts with the research question in mind. Distinct areas of exploration were then identified through the initial coding, and further analysis was conducted within the framework of two domains: (a) what a ‘carer’ is, and (b) how the ‘carer’ role is described within the context of the hospital environment.

An iterative process of identifying subthemes through reflective discussions was conducted throughout the analysis. Labels were attached to each quote during the coding process to identify whether it came from a patient, carer or clinician. Comparisons between the three participant groups were then made at later stages of analysis, once initial

themes had been formed. Clusters of related subthemes were converted to overarching themes, with transcripts and quotes being re-checked to ensure consistency of the themes. For example, initial coding of quotes describing ‘battles’ were further analysed to understand which aspect of the hospital context and/or procedures was resulting in this perception, and what this meant in terms of being a ‘carer’. Largely, these quotes described how carers were perceived by professionals as being ‘difficult’ and there were several examples from different participant groups to support this view. These quotes were placed into themes after the transcripts were checked for alternative views. After finalising the themes, quotes were extracted for the article for transparency and to illustrate the findings, although some demographic information was changed to preserve anonymity.

All transcripts were independently coded and analysed by A.D., a researcher with a primary interest in patient perspectives on family involvement and J.K., a researcher with interests in sociocultural perspectives on mental health. The findings were discussed and agreed with a third researcher (D.G.), an academic and clinical psychiatrist who had also conducted some of the focus groups and was familiar with the transcripts. These backgrounds may have influenced each author’s personal interpretation of the themes. However, efforts were made to maximise the rigour and trustworthiness of the analysis process by analysing the transcripts separately and then having multiple reflective discussions on the development of the themes. Any points of disagreement were discussed and the transcripts were re-checked throughout the analysis process before deciding on the final themes.

Results

Participants

Eighty-six participants attended 16 focus groups held between 2014 and 2016. This included 31 patients, 22 carers and 33 clinicians. Four focus groups were held with carers, five with patients, six with clinicians. Clinician focus groups were broadly separated by profession: ward managers, nurses, psychologists, psychiatrists and support workers. One mixed group was held with both patients and carers. Smaller groups were held for participants currently in acute treatment to support their participation; the size of all groups varied from three to ten participants. Sociodemographic characteristics of the participants have been provided in *Table 1*. All participants had experience of voluntary or involuntary admission to a psychiatric hospital within the past 5 years, either as a patient, carer or staff member. Further demographic details about the participants are available in the linked study.⁸

Table 1 Sociodemographic characteristics of participants											
Patients	Carers	Clinicians									
Gender, n	Men 16	21	Women 15	20	17						
Age Mean (s.d.)	43 (12.3)	51 (15.8)	40 (10.4)	Undisclosed n	8						
Role, n	Patient 31	Parent 14	Partner 3	Sibling 2	Son/daughter 2	Sibling and daughter 1					
Psychiatrist	6	Psychologist	4	Nurse	10	Ward manager	6	Support worker	6	Activity coordinator	1

Thematic analysis

The thematic analysis was divided into two domains: exploring participants’ understanding of the ‘carer’ role and how they describe the role they play in hospital settings. Unless otherwise specified, the themes appeared in all three participant types: patients, carers and clinicians. The Appendix contains a summary of the themes and subthemes within these two domains.

Domain one: who or what is a carer?

It was difficult to find a universally acceptable term for a ‘carer’, as there was diversity in participants’ perceptions of what a ‘carer’ does. To some extent, caring could be seen as an every day part of human relationships. Some carers felt it did not need a label or further recognition, and so they preferred to use everyday terms such as ‘mother’ or ‘father’ instead. However, some carers viewed the caring role as something that is defined by going beyond what a family member would already do. The term ‘carer’ therefore was seen as a title that recognises this. Some clinicians saw it as more of a service term, used between staff only: “‘Like, I would never say, “This is so-and-so’s carer” in front of the person.’ (Clinician 32) ‘No, of course not.’ (Clinician 31)”

Caring in mental health is distinct from physical health

Participants noted how ‘with mental health patients... every bit counts, no matter how small or big’ (Clinician 22) and often, the support was not always clearly defined, but involved ‘being with’ the person. Carers used words like ‘sitting’ ‘minding’ and ‘monitoring’. Through this they said how there was an element of ‘experiencing with’ the person when one is a carer. This was seen as unique to mental health. Participants also described how carers do what staff cannot or do not do. Many participants felt that carers should be rewarded for reducing the pressure on services and for providing the support that nobody else could.

Furthermore, caring in mental health was described as different to physical health in terms of how it ‘crept up’ on people, and one became a carer ‘gradually’, ‘without noticing’. It was a ‘job with no end date’ because the unique nature of the support meant that there was so much uncertainty in the process. It was also felt that carers had little choice in the process. One patient felt that their family being forced to care was akin to a ‘form of slavery’ (Patient 21). “‘Sometimes you could be caring for somebody for such a long time, you don’t even know when you started, or when you stopped so to say, “now you’re a carer”, it doesn’t work like that.’ (Carer 14) ‘Some people don’t want to care and they’re in a carer role. They’re just angry with them, resentful and I’ve met people who resent being positioned in the family, in the genogram. So location-wise they’ve got that role and they’ve got no choice and [Clinician 12: ‘mm’] and others do it because obviously they want to...’ (Clinician 13)”

Disagreement on when caring begins and ends

Participant groups differed most strikingly in their definitions of when someone can be called a ‘carer’. Clinicians discussed at length the idea that the term ‘carer’ had ‘the idea of some sort of chronicity’ (Clinician 1) and was frequently unnecessary or inappropriate to use it in acute mental health settings. “‘You would use it if you have been yeah, in in mental health services for, you know, quite some time or your relative had an illness that was prolonged for months and months or years then you become a carer but it’s not really something in an acute setting.’ (Clinician 5)”

Similarly, patients often felt they only had a ‘carer’ when they were unwell, as their fluctuating mental and emotional states meant they experienced fluctuating levels of need. This left carers in the position of always needing to be available but not knowing when their involvement would be welcomed or rejected. “‘Well “carer” is to me like ... you’re still not well. You’re still being cared for. I mean I’m at a stage within my recovery where, I’m not being cared for. I’m caring for myself. So I’m my care – they’re just people who are there to help me when I do start falling back and so to me they’re not carers, they’re support.’ (Patient 24) ‘He [previously] referred to me as a carer, yes, but now where he feels that he’s on the road of recovery, he feels that I’m not caring for him as much. But, I am caring for him in what I’m doing for him. I do care for him ... I’m having to be the one that has to access the services. I’m the one that has to attend all the meetings [Carer 19: ‘hmm-hmm’] ...’ (Carer 18)” Although some family members felt the term ‘carer’ was ‘a bit patronising’ as it implied the patient needed care all the time, many others described the ‘24/7’ nature of caring as all-encompassing and requiring constant monitoring in case the person’s symptoms return. One referred to their role as a ‘mind-minder’. Some clinicians also described how they felt carers were the ones who had to ‘deal with it 24/7’ and ‘day in, day out’. “‘We care for them overall... is not just physical or mental. It’s everything. [Carer 17: ‘everything’, Carer 18: ‘yeah’] ... I think the trouble is that there may be people who think, “It’s only when I’m ill in hospital that you have become a carer,” but you are 24/7 worried about it. Worried about when it is going to happen again. [Carer 18: ‘yeah’] ... “Has he eaten?” So it’s all the time care.’ (Carer 19)”

Discomfort with dependency

Participants differed in how they conceptualised dependency. Many clinicians and some patients expressed discomfort with the idea of a patient being dependent on a carer. “‘Err it’s yeah it kind of implies a bit of feebleness about someone who needs the one cared for long time which isn’t necessarily the case and isn’t what we’re aiming for.’ (Clinician 16) ‘A lot of us have evolved from ... I mean, there are probably nurses that do, but most people have moved away from that kind of ... You’ve got a mental health problem, so you are obviously rubbish, you can’t do anything, so you must have a carer, kind of thing.’ (Clinician 28) ‘But then I think there’s also the other side maybe “carer” like you can’t do anything for yourself ... you’re helpless.’ (Patient 7)” Others viewed dependency differently. They were comfortable with the idea that there might be a temporary period where someone has lost their independence and needs support to look after themselves again. This was often described as a major point of contention with staff. “‘Yeah, a carer is ... you know the family, someone you rely on when you can’t cook or clean?’ (Patient 27) ‘It’s like we have to retrain our loved ones what they used to love to do, what they used to do, we we’re teaching them all over again it’s like [Carer 7: ‘baby’]. It’s like they’re babies again [Carer 7: ‘yeah yeah’] but while we’re talking to the doctors and people they don’t get it [Carer 7: ‘no’] because they just think “he’s a big geezer ... a big bloke” [Carer 7: ‘mm’].’ (Carer 8)” Although (as above) some clinicians expressed discomfort about disempowering overtones, many carers saw irony in this, as the nature of an involuntary hospital admission itself was viewed as paternalistic by some. “‘They’re saying, “They [will] do what they want to do.” Then why do they restrain them? Why do they pin them down? You know?’ (Carer 19)”

Not all ‘carers’ are caring

A difficult issue specific to mental health was that ‘the one group of people who could be their carers are the problems in some way’ (Clinician 13). This jarred with the idea of calling someone a ‘carer’, as they might be implicated in the person’s mental health problems by ‘adding to the stress’ (Clinician 2). Staff did not always know how to work with this contradiction. “‘... we use it in a quite generic way without really thinking about it but a lot of the time they’re not really carers err ... a lot of time they don’t know enough about the condition to be considered a carer and sometimes they do more harm than good.’ (Clinician 16)”

Patients described harm as being misunderstood and being put under pressure to stop ‘playing up’ or ‘attention-seeking’ and that they felt pressure from family members who were pushing for their progress to be ‘two steps further than what it should be’ (Patient 26). They felt strongly that it was their families’ ‘lack of understanding’ that made them feel worse. “‘I don’t think they should have any [involvement]. My family they don’t understand my illness [Patient 8: ‘mm-hmm’] so I’d rather they don’t know anything you know. They don’t understand the illness at all.’ (Patient 9) ‘... It’s helpful for them to be involved because if they weren’t there, we’d have nobody else to help you but at the same time it’s hard as well because they don’t have the knowledge that they need ...’ (Patient 26)”

Domain two: what is a carer’s role in hospital?

The role of the hospital environment

The hospital environment itself was seen as an important contextual factor that overshadowed all aspects of the patient and carer experience. As described next, participants spoke of the atmosphere and procedures as pertinent factors in determining the role of carers.

Frightening atmosphere

All three participant groups' descriptions of the hospital environment mentioned elements that were unwelcoming and frightening, with one stating it was 'scary for the relative, just as scary it is for the patients' (Clinician 17). This was especially the case during the admission process, which was described as 'a traumatic and chaotic experience for all the involved' (Clinician 10). During this time, family and friends could be an 'invaluable' source of comfort for patients, although this was also a time when both patients and carers were more likely to feel traumatised and in need of information to alleviate concerns. Clinicians described how carers might find it 'distressing' to view their relative being restrained or very heavily medicated. For this reason, they sometimes preferred to keep carers away to prevent them from witnessing upsetting scenes. Carers recounted the reassuring impact of 'very calm staff' during these times. "I was terrified.' (Patient 25)'You're scared of the whole situation, so you don't really talk to anyone, you – you don't wanna talk to staff, 'cause it's a frightening experience and it takes a while before you can actually feel settled enough to talk to people and... if your carer is someone that's spent a lot of time with you, they know how you are, so you're possibly gonna open up more to them.' (Patient 24)'Especially when it's your first time. I remember my first time [Carer 1: 'first time'] was a nightmare [Carer 1: 'nightmare'] [Carer 2: 'yeah'] yeah nightmare, bad memories.' (Carer 3)"

Inflexible systems: wards rounds and the medical model

Moreover, the structure of the hospital system itself was seen as an indirect barrier to the meaningful involvement of carers. Ward rounds were viewed by many participants as the main way families can be involved but also the greatest source of difficulty. Carers described them as inflexible and a source of uncertainty and stress. As most important decisions were made there, carers considered consultant psychiatrists to be the most important people to work with. However, clinicians noted that it is the consultants that often have little time to spend with individual patients and carers. "And it can be quite intimidating as well [Carer 11: 'completely']. You walk in and everyone's kind of all eyes on me.' (Carer 3)'it's like a panel [Carer 11: 'yeah'] isn't it?... I still can't get my head round what care co-ordinator, a social worker and somebody else does [Carer 11: 'mhm']' (Carer 14)'... other than the psychiatrist, who else needs to be in the room?... I don't actually know why so many people have to be in the room if they don't have actual involvement in the patient's care? 'Cause otherwise it looks like they're just ... it's one of their team's meetings and we're part of the entertainment.' (Carer 15)"

Clinicians in the focus groups were able to critically reflect on the system that they work in, recognising that it was very rigid, with medication frequently at the forefront of discussions. This placed carers' role on the periphery, as they were often not seen as a core part of the patient's care or the clinical team's routine procedures. Working with carers was seen as a resource-intensive add-on service that was difficult to provide. "The service itself doesn't lend itself for you to implement –.' (Clinician 28)'Yes, it's not flexible enough.' (Clinician 29)' – It's not flexible enough for a carer to access help.' (Clinician 28)' – Because, we work to a medical model. So the focus is we've got this ward round, we've changed the meds and that's... we'll all sit here, you can walk in, your back is against the wall and you've got 15 min, off you go. If that. Because we've got to talk about meds and everything else... It's chaired by a medic. It's their set time and you suit that.' (Clinician 26)' – And we call ourselves a client-led service –' (Clinician 29)' – Yeah, exactly [laughs].' (Clinician 28)"

Patients and clinicians as gatekeepers

Carers were not perceived as having any rights to involvement – the decision was seen as one that either the patient or clinician had to make. Admission was a particularly difficult time as the patient might not have capacity or might feel 'hostile to family'. Clinicians described how this period was a 'struggle' and how difficult it was to 'balance both needs' in these situations. "It's about them [the patients], exactly.' (Clinician 32)'Yes, so it's their choice and their rights.' (Clinician 33)"

Participants from all three stakeholder groups felt it important to override the patient's wishes in order to act in their 'best interests', as carers were seen as a source of contextual information that could facilitate the admission process and as a source of support for patients. Some patients expressed regret that they had excluded carers. However, many still

felt strongly that they should always be the ones to decide the level of involvement. “‘That’s where the carers come in, doesn’t it? Initially the first, second, third day, that’s where the carer’s voice should be heard more than being pushed aside.’ (Carer 17) ‘I think they – they should be involved even if you’re paranoid. If it’s in your best interests that these people know then I think they should be... should be informed.’ (Patient 30) ‘I want them brought in, then I would bring them in but in ten years I’ve only brought them in once. I tell them not everything but I tell them ... um which stuff’s safer.’ (Patient 8)”

The roles allocated to carers

Within this context, the way carers were described could be broadly allocated to one of three roles: (a) a useful resource, sometimes in need of support themselves; (b) troublemakers, creating a hindrance to everyday clinical procedures or (c) invisibles, having no clear role and not being central to anything. The allocated role largely depended on how clinicians conceptualised the role of carers, as the same carers described being included and valued in some settings and excluded in others.

A useful resource, that requires care

Carers could be seen as a useful resource for the healthcare team. One source of their knowledge came from knowing the patient intimately when they were ‘well’ and were able to contrast this with their current mental state. “‘They’ve gone through the process of you going from being well to getting unwell, so they they’re kind of experts around your care and they need to be involved fully with the psychiatrist, the team.’ (Patient 7)”

Carers were then able to advocate for the patient during a time that they had difficulty expressing their needs. They were also seen as supporters of symptom monitoring and treatment adherence. Staff described examples of the involvement of carers resulting in a positive impact on patients’ outcomes, and speedier recovery.

Some saw the carer’s role as a person who is in need of support themselves. Clinicians described how they saw it as their responsibility to support carers individually, while maintaining the patient’s confidentiality. However, often patients’ and clinicians’ descriptions of how to support carers was limited in nature, required consent from the patient, and was largely aimed at supporting the carer to continue caring. “‘I think that calling your family members or a friend or a relative a “carer” is quite good but then there should be a little bit more input in terms of you know supporting them to care for the patient.’ (Patient 20) ‘I think in the case of acute mental health treatment, I think family ... need the most reassurance and the most education as well about what’s going wrong. They need to have their life – have their mental health right so they can care for someone [else].’ (Patient 1)”

Troublemakers

Conversely, carers in the groups described how they could just as easily be seen as ‘busybodies’ and ‘troublemakers’ who were ‘overinvolved’ and presented a hindrance to services. Related to this, many carers described the hospital as a place of ‘battle’ that was ‘daunting’ and where they had to ‘fight’ and be ‘pushy’ to be included. This subtheme was particularly pronounced, and discussed at length in the focus groups. “‘Who we care for, our loved ones, they don’t realise what we have to go through when confronting professionals. [...] you get seen as the trouble maker ... So it is a massive battle. Until this day I still get missed off the list for CPA [Care Programme Approach] meetings. Recently, I’ve just got told the day before, and that was not even from the [team].’ (Carer 18) ‘I used to go each week and ask to go to the ward round and I wasn’t allowed to go... ’til one day I broke in to one of them.’ (Carer 11)”

This notion was supported by patient and clinician examples, who described clinicians intentionally excluding carers with the aim of ‘facilitating procedures’ and protecting patients and themselves from ‘overwhelm’ due to ‘overinvolvement’. “‘In our ward rounds, we don’t have family involved at all. We used to but I don’t think the consultant liked it. I think it was too much.’ (Clinician 32) ‘... they [carers] intervene too much [Patient 8: ‘mm-hmm’].’ (Patient 9) ‘... there’s a cooling off period before the patients settle down. If there’s a relationship problem ... we will keep them away for a while until such tempers settle down and perhaps they [patients] can explore [if] their presence or involvement will be of any benefit ... That is [a] clinical decision, team decision, yes.’ (Clinician 4)”

However, some patients viewed the solution to these problems as an increase in involvement and education for carers, so they could more appropriately support their needs. Clinicians and carers also felt that carers would participate with ‘better understanding and less interference’ (Clinician 17) when given information and reassurance. “‘My father was displaced as my nearest relative and I think instead of displacing him they should have given him more education and information and raised awareness about my condition so that maybe he could have come to an understanding make a more informed decision, ‘cause he was saying he doesn’t want me to be detained and they said, “okay, we are just gonna displace your nearest relative”, which I found very unhelpful very, very horrible.’ (Patient 7) ‘Yeah, [this time] I was invited to every ward round ... everything was explained and that calms your anxiety, if you’re given the information.’ (Patient 7)”

Invisibles

Finally, a less direct type of exclusion was commonly described. Carers often felt ‘invisible’ on the ward and excluded from ward procedures through omission. Unlike the previous theme, not engaging with carers was not necessarily because of intentional exclusion, but because clinicians were unable to see how their role could support carers. This also related to the non-systemic nature of many hospitals, where the main focus of treatment decisions were regarding the patient’s symptoms and their medication. Carers were described as having at most a peripheral role in these procedures. “‘I was invisible. You know, I was totally invisible. [...] There was never a chance that you could go into there and say, “How was my daughter today?” Because there’s no one person to ask. So I’m lost. So I’m just like a visitor, really, when I go to visit. And I was there all the time.’ (Carer 19) ‘When we come to the hospital ward rounds and this and that, they don’t really wanna to talk to me sometimes. I’m just sitting there like a dummy [Carer 5: ‘yeah’]. I can’t say nothing.’ (Carer 3) ‘You know when you see a mother crying? [Clinician 32: ‘yeah’] It’s more emotive than seeing the service user really unwell...’ (Clinician 30) ‘ – I think it’s because you know that they’re unwell, and there’s a reason that they’re presenting like that. But then – ’ (Clinician 32) ‘ – And you can do something to help.’ (Clinician 31) ‘Yes. You feel you’re actually working to make them feel better. But with the carer, it’s like, what can I do to...?’ (Clinician 32)”

Discussion

Main findings

This was a focus group study exploring patient, carer and clinician views of the role of carers in in-patient mental healthcare. We found some agreement on the types of support carers provide for patients. However, there were differences in opinion between the different stakeholder groups about when someone can be said to be providing care and the point at which someone can ‘justifiably’ be called a carer. Additionally, the hospital setting was seen as both directly and indirectly precluding the involvement of carers. The set-up of the service placed carers in one of three positions: supportive experts that provide collateral information, ‘troublemakers’ who get in the way of ward procedures and, perhaps the most difficult, ‘invisibles’, people who may spend substantial time on the ward but whom staff do not always know how to include in their routine procedures.

There were also multiple differences in opinion regarding the carer role, which might explain why carers often fell into these allocated roles. There was clear disagreement about what constitutes caring and unhelpful behaviour, as was demonstrated in the varying attitudes toward dependency. What some saw as providing essential care, others saw as an impediment to recovery. What emerged was that discomfort with the idea of dependency is not necessarily a universal. Although staff wanted to protect patients from ‘overwhelm’, many patients saw the solution to poor relationships with carers as increased involvement, so they have a better understanding of mental health and can support them more appropriately.

Additionally, although formal definitions of ‘carer’ exist, in reality, there were vast differences in labelling. Family members felt their caring role was all-encompassing in nature, whereas patients and clinicians did not often share this view, and had various personal definitions for when someone can rightly be called a ‘carer’. The disagreement about whether being a ‘carer’ is a constant state, or if it has to be ‘earned’ through caring for someone chronically unwell was linked to mismatched expectations in the clinical setting. It was not always clear if the existence of a ‘carer’ would

be acknowledged or accepted, and if this person would be entitled to inclusion, information and support. However, family members themselves reported a lack of choice about their caring role: it felt simultaneously imposed on them and denied from them.

Another major complicating factor were the fluctuations of mental and emotional state in patients in acute treatment. Carers were often left unsure as to how welcome they were as patients changed their minds between wanting to include them and not. This was combined with a range of positive and negative reactions from different staff members towards carers, which compounded the uncertain and stressful nature of the overall experience. Many people were left with the impression that hospital is a 'frightening' place or a 'battleground'.

Strengths and limitations

The study sample enabled us to explore and compare the views of patients, carers and clinicians from a variety of roles and settings. The diversity in demographics and experiences helped us to identify common experiences across different settings. One potential limitation was the inclusion of people who self-define as a 'carer', as they might represent a small proportion of family and friends who are providing support in clinical settings. However, our recruitment strategy included people from a variety of settings beyond carer organisations, such as asking clinicians to share study details with the visitors of people currently in hospital. This ensured that there was diversity among participants in terms of their understanding of the 'carer' role.

Overall, while focus groups are a good method for generating ideas, they are not ideal for the in-depth exploration of topics. This study may be viewed as a starting point into more in-depth qualitative enquiry into this area, particularly as this field has a lack of patient perspectives. Finally, this study mainly focused on in-patient treatment, and there might be other complicating factors that have an impact on peoples' experiences in other settings. Further discussion of strengths and limitations may be found in our linked article.⁸

Interpretation and comparison with literature

Previous literature highlights the difficulties experienced by families in the clinical setting. Jankovic and colleagues mapped out carers' experiences and found that difficulties begin to arise long before reaching the hospital admission stage.⁷ This might explain some of the discrepancies in participant views on when someone can be called a 'carer'. For carers, the less visible process of monitoring to prevent relapse might be experienced as a constant state, not just confined to when the person is unwell. Furthermore, the process leading to admission is often described as traumatic for the family members themselves, resulting in them needing higher levels of information and reassurance, but being unsure if they will receive this, or face exclusion or invisibility.

Studies of carer perspectives describe how they feel that confidentiality is used by clinicians as a reason to exclude them in in-patient settings.¹¹ Wilkinson & McAndrew describe families' feelings of powerlessness that can arise from being excluded and feeling invisible in in-patient settings.¹² By including clinicians and patients themselves in these focus groups, we demonstrate some of the reasons why carers might be excluded beyond the desire to protect patient confidentiality. In some cases, there appears to be a fundamental clash of values in terms of what is best for the patient. The patient voice itself, however, is not always included in these decisions, as illustrated by examples of family members being excluded to protect patients from overwhelm or because the carer disagrees with the treatment plan.

Each type of exclusion requires a different approach to address it. Intentional exclusion might be avoided through increased communication at the outset. This might include efforts to find common goals and values during the treatment process, or by addressing families' underlying needs for acknowledgement and reassurance. However, unintentionally leaving families out due to not considering them as central to ward procedures might be a more difficult, systemic issue to address.

The hospital setting being a barrier in itself is usually discussed in terms of the individualistic, non-systemic nature of the setting.^{13,14} Our study specifies some of the most difficult aspects, and why it may be such a challenge to overcome them. The centrality and time-limited nature of ward rounds, for example, emerged as a frustration for all stakeholders. Our linked studies specify some of the practicalities of what could be done to overcome some of these organisational

barriers.^{6,8} Frameworks such as the Triangle of Care¹⁵ or intervention models such as SYMPA (systems therapy in acute psychiatry)¹⁶ or Family Intervention¹⁷ can also provide some structure and guidance to this process.

Finally, Landeweer and colleagues highlight differences in what patients, carers and clinicians view to be barriers to family involvement. They suggest these discrepancies are the result of differences in their underlying beliefs and values.¹⁸ This study illustrates that indeed, even the definition of 'carer' is not necessarily agreed among all stakeholders. The reasons for this might be because of different motivations and belief systems about what mental health is and what treatment should entail.⁴ While all parties might view the patient's independence as the ultimate aim, the route to this and the speed at which it happens might not be universally agreed, resulting in conflict in the acute setting.

Implications for practice

The role of families in hospital settings is not universally agreed. They can present a variety of needs ranging from basic information, emotional support or collaboration to support the patient's treatment. This can pose difficulties for clinicians, who describe the conflict of having to attend to the individual patient while trying to best manage the needs of carers. This is dealt with in different ways, as some choose to work more closely with families and others exclude them from ward procedures. Families therefore face strong uncertainty in the in-patient process, not knowing if they will be welcomed, supported, ignored or excluded.

A further complicating factor emerged that not all clinicians viewed family members as carers and did not see it as their role to include them in clinical procedures. This may be related to what the fundamental purpose of a hospital is perceived to be. If it is solely to attend to the presenting symptoms of a patient, the presence of additional family members will indeed be seen as a hindrance to ward procedures. If a broader, systemic view is taken, those same family members might be conceptualised as major members of the patient's social network, whose presence can be beneficial, whether they are 'carers' or not. In reality, many clinicians placed themselves somewhere between both of these views, depending on the 'ideal' and 'realistic' service they could provide on a given day. However, this inconsistent approach might compound the high level of uncertainty already present in this setting. Structured procedures to routinely identify and support carers might alleviate some of the difficulties described above.

Additionally, as acknowledged by all three participant groups, patient choice is important, but it does not preclude meaningful interactions with carers. Although it must be acknowledged that many ward procedures and confidentiality rules are not set-up to favour carer involvement, positive examples of other ways of engaging carers demonstrated that it is still possible to improve upon patient, carer and clinician experiences in the in-patient setting.

Overall, this study highlights the importance of clarity when considering the 'carer' role, as misunderstandings can have the potential to have a negative impact on patient, family and staff experiences. As demonstrated by participant examples, excluding carers might appear to help clinical procedures in the short term, but could create more divisions between patients, carers and clinicians in the long term. Establishing wishes and expectations at the beginning of admission might be one way of opening up the potential for communication and reducing the likelihood that a patient or carer feels they have not been listened to. Finally, giving clinicians the space to have open conversations and critically reflect on core fundamentals such as the role of carers in their work might help them to problem-solve, and decide how to adapt their approach to carer involvement within their own local context.

In conclusion, there is no single agreed definition of 'carer'. This conflict in how a carer is viewed has the potential to have a major impact on their experience in in-patient settings. The implementation of carer involvement initiatives should incorporate addressing this fundamental aspect. Overall, it could be concluded that there needs to be clearer agreement about the role of carers in hospital settings, as they fluctuate between being perceived of as important resources, passive visitors or adversaries.

Data availability

All authors had access to the study data for the duration of data collection and analysis. A.D. and S.P. have ongoing access to the transcripts.

D.G., S.P. and A.D. designed the study. A.D. and J.K. carried out focus groups and data analysis under D.G.'s supervision. A.D. and J.K. prepared the first draft of the manuscript. All the authors critically reviewed the paper and approved the final draft. All authors read and approved the final manuscript.

The research was funded by the UK National Institute for Health Research (NIHR) Collaboration for Leadership in Applied Health Research and Care North Thames at Barts Health NHS Trust. AD is funded by the NIHR Doctoral Research Fellowship (DRF-2015-08-071). D.G. and J.K. were supported by the NIHR Collaboration for Leadership in Applied Health Research and Care (CLAHRC) North Thames at Barts Health NHS Trust. The views expressed are those of the author(s) and not necessarily those of the NHS, the NIHR or the Department of Health and Social Care.

Abstract**Background**

The steep rise in the rate of psychiatric hospital detentions in England is poorly understood.

Aims

To identify explanations for the rise in detentions in England since 1983; to test their plausibility and support from evidence; to develop an explanatory model for the rise in detentions.

Method

Hypotheses to explain the rise in detentions were identified from previous literature and stakeholder consultation. We explored associations between national indicators for potential explanatory variables and detention rates in an ecological study. Relevant research was scoped and the plausibility of each hypothesis was rated. Finally, a logic model was developed to illustrate likely contributory factors and pathways to the increase in detentions.

Results

Seventeen hypotheses related to social, service, legal and data-quality factors. Hypotheses supported by available evidence were: changes in legal approaches to patients without decision-making capacity but not actively objecting to admission; demographic changes; increasing psychiatric morbidity. Reductions in the availability or quality of community mental health services and changes in police practice may have contributed to the rise in detentions. Hypothesised factors not supported by evidence were: changes in community crisis care, compulsory community treatment and prescribing practice. Evidence was ambiguous or lacking for other explanations, including the impact of austerity measures and reductions in National Health Service in-patient bed numbers.

Conclusions

Better data are needed about the characteristics and service contexts of those detained. Our logic model highlights likely contributory factors to the rise in detentions in England, priorities for future research and potential policy targets for reducing detentions.

Rates of detention in psychiatric hospital have more than doubled in England since 1983 and risen faster than almost anywhere else in Europe during the past decade.¹ Detention in hospital is inherently coercive: it is experienced by most patients as such,^{2,3} and 3 months after detention many patients still disagree with the decision to detain them.⁴ Involuntary hospital admissions are typically longer and more costly than voluntary admissions. Patients experience only limited improvements in health and social circumstances following detention.⁵ Understanding and addressing the rising rate of detentions is therefore a priority for mental healthcare in England, which prompted the recent Independent Review of the Mental Health Act (MHA Review), which reported in December 2018.⁶ To support the review, an expert topic group was convened, supported by the National Institute for Health Research (NIHR) Mental Health Policy Research Unit (MHPRU). This group was tasked with exploring why rates of detentions in psychiatric hospital in England have risen since the introduction of the Mental Health Act 1983 (MHA), and most rapidly over the past decade. This work is reported here.

We sought to identify hypotheses for the rise in detentions in England, test their plausibility in relation to available evidence, and then develop an explanatory logic model for the rise in detentions in England between 1983 and 2016. The term ‘detentions’ is used here to include compulsory admissions to psychiatric hospital and detentions of people in psychiatric hospital following a voluntary admission, including civil and forensic MHA detentions, for people of all ages. We excluded uses of the MHA that direct conveyance to a place of safety or to permit short-term detention (72 h or less) for the purpose of assessment only.

Method

The study comprised: (a) generating hypotheses to explain the rising rate of detentions; (b) rapid scoping for evidence relevant to each hypothesis; (c) testing each hypothesis (in so far as data permitted) and rating its plausibility as an explanation for rising rates of detention; and (d) developing an explanatory model of the rising rate of detentions in England.

Hypothesis generation

A list of potential explanatory factors for the rising rate of detentions was generated from three sources. Reports and literature, chiefly the recent report from the Care Quality Commission⁷ and the evidence submitted to the MHA Review,⁶ which included over 50 focus groups with patients and carers, evidence submissions from over 200 mental health organisations, practitioners, patients and carers, and seven public workshops across England. Consultation with an expert topic group convened for the MHA Review. This comprised eight academics, six of whom were psychiatrists, one a social worker and one a researcher with lived experience. The group included two women and two members of Black, Asian and minority ethnic (BAME) communities, one of whom co-chaired the Mental Health Act Review African and Caribbean Group (MHARAC), which supported the MHA Review. Consultation with 14 members of the Lived Experience Working Group of the Mental Health Policy Research Unit (MHPRU), all with lived experience as a mental health patient or family carer. All members of this group were adults; the group was demographically varied with respect to age, gender and ethnicity.

Through discussion in the MHA Review topic group, all proposed explanations were considered and clarified into hypotheses where necessary, describing how proposed explanatory factors might contribute to an increase in detentions. Types of information that could support or contradict each hypothesis were agreed.

Evidence gathering

Relevant data sources were sought for variables relating to each hypothesis, with advice from academics with epidemiology, health economic and health services research expertise. We investigated the relationship of each variable to the rising rate of detentions in England through the following process.

First, an ecological study explored the associations over time between national population-level indicators for a range of explanatory variables and the rate of detentions. Where more than one relevant data source was identified for a proposed explanatory variable, the most appropriate variable was selected through discussion in the study team, with priority given to well-established measures used in previous research or national reports, and variables with the most years of data available. Annual data for all explanatory variables were collected from 1983 onwards, where available. Descriptive data from each variable were reviewed to assess whether exposure to the explanatory variable appeared to have changed over time (in the direction compatible with contributing to a rise in detentions). The association between each indicator variable and rates of involuntary hospital admission was assessed using regression analyses. Following guidance,^{8,9} only indicator variables with at least 10 years of annual data were included in the analyses, to avoid reporting imprecise statistical results based on limited data. Breusch–Godfrey tests were used to identify the presence of serial correlation (in which the model residuals are correlated over time). Such correlation can be present in time series data and can result in biased estimates if inappropriate regression methods are used. When there was evidence of serial correlation, Prais–Winsten regression¹⁰ was used; otherwise simple linear regression was used. Analyses were performed using Stata version 15 for Windows. The outcome variable in all analyses was annual number of detentions per 100 000 population, derived from publicly available English KP90 detentions data.¹¹ If prevalence of exposure to an explanatory variable was unchanged or was not associated with detention rates in the expected direction, it was considered less plausible as a contributory factor for the rise in compulsory admissions.

Second, available research was scoped by MHPRU researchers (L.S.R., N.L., L.M.) for additional evidence relevant to our hypotheses, including: studies exploring predictors of detention at individual patient, local area or international level, and qualitative literature regarding perceived changes in explanatory factors over time. Relevant literature was identified through: (a) a programme of systematic reviews and data analysis conducted for the MHA Review by the

MHPRU.⁶ These provided a range of types of evidence from quantitative and qualitative research, and included systematic reviews of social and clinical predictors of detention, interventions to reduce detention, qualitative literature on patients' and carers' experience of detention, an international comparison of detention rates and factors associated with detention rates, and an analysis of routine health records data regarding the nature of changes over time in patterns of detention in two London National Health Service (NHS) trusts; (b) keyword searching for relevant terms in electronic databases (MEDLINE and PsycInfo); and (c) asking subject experts in the MHA Review topic group, authors of this paper and others (acknowledged at the end of this paper) to identify other relevant literature.

Assessing the plausibility of hypotheses

Findings for each hypothesis were synthesised and summarised. The likelihood of any hypothesised or observed ecological relationship between explanatory variables and rates of detentions being causal in nature was assessed, where applicable and as far as evidence was available, with regard to established criteria for causality,¹² including the strength and consistency of associations, their perceived plausibility as causal mechanisms and, where possible, the specificity of relationships to populations at increased risk of detention, and temporality, i.e. evidence that rises in explanatory factors preceded rises in detentions. Hypotheses were then graded by the study team for plausibility as a contributory factor to the rising rate of detentions in England: 0, contradicted by available evidence; 1, lack of evidence or available evidence is ambiguous or mixed; 2, supported by the balance of available evidence. Two factors were considered in grading each hypothesis: evidence for change over time in the direction expected; and evidence, or self-evident face validity, that the hypothesised factor was causally related to risk of detention. Ratings were made initially by the lead authors of this paper (L.S.R, B.L.-E.), then reviewed by all authors and revised if necessary following discussion.

Logic model development

Following guidance,¹³ we developed a visual logic model to show how plausible proposed contributory factors (i.e. hypotheses rated as 1 or 2 for plausibility) might contribute to the rising rate of detentions in England and might interrelate. In developing the model, we worked backwards from the final outcome to be explained (the rising rate of detentions) to identify proximal outcomes, mental health service activities, inputs and contextual factors. We differentiated elements of this explanatory model that were supported by available evidence from hypothesised elements with ambiguous or absent evidence. Proposed causal pathways and mechanisms of change in the rate of detentions were illustrated in the model with arrows. An initial draft of the logic model was developed by B.L.-E., informed by a preliminary draft of relevant data tables and evidence reviews (supplementary Appendices 1 and 2, available at <https://doi.org/10.1192/bjo.2020.64>). This was then discussed with the study co-authors and revised with feedback and reference to additional retrieved evidence in five iterative stages.

Results

Rates of detention in England

Data for the number of detentions in England were not available from NHS Digital before 1988. National detention data collection methods changed from April 2016,¹¹ so data after this point are not comparable with previous data.

The annual rates of detentions per 100 000 population in England from 1988 to 2016 are shown in *Fig. 1*. Detention rates more than doubled during this period, from 52 to 114 per 100 000 population. A 1-day census of the number of people per 100 000 population detained at year-end each year also rose, from 26.0 in 1998 (the first year for which data are available) to 36.5 in 2016. The rise in the rate of detentions was steepest in the periods 1988–1996 and 2011–2016, plateauing in between. Increases in detentions were greatest at the point of admission. Overall detention rates, and detentions for assessment (section 2 of the Mental Health Act 1983, MHA), rose significantly during the study period. Rates of detention for treatment (s.3 MHA) and use of forensic detentions did not change significantly (supplementary Appendix 1). Use of legal powers by the police to bring people to a hospital-based place of safety (s.135 or s.136 MHA) for assessment – which were not included in our overall detention rate variable – also increased significantly

during the study period. Individual patients are not distinguished in government KP90 detentions data, which therefore cannot distinguish to what extent the rise in detentions reflects more people being detained, or the same number of people being detained more frequently. The data also cannot identify in which clinical or demographic groups the rise in detentions occurred. Fig. 1 Rates of involuntary detentions per 100 000 population in England 1988–2016. Proposed explanations for the rising rate of detentions in England

Seventeen hypotheses for the rising rate of detentions in England were generated. These are presented in the Appendix (immediately preceding the References), with a brief description of the proposed mechanisms of effect on detention rates. Consistent with previous work⁷ we have grouped the hypotheses as: social factors, service provision, legal factors and data recording problems.

Available data relevant to each hypothesis are summarised in *Table 1*, along with results of statistical tests of association with detention rate, where undertaken. Serial correlation was present for all but one indicator variable, so Prais–Winsten regressions were used. Full descriptive data and illustrative graphs showing change over time for each explanatory variable are provided in supplementary Appendix 1. Research evidence regarding the nature of the relationship of each of these factors to detention rates is summarised below and reported fully in supplementary Appendix 2. *Table 1* The relationship of potential explanatory factors to detention rates: exploration of available national data

Social factors

We considered whether the rise in detentions was related to: increased social and economic hardship, reduced social support, demographic change, increasing psychiatric morbidity, and increasing drug and alcohol use in the population.

Internationally, wealthy countries tend to have higher rates of detention.¹ However, at individual level, poverty and economic hardship, and lack of social support, are associated with increased risk of detention.³² The two periods of economic recession in the UK during the study period (1991 and 2008–2009)³³ coincide with or immediately precede periods of steepest rise in detentions in England. However, many established markers of economic hardship, including unemployment rate, poverty/relative poverty and income inequality, do not show clear evidence of change nationally over the study period (*Table 1*). Evidence of reduced informal social support or increased social discord during the study period is also limited: median scores for social fragmentation – an established indicator of informal social support,³⁴ collected every 10 years through national census data – have changed little. More specific indicators of social discord and discrimination, such as recorded hate crimes and racist incidents, have available data only for recent years and provide an inconclusive picture. Public attitudes to mental illness also appear to be unchanged or to have become more positive, based on available data from 1994 to 2014 (*Table 1*).

Men, younger adults (age 18–35) and people from Black, Asian and minority ethnic (BAME) groups are at increased risk of detention in England.^{35,36} The proportion of the population in England from all BAME groups has more than doubled between 1988 and 2016, as has the proportion of non-UK-born people in the population. The proportion of the population who are male has risen marginally. These rises may contribute to a rise in detentions (*Table 1*). Conversely, the proportion of the English population who are adults aged 18–35, the highest-risk age group for detentions, has fallen as the number of older adults has increased.

Available data suggest that psychiatric morbidity in England has increased during the study period, consistent with our fourth hypothesis. Adult Psychiatric Morbidity Survey (APMS) data collected every 7 years indicate a consistent rise in prevalence of people with common mental disorders with severe symptoms from 1993 to 2014, and a possible recent rise in prevalence of people with psychosis.²⁶ A clear causal pathway between increased overall psychiatric morbidity and more detentions is lacking, however. The increasing number of people seen in secondary mental health services (*Table 1*) may reflect increased numbers of people with a severe mental health problem, who are also at risk of detention. Alternatively, however, it could reflect increases in help-seeking or service accessibility, which do not influence rates of detention.

Contrary to our hypothesis, rates of drug and alcohol use in the general population in England have fallen over the

past 20 years). However, psychiatric hospital admissions for people with substance use disorders have risen since 2010 (supplementary Appendix 1), with a significant association with detention rate across the whole study period for cannabis use (*Table 1*). Three potential, not mutually exclusive, explanations for this discrepancy are: (a) drug use has increased among people accessing mental health services, in contrast to the general population; (b) the greater availability of potent drugs, including forms of cannabis such as skunk,³⁷ and novel psychoactive substances with mental health risks³⁸ has increased the risk of detention among drug users with mental health problems; and (c) changing attitudes among mental health practitioners to risk and safety and perceived treatability have led to more detentions of people with mental health problems who use drugs, independent of changes in patterns of drug use. We lack evidence to definitively support or reject any of these explanations, and the causal association of drug use and detention rates is uncertain (supplementary Appendix 2, section 2).

Service provision

Changes in the availability or quality of (a) in-patient care, (b) community crisis care, (c) longer-term community care, (d) reduced continuity of care during assessment for compulsory admission, (e) staff attitudes to risk and safety and (f) changes in prescribing practice were all considered as potential contributors to the rising rate of detentions.

In-patient care

The rise in detentions has coincided with a dramatic reduction in NHS psychiatric beds in England (*Table 1*). Plausible mechanisms have been proposed for why reduced bed availability may lead to more detentions.³⁹ Offer of in-patient admission may be delayed until illness becomes more acute. Relapse and re-detention may be more likely if patients are discharged prematurely because of bed pressures. Patients may not accept voluntary admission if the only available beds are far from home or because levels of disturbance in in-patient wards have increased, as only the most severely unwell, mainly non-consenting patients are admitted. Some psychiatrists report a perceived need to (unlawfully) detain patients who could have been voluntarily admitted, in order to secure prompt access to a bed.⁴⁰ P.K. and colleagues³⁹ found that the association between bed reductions and detention rates at local level in England was strongest with a 1-year time lag, i.e. increases in detentions follow bed cuts. This suggests a possible causal relationship.

However, the same study found that a moderate correlation remained between NHS bed reductions and rises in detentions, both contemporaneously and with a time lag in the other direction, i.e. bed reductions following rises in detentions,³⁹ which less clearly indicates that bed reductions cause detentions. Increasing use of private beds (*Table 1*) and increasing access to community crisis alternatives⁴¹ may mitigate some pressures caused by NHS bed reductions. A recent systematic review found no studies that had demonstrated a relationship between detention rates and bed occupancy rates, another indicator of pressures on available beds.³² An even more recent study has reported no significant association between in-patient bed numbers and detention rates in a multivariate model, for the period from 1999 to 2016.⁴² Internationally, greater in-patient bed availability is associated with higher, not lower, rates of compulsory admissions.¹

Community crisis care

Specialist community crisis care has proliferated in England following the national mandate in 2000 to introduce crisis resolution teams in the NHS Plan,⁴³ and the accessibility of community crisis care may have increased further since 2011.⁴¹ However, no community crisis service models have been shown to reduce compulsory admissions.⁴⁴ Improvements in service quality in crisis resolution teams had no impact on rates of compulsory admissions in a recent English trial.⁴⁵ Hypotheses that reduced availability or quality of community crisis services has contributed to rising detention rates are not supported by available evidence.

Longer-term community care

We have limited evidence about how the quality of care in community services has changed since 1983. Over the past 15 years, the number of patients seen by mental health services has increased substantially, while overall mental health funding has increased only slightly and community mental health service staffing has remained relatively stable. Similar resources, spread across a larger patient group, have therefore led to a reduction in mental health spend per patient in secondary care, and in the number of contacts provided per patient in recent years in some service settings, for example community mental health teams (*Table 1*).

The extent and quality of community mental health service provision may relate to rates of detentions, although the relationship is complex. Interventions delivered in longer-term community care are best supported by current evidence as promising means to reduce detentions.⁴⁴ Weich and colleagues³⁵ found that higher spending on community mental health teams in England was associated with lower local detention rates, but that health service areas with community teams assessed as lower quality than others also had lower rates of detention. As their reach increases, community mental health services, especially higher-quality teams, may be getting better at detecting the need for detention, but at the same time becoming less able to provide intensive support to individuals where necessary to prevent detentions, as their resources are spread more thinly across a larger patient group. Adult social care spending has fallen since 2010–2011:⁴⁶ this could further reduce available support to prevent mental health crises and subsequent detentions.

Changes in prescribing practice

Regarding prescribing practice, reductions in use of clozapine and depot injections were proposed as factors that might increase patients' risk of relapse and therefore of detention. However, there has been no clear reduction in the prescription of clozapine since 2007.⁴⁷ National prescription cost data suggest that the number of items of depot antipsychotic medication prescribed has reduced marginally since 2000. However, although the association between depot prescriptions and (reduced) detentions was in the anticipated direction, this association was not statistically significant (*Table 1*). Furthermore, given variable dosing schedules, fewer prescriptions do not necessarily reflect a reduction in the number of people for whom depot medications are prescribed. Finally, there is some evidence that depot injections may not increase adherence in any case.⁴⁸

Staff attitudes to risk and safety

Risk and safety are important considerations for mental health staff,⁴⁹ and clinicians' attitudes and responses to risk are highly variable and subjective.^{50,51} Perceived risk has consistently been identified as the strongest predictor of outcome of assessments for involuntary admission in English studies.^{52–54} The amendments to the MHA in 2007 extended the reach of coercion in response to perceived risk by broadening legal definitions of mental disorder and treatability, and introducing community coercion through community treatment orders, and has been characterised as reflecting a more general societal preoccupation with risk minimisation.⁵⁵ Szmukler & Rose⁴⁹ identify an increasing salience for risk assessment in mental healthcare internationally. It is plausible that increasing focus by mental health staff on risk and safety may have contributed to the rise in detentions since 1983. The increase in detentions for assessment under section 2 of the MHA, rather than treatment under section 3, may be consistent with an increasing willingness by mental health staff to detain people in the context of potential perceived risks, not just established known risks. However, we cannot quantify any such change in attitudes or its impact on detention rates.

Continuity of care

We found little evidence regarding how changes in the continuity of care at MHA assessments may affect the outcome of assessment and thus detention rates. One small study suggests that presence of a community professional, such as the patient's care coordinator, may reduce the risk of a formal assessment for compulsory admission resulting in detention.⁵⁴ However, we lack information about the extent of any changes over time in the involvement in MHA assessments of practitioners, including general practitioners, who know the patient being assessed.

Legal factors

Three legal factors potentially relevant to detention are: (a) changing legislative approaches to patients who lack decision-making capacity but do not actively object to hospital admission; (b) the introduction of compulsory community treatment; and (c) the police's use of legal powers to bring people with suspected mental health problems to a place of safety for assessment.

Capacity and consent to treatment

Since the Human Rights Act 1998 came into force in England in 2000, enshrining the European Convention on Human Rights, it has been unlawful to admit anyone to psychiatric hospital on a voluntary basis who lacks the capacity to consent to this treatment. This requirement has been reinforced by subsequent English case law, most notably the 'Bournewood judgment' in 2004 and the 'Cheshire West' case in 2014. Deprivation of liberty safeguards (DoLS) were introduced in 2008 as an addition to the Mental Capacity Act 2005 (MCA): DoLS provide a legal framework for approving in-patient admission and treatment for people who lack decision-making capacity, without using detention under the MHA. It is hypothesised that the rising rate of detentions in England may reflect increasing compliance with human rights law through the application of the MHA rather than DoLS to those who might previously have been admitted voluntarily.

Available research suggests that, prior to the introduction of DoLS, as many as 20% of in-patients were non-objecting and voluntarily admitted, but lacked capacity to consent to admission.⁵⁶ In 2017–2018, however, fewer than 4000 DoLS applications were completed for patients in psychiatric hospitals,⁵⁷ i.e. only about 4% of roughly 100 000 admissions per year in total.⁵⁸ The uncertainty in extrapolating from one small research study's findings is acknowledged, and we do not know whether, in practice, some non-objecting patients who lack decision-making capacity may still be (unlawfully) admitted to hospital voluntarily. However, if detention under the MHA is always now used to admit the remaining non-objecting patients who lack capacity but are not subject to DoLS, this could explain a substantial proportion of the rise in detentions in the past decade.

Compulsory community treatment

The introduction of community treatment orders (CTOs) in 2008 has been proposed as a potential contributor to the rising rate of detentions, either by lowering the bar for readmission of patients subject to a CTO (through the use of recall to hospital) or by increasing the risk of relapse by facilitating earlier, premature hospital discharge following the index admission leading to the CTO. The use of CTOs in England increased year on year from 2008 to 2016, with the numbers of people readmitted to hospital from a CTO rising correspondingly (*Table 1*). However, a recent systematic review⁵⁹ provides clear evidence that internationally and in England, compulsory community treatment has no effect on raising or reducing readmission rates. This hypothesis is therefore not supported by available evidence.

Police use of place of safety powers

Police use of legal powers (s.135 or s.136 MHA) to convey someone to a health-based place of safety has risen markedly during the study period. This has led to a corresponding increase in the number of people admitted to psychiatric hospital following use of a police place of safety order (*Table 1*). It is unknown what proportion of these people might otherwise have been detained via a different pathway, but it is plausible that police are becoming better at identifying people who meet criteria for detention in hospital and bringing them to the attention of health services. Some of those who are now detained via a place of safety order may previously have been arrested or left in public spaces or at home.

Data recording

The Care Quality Commission proposed that more complete reporting of detentions by provider organisations may have led to an artefactual rise in recorded detentions over the study period.⁷ An analysis of patient records from 2007 to 2016 in six London boroughs⁶⁰ found substantially lower increases in detention rates in these boroughs than those observed nationally. However, the extent of missing data in the routine nationally collected KP90 data on detentions, and whether this has changed over time, are unknown.

'Double-counting' in official statistics may contribute to a rise in the recorded rate of detentions. Detention episodes within one provider organisation are reported in the KP90 data used for this paper as a single detention, even if a person is transferred from one form of detention to another during this episode (e.g. transfers from a MHA section 2 detention for assessment to section 3 detention for treatment). However, recorded detentions in the KP90 data are inflated by double-counting of transfers in care, where a patient is moved during detention from one hospital to another run by a different provider organisation.³⁶ This may account for between 12 and 20% of all detentions recorded in the data, and accounts for the big drop in English national detention records in 2017, when a new reporting system was adopted.³⁴ The increase in the use of private hospitals during the study period is associated with the rise in detentions (*Table 1*) and suggests that transfers of care during detentions might have increased, leading to more double-counting and an artefactual rise in reported detentions. However, the extent of any such rise over time is unknown.

Development of an explanatory logic model

From the evidence summarised above, and presented more fully in supplementary Appendices 1 and 2, ratings were made regarding the strength of evidence for each proposed hypothesis to explain the rise in detentions (*Table 2*). Table 2 Strength of evidence ratings for hypothesised explanations for the rise in detentions Explanatory factor Evidence for temporal relationship with change in detention rates a Evidence for, or self-evident plausibility of, causal relationship to risk of detention a Rating b (1) Social and economic hardship Equivocal Equivocal 1 (2) Increased drug and alcohol use Equivocal Equivocal 1 (3) Demographic change (increased numbers of those at risk of detention) Supported Equivocal 2 (4) Increasing rates of mental illness Supported Equivocal 2 (5) Reduced informal social support Equivocal Supported 1 (6) Reduced availability and quality of community mental health services Equivocal Supported 2 (7) Reduced availability of alternatives to admission Contradicted Equivocal 0 (8) Reduced quality and/or responsiveness of crisis services Equivocal Contradicted 0 (9) Reduced in-patient bed capacity Supported Equivocal 1 (10) Less continuity of care at MHA assessments Equivocal Equivocal 1 (11) Greater aversion to risk among mental health professionals Equivocal Supported 1 (12) Changes in prescribing practice Contradicted Equivocal 0 (13) Changes in legal and clinical practice in respect of capacity Supported Supported 2 (14) Introduction of CTOs (and earlier discharge) Supported Contradicted 0 (15) Police more likely to bring people to a health-based place of safety Supported Equivocal 2 (16) Better data reporting in recent years Equivocal Supported 1 (17) Increase in transfers between hospitals during admission leads to double-counting Equivocal Supported 1³⁴⁵

³ MHA, Mental Health Act 1983; CTO, community treatment order.

⁴ Contradicted, contradicted by current evidence; equivocal, absent or ambiguous evidence; supported, supported by current evidence.

⁵

0, hypothesis is contradicted by available evidence; 1, lack of evidence or available evidence is ambiguous or mixed; 2, hypothesis is supported by the balance of available evidence.

An explanatory logic model was then developed (supplementary Appendix 3). Hypotheses contradicted by available evidence were excluded from the model. Bold and dashed text boxes were used to distinguish components of the model supported by available evidence, and those for which available evidence was ambiguous or lacking. Arrows highlighted possible relationships between components of the model.

Following reviewers' feedback on the full logic model described in supplementary Appendix 3 and the initial paper draft, we decided to develop a second visual explanatory model for the observed rise in rates of detentions from 2010 onwards. The rationale for this second model is that more data are available for potential explanatory factors in this period. This complementary but simpler and clearer explanatory model distinguishes two overarching pathways to the rise in detentions during this decade: an increase in perceived need for detention; and an increase in actual need. This second model is shown in *Fig. 2*. *Fig. 2* Two proposed pathways to the rising rate of detentions in England 2011-16: a provisional explanatory model.

Discussion

Main findings

Our explanatory model shows that societal, service-related and legal factors may all contribute to the rise in detentions in England since 1983. Changes in legal approaches to safeguarding the rights of patients who lack decision-making capacity are a probable major contributor to the rapid increase in detentions in this decade. Rising levels of mental illness and demographic change in the population may both contribute. Mental health services and the police may be getting better at identifying people who meet criteria for detention, while in some community mental healthcare settings, increasingly stretched resources may reduce the availability and intensity of the preventive support that can be provided to patients to avert relapse or subsequent detention.

Other factors may be important, but we lack confirmatory evidence. These include: increased exposure of vulnerable groups to economic and social hardship, reduction of available informal social support, changes in drug use among the patient population, changes in public and practitioners' attitudes to risk and safety, and reduced NHS in-patient bed availability. The reported rise in detentions may have been inflated by the unreliability of available data.

Available evidence suggests that reductions in the availability or quality of community crisis care and the introduction of community treatment orders have not contributed to the rise in detentions. We also found evidence that public fear and exclusion of people with mental illness has decreased in England during the study period, in contradiction to a hypothesis that reduced tolerance of people with mental health problems has driven the rise in detentions.

Strengths and limitations

Our paper collects and appraises the available evidence for and against 17 hypotheses for the rising detention rate, finding evidence to support 4 and reject 3 hypotheses. It thus provides the most comprehensive and informed exploration to date of the rising rate of detentions in England. We identify ten limitations of this paper. First, reported detention rates are based on routinely collected national data that are not wholly reliable. Second, our list of hypotheses to explain the rising rate of detentions may not be exhaustive. For example, the impact on detention rates of changing practices in discharge and transfer of patients with mental health conditions from accident and emergency and general hospitals was raised during the peer review process for this paper. The selection and framing of hypotheses, and ratings of the strength of evidence supporting each hypothesis, will inevitably reflect the perspectives and biases of those involved. Both the MHA Review topic group and the paper's authors comprised a range of mental health stakeholders, but the most

represented group in both was academic psychiatrists. Third, because of the breadth of the topic, searches for available evidence were not systematic, and relevant data or research may have been overlooked. Fourth, our evaluation has highlighted hypotheses for which corroborating evidence from explanatory variables is available. However, hypotheses for which we lacked any relevant data to explore associations with detentions may be equally important – for example, changes in attitudes to risk and safety and risk assessment practice among mental health professionals. Fifth, for some hypotheses for which potential explanatory variables were identified, we lacked sufficient data points to allow statistical exploration of their relationship to detention rates. For variables with at least ten data points for which we did conduct analyses, these were not informed by power calculations: potentially important relationships may not have achieved statistical significance. Sixth, identified associations between explanatory variables and detention rates do not determine whether relationships are causal. With the exception of in-patient bed numbers, we were rarely able to establish temporality to inform consideration of the direction of causation in associations. For many hypotheses, additional available research was insufficient to confidently infer or reject causality or establish mechanisms. For example, it is unclear why men and people from BAME ethnic groups are detained more often, and many proposed explanations lack empirical support.⁶¹ Seventh, for many of the explanatory variables that we examined, data regarding changes over time were only available at whole-population level, not specifically for those people who are detained, or vulnerable to detention, thus creating risks of ecological fallacies. This may have particularly limited our exploration of the impact of social and economic factors on detention rates. For instance, falls in overall poverty levels in England have not been experienced equally among all demographic groups,⁶² while the measure of income inequality used in our analyses (the Gini coefficient) has been criticised as being insufficiently sensitive to change.⁶³ We have been unable to locate evidence specifically for people with mental health problems regarding change over time in levels of unemployment, work precarity, disposable income, benefits sanctions, living alone or similar variables, with which to interrogate our hypotheses in more depth. Eighth, we used a single source of data for each population-level indicator used as potential explanatory variables, to allow comparisons of change over time. However, for some indicators, there were changes during the study period in data-reporting methods or acknowledged concerns about data quality, which may limit the validity of comparisons over time. Where identified, these are reported for each variable in supplementary Appendix 1. Ninth, for mental health service provision, staffing and funding, we have relied on available national data for mental health services in general. Specific changes or pressures for children’s or older adults’ services may be obscured. Last, we have mainly looked at the relationship between proposed explanatory factors and detention rates individually. We were limited in how far we could explore interrelationships between explanatory factors and cumulative effects of exposure to several factors.

For these reasons, our proposed explanatory logic model has limited empirical support. It does not offer certainty, but does illustrate likely and possible contributory factors to the rising rate of detentions in England between 1983 and 2016. We have looked specifically for evidence to explain the rise in detentions in England during this time period: our explanatory model may have less validity for other countries and time periods.

Implications for research

This study was limited by the limited information available from routine data about detentions in England. The complete KP90 data held by NHS Digital, which allowed us to compare rates of detention over time, could not yield answers to basic questions regarding in which clinical or demographic groups the rise was occurring. Better routine data are required. The change by NHS Digital in 2016–2017 to collecting complete data about detentions at individual patient level²⁶ may address this need to some extent over time. The development of local NHS systems that allow researchers to access detailed, anonymised records for all patients using local secondary mental health services⁶⁴ also enables more sophisticated understanding of risk factors for detention and changes over time.

Our study highlights numerous areas where further research is needed regarding the relationship of potential explanatory factors to rates of detention, especially for social and economic factors, and attitudes to risk and safety.

Public health research indicates that increasing psychiatric morbidity in England may be a result of increasing social deprivation,⁶⁵ and that specific social and administrative measures may also influence mental health outcomes: for instance, increases in ‘fitness for work’ tests being associated with more suicides.⁶⁶ We need a clearer and more nuanced understanding of the extent of exposure to social and economic stressors among people with mental health problems, how this may change over time and how, if at all, it relates to changes in rates of detention.

Practitioners' attitudes to risk and safety are variable and highly important regarding decisions to detain,^{48–51} but changes over time in clinical culture and practice are not easily evaluated empirically. More qualitative research to understand the nature and extent of practitioners' biases and group-level stigma has been called for, to aid understanding of the rise in detentions and the disproportionately high rates of detention for people from BAME groups.⁶¹ A better understanding of what drives clinicians' decision-making regarding detention is desirable, as is development and evaluation of interventions to improve the quality of risk assessment and encourage appropriate positive risk-taking.

In this context, three elements of the legal processes for detention are priorities for further research. First, there is a need to understand the causes and consequences of the specific rise in the use of section 2 of the MHA for assessment, rather than section 3 for treatment. Although this may simply be an appropriate response to more new people requiring detention,⁶⁰ the MHA Review expressed concerns that section 2 is being 'overused',⁶ either through a growing perception that it is less restrictive than a detention for treatment, or because it can be easier to complete, as does not require a place of treatment to be identified. Exploration of patient-level data is desirable regarding circumstances and rates of conversion from assessment and treatment sections, and their relationship to subsequent readmission rates. Second, research is required to understand clinicians' decision-making processes in using MHA or MCA DoLS processes to detain patients who are not objecting to admission but lack decision-making capacity, and how this choice affects patients' experiences and outcomes. Third, research is needed to understand the circumstances in which patients are discharged from detention following appeal to a tribunal. This may help identify uses of detention that were unwarranted or avoidable, and how these may contribute to the rising detention rate.

Implications for policy and practice

There is considerable uncertainty about many of our proposed explanations for the rise in detentions in England. Furthermore, interventions might help to reduce detentions, even if they are unrelated to the reasons for the rise: for example, improving community crisis care. For these reasons, implications from our study for policy and practice should be proposed with caution. However, we suggest three areas of priority for reducing detentions.

First, an increase in detentions appears to have been an unintended consequence of legislation and English case law regarding safeguarding the rights of non-objecting patients who lack decision-making capacity and require hospital admission. Clear guidance and training are required for practitioners regarding assessment of capacity and when detention under the MHA is indicated rather than use of DoLS provisions under the MCA. Sufficient staff, appropriately trained in both processes, are required to ensure that the most appropriate course of action can be used in each case.

Second, the past decade has seen a large increase in the number of people treated by secondary mental health services (in addition to the expansion of psychological services in primary care), and a corresponding reduction in the amount of care offered to each individual patient in some service settings. This appears to have been a *de facto* change in mental healthcare over the past decade rather than one explicitly planned in policy. Within any level of total investment, achieving the optimal balance between breadth and depth of care involves weighing many different aims and priorities. Consideration should be given by policy planners and commissioners to the share of healthcare funding provided to mental health services, and to the potential effect on detention rates of spreading mental health resources increasingly widely, and thus away from the high-need, low-number group of patients most vulnerable to detention.

Third, our study shows that not all the rise in detentions in England necessarily relates directly to mental health service provision: wider societal factors may be equally important to address. Potential contributory factors such as increasing psychiatric morbidity and social deprivation and inequalities require a broader public health and governmental response. More attention to the potential mental health impact of wider social policy is desirable.

Lived experience: commentary by Stephen Jeffreys and Stella Branthonne-Foster

Collectively, we have personal experience of community and in-patient mental health services. We commented on drafts of this paper but did not contribute to the design and scope of the project.

The authors highlight gaps in detentions data: lack of individual-level data and failure to differentiate between frequent individual detentions and detention of more people, plus limited monitoring of Equality Act 2010 protected characteristics.

The paper suggests that detaining more patients lacking capacity, who were previously admitted informally, is a major factor. However, this hypothesis relates only to the second period of steepest rise in detentions. Furthermore, it would be interesting to specifically examine child and adolescent mental health services data for similar trends.

The children and young people's landscape is vastly different from that of their adult counterparts and needs specific consideration. We regret that data on children and young people are merged into the overall national data-set; it is important to note the differences in services (both in-patient and community), and the needs and presentations of under-18s. We anticipate that absence of these data obscures factors specific to that age group.

The biggest increases in detention rates have coincided with two periods of recession, but the authors were unable to demonstrate the impact of austerity or find data specific to those with mental health problems. We suggest widening this investigation to encompass other and more intangible factors associated with austerity and neoliberal ideology, such as individualism, cuts in local services and financial uncertainty. As there has also been a substantial increase in demand on community mental health teams, this work should not be limited to rates of detention.

The paper reveals that MHA section 2 detentions have increased, with section 3 figures remaining stable. Are hospitals discharging patients more quickly and perhaps too quickly owing to pressure on beds, are they finding swifter methods of support and treatment, or are more people being detained under the MHA unnecessarily?

Dr Gareth Owen, Professor Paul McCrone and Joe Botham from King's College London helped to identify relevant data or research papers for some of the evidence summaries in this paper. We thank Stephen Jeffreys and Stella Branthonne-Foster, both members of the Lived Experience Working Group in the National Institute for Health Research (NIHR) Mental Health Policy Research Unit, for their commentary on this paper.

Proposed hypotheses for the rising rate of detentions in England since 1983

We hypothesised the following 17 potential contributory factors to the rising rate of detentions, listed here with possible mechanisms for the hypotheses (how might exposure to the hypothesised risk factors cause or modify the risk of detention?)

Social factors

Social and economic hardship: increased exposure to social stressors leads to more frequent relapses in the patient population and/or increase in rates of people developing a mental illness, leading to more detentions (social stressors could include: poverty, unemployment, social inequality, benefits sanctions, exposure to discrimination or hate crime). Increased drug and alcohol use: increased substance misuse leads to increased risk of relapse in the patient population and/or increased rates of mental illness. Demographic change (increased numbers of those at risk of detention): some demographic groups are at higher risk of detention than others (i.e. men, people from BAME groups and young adults age 18–35): if the proportion of the population from these groups increases, we would expect higher rates of detention. Increasing rates of mental illness: a proportion of those with mental illness become so unwell that detention is required: higher rates of mental illness lead to more detentions. Reduced informal social support: the absence of informal support (and perhaps the increase in people living alone) leads to higher rates of relapse; it also makes delivery of community-based crisis care difficult, and admission more likely; bed pressures result in the eventual need for detention.

Service factors

Reduced availability and quality of community mental health services: reductions in the reach (number of patients seen) by community mental health ongoing care services leads to reduced capacity to prevent detentions. Reductions in the quantity and quality of care provided to current patients (possibly due to reduced investment in community mental health services) lead to increased rates of relapse, leading to more detentions. Reduced availability of alternatives to admission: reduced availability of less restrictive community alternatives to admission leads to more compulsory admissions for patients not prepared to go into hospital. Reduced quality and/or responsiveness of crisis services: later intervention, or the lack of home treatment services, will result in more patients needing to be admitted. Reduced in-patient bed capacity: lack of availability of beds (evidenced by reduction in bed numbers or increased bed occupancy rates) means that patients have longer to wait for a bed and are therefore more unwell at the time of admission; or are detained when voluntary admission was possible, in order to secure a bed; or are discharged prematurely to free beds, leading to more frequent relapse and re-detention. Less continuity of care at Mental Health Act (MHA) assessments: assessment of risk may be more conservative (and overestimated) by professionals who do not know the patient. Increased focus on safety and risk among mental health professionals: section 12 doctors and approved mental health professionals (AMHPs) have become more likely to detain patients with a risk and clinical presentation that would not have led to detention in the past, owing to changes in professional culture and attitudes to patient safety and risk management. Changes in prescribing practice: reduced use of depot medication over time has led to reduced medication adherence, resulting in

more relapses and subsequent detentions. Reduced use of clozapine over time has led to more relapses and subsequent detentions.

Legal factors

Changes in legal and clinical practice in respect of patients who lack decision-making capacity: following the *Bournewood* judgment (*HL v. UK* [2004] ECHR 471) in 2004, non-objecting patients who lack decision-making capacity, who might previously have been admitted to hospital informally, must now be subject to a 'lawful process', i.e. detention under the Mental Health Act 1983 or the Mental Capacity Act 2005 deprivation of liberty safeguards (DoLS). Introduction of community treatment orders (CTOs) (and earlier discharge): (a) there is a lower threshold for CTO recall than for admission following an MHA assessment, so CTO patients are recalled to hospital who would not otherwise have been detained, leading to an increase in compulsory admissions since introduction of CTOs in 2008; (b) CTOs are used as a means of facilitating early (premature) discharge, leading to frequent relapse and recall/readmission. Police more likely to bring people to a place of safety under section 135 or 136: increasing mental health awareness and use of MHA sections 135 and 136 by the police lead to patients being brought to a place of safety and subsequently detained, who would previously have been arrested or left at home/in public places and not have ended up detained through other routes.

Data-recording factors

Better data reporting in recent years: over time, service providers are submitting more complete data returns regarding detained patients, so underreporting of detentions in official statistics reduces. Increase in transfers between hospitals during admission leads to double-counting: increasing bed pressures lead to an increase in transfers between hospitals for patients during a detention (out-of-area NHS placements and use of private hospitals), leading to increased double-counting of detentions in KP90 data.

1.3.18 Dismantling the social safety net: social security reforms, disability and mental health conditions

2020-10

Abstract

This article examines the effects of UK welfare reform since 2008 on people with mental health conditions and disabilities. The results have been profound, particularly during a time of economic austerity, damaging the social safety net and pushing many vulnerable people into poverty and hardship. It has perpetuated inequalities and increased the social exclusion of disabled groups. The holes in the safety net require repair, alongside extensive social policy reform to both protect and empower people with disabilities and long-term conditions.

In his report following a visit to the UK in 2018, the UN special rapporteur on extreme poverty and human rights, Philip Alston, said that ‘the social safety net has been damaged by drastic cuts’ and that the net ‘has been systematically and starkly eroded, particularly since 2010’.¹ His report highlighted the effects of social service cuts, welfare reforms and austerity on poverty in the UK. This followed comments by the UN’s Committee on the Rights of Persons with Disabilities that the welfare reforms had led to ‘grave and systematic’ violations of disabled peoples’ rights.²

I examine here the results that this damage to the safety net has had on people with disabilities and mental health conditions in the UK with reference to the changes in welfare benefits that have taken place over the past 12 years.

Disabilities and mental health conditions

I have chosen to examine the effect of UK welfare reforms across all disability groups for several reasons. The first of these is practical, as many official statistics do not separate people with disabilities into those with mental or with physical problems. The groups of people and their conditions that are contained in the category of ‘disability’ is fluid and has changed over time.³ Recent shifts have broadened the scope, adding people with mental health conditions, intellectual disabilities, developmental disorders and sensory impairments. This is reflected in our anti-discrimination laws: the Equality Act 2010 defines disability as ‘a physical or mental impairment which has a substantial and long-term adverse effect on the ability to carry out normal day-to-day activities’. The terminology is also reflected in the term ‘long-term conditions’, which applies to many of the people who are receiving sickness and disability benefits and are commonly users of health and social services. People with long-term mental health conditions are likely to be: living in households below the poverty threshold, to be in debt or have financial problems, to be in receipt of benefits, to be without a paid job and to live in social housing, and they are about three times more likely to have multiple social disadvantages than the general population.⁴ Many people who have mental or physical disabilities are on low incomes, they share common difficulties and are vulnerable to the effects of benefit changes.

Welfare reforms in the 21st century

The provision of services and income transfers by the state to meet the welfare needs of the UK population and the concomitant expenditure grew in the 20th century. These provisions include personal social services, services for healthcare, education and housing and income transfers such as pensions and out of work payments. One function of the welfare state is to protect people in times of hardship.

Most agree that the golden age of the British welfare state occurred after the Second World War, with rapid reforms to create a more comprehensive and universal welfare state with an increase in resources to extend benefits and coverage.⁵ This was associated with a commitment to economic growth and full employment. The development of the modern welfare state has been a driver for the improvements in provisions for people with disabilities, including those for people with mental health conditions and intellectual disabilities.⁶

The golden age declined in the 1970s, and the 1980s saw a period of retrenchment and recalibration, with an abandonment of full employment and cuts to welfare provision, despite continuing growth in public expenditure.⁵ This was set against a background of increasing income and wealth inequality. In the late 1990s and most of the 2000s, the New Labour government's vision for welfare was for a system that enabled rather than provided. The challenge was to reduce worklessness and introduce new benefits and tax credits as well as introducing work support schemes. The recession in 2008 and the election of the coalition government in 2010 brought in a period of austerity and the introduction of further welfare reforms in 2012. The squeeze on expenditure and the roll out of the new benefits continue to this day, and the welfare state may face further retrenchment following the COVID-19 pandemic.

Changes in sickness and disability benefits

The two main direct payment benefits that are specifically aimed at people with ill health and disability are those that provide out of work payments (Employment and Support Allowance – ESA) and those that cover the extra costs of disability (Personal Independence Payment – PIP).⁷

ESA was introduced in 2008 as a result of the Welfare Reform Act 2007 and replaced Incapacity Benefit. Claimants for ESA are assessed through the process of the Work Capability Assessment (WCA) that includes face-to-face contact with a clinical assessor, who determines their ability to manage a variety of daily activities (physical and mental). The WCA process assesses whether a person is entitled to ESA based on their 'limited capability for work' (LCW) and their 'limited capacity for work-related activity' (LCWA). Those found to have LCW and not LCWA are placed in the work-related activities group (WRAG) and are expected to engage with job centre staff in seeking work. Those found to have LCW and LCWA are placed in the Support Group and are not expected to engage with work-related activity. For those in the WRAG, failure to engage with Job Centre staff can result in sanctions that may reduce or suspend benefit payments.

PIP, designed to replace the Disability Living Allowance (DLA) for people 16 years of age and over, was introduced as part of a range of benefit changes in the Welfare Reform Act 2012. Assessments for PIP, unlike those for DLA, are done by face-to-face interviews with a clinical assessor. Payment is given depending on the degree of difficulties experienced in activities of daily living and mobility.

Although these benefits represent the main direct payment to people with a range of disabilities, the 2012 Act also introduced further changes that have a significant effect on people with low incomes. These include: Universal Credit, the under-occupancy charge ('bedroom tax'), a benefit cap and the up-rating of local housing allowance rates by the Consumer Price Index.

Universal Credit was introduced in an attempt to simplify the delivery of benefits and is a single monthly payment that applies to people who are looking for work or are on a low income. It brings together six working-age benefits: ESA, along with the income-based Jobseeker's Allowance, Income Support, Child Tax Credits, Working Tax Credits and Housing Benefit. It rapidly hit the headlines because of its delayed payments, and its full roll-out has been delayed.⁸

Disability and poverty

Changes to the welfare state have effects on almost the entire population, but it is those on low incomes that are often disproportionately affected.⁹ This includes many with mental health conditions and disabilities. The latest figures on poverty in the UK (2017–2018) show that, of the 14 million people who live in poverty, 4 million have a disability and a further 3 million live with someone who has a disability. An estimated 13 million adults and children in the UK have a disability, 31% of whom live in poverty (the poverty rate among the non-disabled population is 20%). Nearly half of those who are disabled have a disability due to a mental health condition – for this group the poverty rate is 39%, compared with 30% among those with a physical disability.¹⁰ These figures have changed little over the past 8 years.

These figures reinforce the UN rapporteur's findings and point to a significant number of people with disabilities falling through the poverty safety net. It seems that benefits may not necessarily protect people with disabilities from falling into poverty.

Financial impact of welfare reforms on people with disabilities

Since 2012, organisations have warned about the impact of the cuts in benefits on people with long-term conditions.^{11,12} Recent economic modelling examining the impact of the benefit changes since 2008 shows that disabled people have lost, on average, £1200 each year, compared with £300 for non-disabled people.¹³ The benefit changes have most impact on those with intellectual disabilities, social interaction difficulties and mental health conditions.

Problems with benefit assessments

From the start of its implementation, the WCA process was reported to present difficulties for those being assessed. The Citizens Advice Bureau (CAB) reported that the assessment was not effectively measuring fitness for work, often ignored independent clinical evidence and was producing inappropriate outcomes.^{14,15} Claimants reported rushed assessments, inaccurate recording of their accounts and poor recognition of mental health problems.¹⁴ Many people report the process to be anxiety-provoking and a cause of deterioration in their health. The WCA remains widely condemned and seen in need of review.^{16,17} Official Department for Work and Pensions (DWP) reviews of the WCA have questioned whether descriptors are fit for purpose and whether the assessment is sufficiently fair and effective.¹⁸

The Court of Appeal in 2013 judged the WCA to substantially disadvantage people with mental health problems and said that the DWP had failed to make reasonable adjustments to ensure that people with mental health problems were treated fairly by the system.¹⁹ Disadvantages for people with mental health conditions include: finding it difficult to report on the nature of their condition or the way that it affects their functioning; difficulty in attending for interviews or expressing themselves at interview; the fluctuating nature of their conditions, symptoms, impairments and functioning, which may be difficult to describe or to assess; the subjective nature of many mental health conditions; and the presence of coexisting physical health conditions.

The actual rate of incorrect decisions made at ESA and PIP assessments is not known. People can appeal their ESA and PIP decisions, but first they must ask for a mandatory reconsideration from the DWP. Few of these mandatory reconsiderations lead to a change in the award (around 15% for PIP). However, for those who go on to be seen by an independent appeals panel, the majority win their appeals. In 2019, 73% of ESA appeals and 68% of PIP appeals were won by the appellant.²⁰

The failure of the WCA and the assessments for PIP to reliably identify those who are eligible for benefits is costly, not only in financial terms but also in human terms.²¹ Removal of benefits is experienced by claimants as rejection, with applicants feeling mistrusted and invisible, coupled with the stress of being in a cycle of assessments, rejections and appeals.²² People describe experiences of their difficulties being trivialised or seen as fraudulent. Overall, people with mental health conditions are relatively disadvantaged when applying for PIP. For people transferring from DLA, the likelihood of being found not entitled to PIP was almost two and a half times greater among people with mental health conditions than among claimants with physical disorders.²³

Many anomalies with the specific details of the assessments for PIP and ESA have been dealt with through the court system. In 2017, the High Court quashed the new government PIP regulations for mobility activities as they discriminated against people with mental health difficulties.²⁴ In 2019, the Supreme Court ruled on the scope of the term 'social support' in relation to the PIP activity of 'engaging with others'.²⁵ In 2020, the Court of Appeal upheld two successful High Court challenges brought by individuals and found that the government had unlawfully discriminated against people with severe disabilities who had moved onto Universal Credit.²⁶

One high-profile result of the financial insecurity experienced by people on welfare benefits is the rise of food banks in the UK. Prior to the current COVID-19 pandemic, many of the people using food banks were those who had been affected by the recent welfare reforms, particularly those with disabilities, lone parents and large family households. A large-scale survey of people using food banks in 2016–2017 found that two-thirds had a health condition and almost one-third had a mental health condition.²⁷ Half of the households included someone with a disability – these households were three times more likely to use foodbanks than other low-income households.

Perhaps the most serious outcome of the WCA process is its relationship to suicide. It is known that the occurrence of completed suicide increases during recessions, but there is also good evidence that the government's programme of reassessing for ESA is independently associated with an increase in suicides.²⁸ There are also several case reports of

the deaths of people by suicide or neglect whose benefits had been removed,²⁹ including the death of Errol Graham, a man with long-term mental health problems.³⁰

A recent report from the National Audit Office³¹ has revealed 69 suicides linked to the DWP's handling of benefit claims in the past 6 years. This is likely to be an underestimate, as the information held by the DWP on suicides is not exhaustive. The DWP is looking to improve the data collection and review process.

Conditionality and sanctions

The principle of conditionality (the attachment of behavioural conditions to the receipt of benefits) has long been part of welfare policy. It was, however, usually applied to recipients of unemployment benefits, who were expected to seek work. This has now changed, and under ESA regulations, conditionality is applied to sick and disabled people, many of whom are expected to engage in 'work-related activity' and who may receive sanctions, including the reduction of benefits, if they do not. The aim of conditionality for these groups is to help move people off sickness benefits into work. This has been combined with schemes to support people into work, such as the Pathways to Work and Work Programme schemes. The use of conditionality is widely debated and, as a policy, it ignores the barriers that people with disabilities face in getting into employment.^{32,33} It is unpopular, often regarded as punitive, undermines social citizenship, is ineffective in moving people into work and can damage people's health, thus making employment less likely.³⁴⁻³⁷ Disabled unemployment claimants are more likely to be sanctioned than non-disabled claimants.³⁴

Benefit stigma

Not only do people with disabilities associated with physical and mental conditions experience prejudice and discrimination linked to their conditions, they may also experience the stigma associated with claiming benefits and the shame associated with poverty. Overall, the UK public have low levels of understanding of the benefits system and people see the bulk of what the welfare state does as providing handouts to those who do not work.^{9,39} The largest proportion of the UK welfare budget is spent on pensions (42%), with 1% spent on unemployment benefits and 10% on incapacity, disability and injury benefits.⁴⁰ Overall, the public's impression is one of a system involving 'Them and Us'.⁹ These dichotomies have pervaded the language of welfare. Traditionally, for the poor the division is between the 'deserving' and the 'undeserving' poor. In contemporary government policy, the rhetoric has been one of 'a culture of welfare dependency', 'making work pay', 'scroungers', 'benefit cheats' and the 'hard-working majority', which has been reinforced by newspaper headlines and television programmes such as *Benefits Street*. It appears that in the 21st century we have shifted our gaze from the 'deserving' and 'undeserving' to 'strivers' and 'shirkers'.⁴¹

Effects on health and social services

Several recent reports have shown that dealing with people's benefit problems is putting increased pressure on mental health services and benefit and financial advice agencies^{42,43}. Community mental health teams are spending increased time managing patients' practical problems, including benefits, debt, housing and employment. Practitioners are aware that it is difficult to treat people's mental illness without finding solutions to their practical problems, which are in turn having a significant impact on the patients' mental health. Many of these problems require assistance beyond what can be provided by mental health practitioners, but accessing alternative forms of help and advice can be difficult, especially in the complex world of financial and welfare benefit systems. Nevertheless, access to help to resolve these practical issues is important to the patient's recovery and continuing engagement with health and social services (*Box 1*).
Useful information sources
Further information about social security benefits and mental health conditions can be found on the Royal College of Psychiatrists' webpages on social inclusion (<https://www.rcpsych.ac.uk/improving-care/campaigning-for-better-mental-health-policy/other-policy-areas/social-inclusion>). Advice to clinicians regarding assisting patients in their application for benefits can also be found on those pages.

Conclusions

This article has documented some of the problems faced by people with mental health conditions and disabilities resulting from the changes that have emerged from welfare reforms instituted over the past 12 years. These changes, rather than enhancing support for people with disabilities, have been unjust and ethically unsound, undermining citizenship and damaging to peoples' health and well-being. It reinforces the extent to which many people with long-term mental health (and physical health) conditions are stigmatised and socially excluded and highlights the ways in which they are vulnerable to falling into poverty. This is not inevitable and can be changed by improving the social policies that determine our present welfare state. In narrow terms this means overhauling the current system of the provision of welfare benefits, starting with the ways in which people are assessed for ESA and PIP, removing sanctions for people with sickness and disability, increasing the actual benefit payments and improving the employment support offered to people on ESA. More generally, the broader aspects of welfare state provision (health, education, housing, social services) must become more sensitive to the needs of the range of people with disabilities. At present, the system appears at worst to be punitive and at best to provide an inadequate sticking plaster. The system needs to ensure that people with disabilities are not just supported but encouraged to thrive.

The welfare reforms have had a negative effect on our already stretched mental health and social care services. If we are to provide 21st century mental health services we need to acknowledge the role they play in our welfare state and in the treatment and care of people who live in the hinterlands of low income and poverty. We must also recognise the role of broader social and economic factors in the causation and exacerbation of mental ill health. At the minimum we must find ways of providing people who use services with access to good financial and welfare advice, but more broadly create a benefits system alongside health and social services that addresses the very problems that exclude many people with long-term conditions from playing an active role in society. We anticipate a further economic recession, this time with high levels of unemployment, following the COVID-19 pandemic. This may mean a further tightening of the screw for people with disabilities and long-term conditions. On the other hand, there exists a glimpse of a better world that offers the possibility of improving the social and economic environment for those vulnerable to the vicissitudes of economic, political and social forces.

Jed Boardman is a senior lecturer in social psychiatry at the Institute of Psychiatry Psychology & Neuroscience, King's College London and the Lead for Social Inclusion at the Royal College of Psychiatrists London, UK.

1.3.19 Attitudes of care staff towards video consultations

Rory Shadwell Colin Hemmings Max Pickard

date

2020-10

Contents

- *Attitudes of care staff towards video consultations*
 - *Declaration of interest*

We read with interest the excellent article by Johns et al on video consultations in mental health services.¹ Such video consultations can also be used with key informants such as care staff. In our specialist mental health service for people with an intellectual disability (also known in UK health services as learning disability) in Kent we have just completed a quality improvement project on attitudes towards video consultations among the staff in care settings.

We found that the majority of the care staff interviewed felt that video consultations would not have a negative impact on access to (67%) or on the quality of care (69%) provided by our mental health service for people with intellectual disability. Additionally, we asked care staff if they would consider using video consultations in place of face-to-face consultations beyond the time frame of the coronavirus disease 2019 (COVID-19) pandemic. Again, we found that the majority (66.7%) said they would.

Around a third of care staff stated that video consultations could be a good alternative to face-to-face appointments as they would allow them to still go ahead even if the service users declined to leave their accommodation. Other care staff explained that video consultations would allow clinicians to see the service users in their own environment and that they may make it easier to involve multiple healthcare professionals in an appointment. The most frequently cited benefit of video consultations was the potential to alleviate the worry and anxiety that some service users experience when going to a clinic appointment.

The attitudes towards video consultations among care staff were overall positive but they were not uniformly so. For example, it was mentioned that having a video consultation may mean that the service user is more likely to become distracted. Another respondent mentioned that for their service users, much of the information needed is derived from non-verbal communication and observed behaviour, which may be more difficult to assess over video. One carer stated that it would be too difficult to get their service user to cooperate with using the communication device.

These findings may be of particular significance in the world we face post-COVID-19 lock-down where individuals may experience increased anxiety associated with healthcare settings. The month of April 2020 saw a 48% fall in attendances to accident and emergency departments when compared with the previous year, and the fall was 72% for minor injury units and urgent care centres.² There may be some long-lasting public fear surrounding healthcare settings that disproportionately affects the most vulnerable patients and telepsychiatry may prove critical in reaching those individuals as well as the staff who care for them.

1.3.20 Sabyasachi (Sab) Bhaumik, OBE, MD, DPM, FRCPsych (Hon)

Regi Alexander Sheila Hollins

date

2020-10

Contents

- *Sabyasachi (Sab) Bhaumik, OBE, MD, DPM, FRCPsych (Hon)*

Formerly Medical Director, Leicestershire Partnership NHS Trust, and Honorary Chair in Psychiatry, Department of Health Sciences, University of Leicester, UK

Sabyasachi (Sab) Bhaumik, who died of a massive cardiac infarction at the age of 66 years on 8 November 2019, was a leading figure nationally and internationally in the psychiatry of people with developmental disabilities. He served as Chair of the Faculty of the Psychiatry of Intellectual Disability at the Royal College of Psychiatrists (RCPsych) between 2006 and 2010, and before that as Chair of the Trent Division. In 2007, he established an international links group that brought together all the activities related to intellectual disability undertaken internationally by RCPsych members. Members of this committee have undertaken numerous educational, research and service development projects in India, Pakistan, Sri Lanka, Sudan, Egypt and other parts of Africa and East European countries. More recently he had taken on the role of the World Psychiatric Association's Intellectual Disability Taskforce Lead. On the national scene he was appointed an expert advisor to both the National Institute for Health Research and the National Institute for Health and Care Excellence.

Having recognised a real gap in the body of knowledge on the use of prescribed medications with people with intellectual disabilities, he and David Branford developed the *Frith Prescribing Guidelines for People with Intellectual Disability* (now in its third edition)¹ and started the annual conference on Therapeutics in Intellectual Disabilities, now in its 11th year. He published over 100 articles and book chapters in his field on a wide range of subjects, including the development of a competency-based framework in intellectual disability psychiatry, the relationship between autism spectrum disorder and visual impairment in individuals with intellectual disabilities, and health promotion in people with intellectual disabilities. Most recently he had (with R.A.) edited the *Oxford Textbook of the Psychiatry of Intellectual Disability*² and, with others, was in the process of editing a textbook on the psychiatry of intellectual disability across cultures.

He had a leadership role among UK psychiatrists belonging to ethnic minorities and served as President of the British Indian Psychiatric Association and Chair of the RCPsych's Diaspora Groups Committee. He spent a considerable amount of time abroad on visits to India training doctors in the psychiatry of intellectual disability and, in recognition of his academic contribution, was appointed Visiting Professor of Psychiatry at SRM University, Chennai, and the Father Muller Medical College, Mangalore, India.

Sab was born in Calcutta in 1952 to Gopal Bhaumik, a well-known Bengali poet, and Uma Bhaumik. After primary and secondary education in Calcutta, he graduated in medicine from R.G. Kar Medical College, Calcutta, in 1978. He then went to work in Khatra, a remote rural area. Equipment, medication and infrastructure were lacking but Sab made up for these with his commitment, compassion and honesty. When he left after 3 years to join an MD programme in pharmacology at Benares Hindu University, there were at least 200 people there waiting to see him off. Moving to the UK in 1985, Sab worked first on a psychiatric rotation in north Wales. He joined the Leicester Frith Hospital as a consultant in intellectual disability in 1992. Subsequently, he was appointed to various senior roles at the hospital – lead clinician, clinical director and medical director. After his retirement in 2013, he worked as a consultant psychiatrist and senior medical advisor to the hospital's board.

Sab was a man of extraordinary energy, generosity and kindness. He was always a powerful advocate for his patients, whom he saw as a marginalised group of people with developmental disabilities who often had neither equity of access nor equity of treatment. His Saturday mornings were spent at the hospital surrounded by people wanting his help and advice – psychiatrists preparing for the RCPsych membership examinations, registrars getting ready for consultant interviews and consultants seeking guidance on a range of assorted issues.

In 2005, he was awarded the Hospital Doctor of the Year award at the London Hilton on Park Lane, where his colleagues spoke warmly of his multidisciplinary approach. In 2006, his enormous contribution was recognised with an OBE for services to medicine. In 2012, he was appointed to an Honorary Chair in Psychiatry in the Department of Health Sciences at Leicester University, a reflection of his contribution to research and teaching. In 2015, the RCPsych awarded him its highest honour – an honorary fellowship.

Soon after his unexpected demise, his wife Susmita Hoare wrote eloquently about how Sab had a ‘magnetic quality to attract people’ and how ‘his honesty, compassion and ability to rise above petty jealousies made him one of a kind’. She spoke for many when she said, ‘Like a comet he blazed into our lives, touching everyone with love, laughter and hope – the world darkening as he left’.

Sab Bhaumik is survived by Susmita and his son Sugato, a junior doctor.

1.3.21 Homelessness, housing instability and mental health: making the connections

Deborah K. Padgett

Correspondence

Deborah K. Padgett (dkp1@nyu.edu)

date

2020-10

Abstract

Research on the bi-directional relationship between mental health and homelessness is reviewed and extended to consider a broader global perspective, highlighting structural factors that contribute to housing instability and its mental ill health sequelae. Local, national and international initiatives to address housing and mental health include Housing First in Western countries and promising local programmes in India and Africa. Ways that psychiatrists and physicians can be agents of changes range from brief screening for housing stability to structural competence training. Narrow medico-scientific framing of these issues risks losing sight of the foundational importance of housing to mental health and well-being.

Mental illness and homelessness

The bi-directional relationship between mental ill health and homelessness has been the subject of countless reports and a few misperceptions. Foremost among the latter is the popular notion that mental illness accounts for much of the homelessness visible in American cities. To be sure, the failure of deinstitutionalisation, where psychiatric hospitals were emptied, beginning in the 1960s, led to far too many psychiatric patients being consigned to group homes, shelters and the streets.¹ However, epidemiological studies have consistently found that only about 25–30% of homeless persons have a severe mental illness such as schizophrenia.²

At the same time, the deleterious effects of homelessness *on* mental health have been established by research going back decades. Early epidemiological studies, comparing homeless persons with their domiciled counterparts, found that depression and suicidal thoughts were far more prevalent, along with symptoms of trauma and substance misuse.^{2,3} A recent meta-analysis found that more than half of homeless and marginally housed individuals had traumatic brain injuries – a rate far exceeding that of the general population.⁴ Qualitative interviews with street homeless persons bring to life the daily struggles and emotional toll of exposure not only to the elements but to scorn and harassment from passers-by and the police.⁵

In the USA, healthcare professionals were among the first responders to the homelessness ‘epidemic’ of the 1980s. The Robert Wood Johnson Foundation Health Care for the Homeless initiative funded 19 health clinics around the nation, beginning in 1985. Individual physicians, including Jim Withers in Pittsburgh and Jim O’Connell in Boston, made it their mission to go out on the streets rather than participating in the ‘institutional circuit’⁶ that led so many homeless men and women to cycle in and out of emergency departments, hospitals and jails. Health problems such as skin ulcerations, respiratory problems, and injuries were the visible indicia of what foretold a shortened lifespan.⁷ Less visible but no less dire are the emotional sequelae of being unhoused – children are especially susceptible to the psychological effects of homelessness and housing instability.⁸ The gap between mental health needs and service availability for the homeless population is vast.

The bigger picture: global housing instability and structural factors

Literal homelessness – sleeping rough in places unfit for human habitation – can be seen as the tip of an iceberg of housing insecurity affecting millions of people around the world.⁹ As with attempts to count the number of homeless people and the definitional difficulties attending such counts,¹⁰ providing an estimate of the number of housing-unstable persons globally is definitionally and logistically challenging. In terms of slum dwellers (a prevalent form of housing instability), Habitat for Humanity cites estimates ranging from 900 000 to 1.6 billion.¹¹ The Dharavi slum in Mumbai has one million residents squeezed into two square kilometres, one of the densest human settlements in the world.¹¹ Substandard housing affects the well-being of inhabitants – crowding, poor sanitation and infestations bring their own risks to health and mental health.¹²

Severe housing shortages in low-income countries contrast with the greater availability of housing in higher-income countries. And yet the visibility and persistence of homelessness in wealthier nations attests to the effects of growing income inequities in the midst of plenty. In the USA, attempts to address homelessness must take several structural barriers into account. First, housing is fundamentally viewed as a commodity and is bound up with economic gains in the

forms of tax benefits for homeowners and builders, equity or wealth accumulation from owning property, and developers' profits from housing market speculation.¹³ The worst 'slumlords' (landlords who own and rent decrepit properties to poor families) reap greater levels of profit than their counterparts who build for affluent buyers or renters.¹⁴ Second, exclusionary zoning ordinances ensure protection of single-family properties, thus reducing housing availability for renters and preventing multi-family dwellings.¹⁵ Finally, access to housing is not a purely economic proposition. The effects of centuries of *de facto* and *de jure* racial exclusion continue to uniquely harm African Americans in denying them access to housing and associated wealth accumulation, thus contributing to their disproportionate representation among homeless persons in the USA.¹⁵

The ultimate causes of homelessness are upstream, i.e. a profound lack of affordable housing due in large part to neo-liberal government austerity policies that prevent or limit public funding for housing, gentrification that displaces working and poor families, and growing income disparities that make paying the rent beyond the means of millions of households. Currently, more than half of US households must devote over 50% of their income to paying for housing, an unprecedented level of rent burden.¹⁴ Farmer refers to this phenomenon as 'structural violence': the combined and cumulative effects of entrenched socioeconomic inequities that give rise to varied forms of social suffering.¹⁶ Social suffering does not easily align with existing psychiatric nomenclatures and diagnostic algorithms, but its influence on health through chronic stress and allostatic overload weakens immune systems and erodes emotional well-being.¹⁷

International and national initiatives

Interestingly, since its 1948 declaration of a right to housing,¹⁸ the United Nations (UN) has generally steered clear of re-enunciating such a right until the Sustainable Development Goals (SDGs) were announced in 2015. Subsumed within SDG #11, labelled 'sustainable cities and communities', is Target 11.1 of 'safe and affordable housing for all by 2030'.¹⁹ The UN Special Rapporteur on the right to adequate housing, Leilani Farha, recently submitted a set of guidelines for achieving this goal.²⁰

In the global south, access to mental healthcare for the most vulnerable is extremely limited despite legislative initiatives to expand such care^{21,22} and reduce human rights abuses against psychiatric patients.²³ The Global Mental Health Movement (GMHM), which began with a series of articles in the *Lancet* in 2007 asserting 'no health without mental health',²⁴ came together to address a crisis that results in a 'monumental loss in human capabilities and avoidable suffering'.²¹ The *Lancet* Commission on Global Mental Health and Sustainable Development, part of the GMHM, has strategically partnered with the UN's SDGs to ensure that mental health and substance misuse are integral to the SDGs moving forward.²¹ And there are signs of progress – most originating in the work of citizen advocates and patients working through non-profit rather than formal government channels. In Chennai, India, a visionary non-profit known as The Banyan has pioneered a culturally and socially innovative approach, 'Home Again', to help homeless persons with severe mental illness recover their lives and live independently or return to their family homes.²⁵ In West Africa, advocates for AIDS and leprosy patients have turned their talents and expertise to developing programmes for persons with mental illness that are inclusive, rehabilitative and rights based.²³ Zimbabwe's 'Friendship Bench' programme, which situates attention to mental health within ongoing community activities, has been replicated worldwide.²⁶ Although the African approaches are not targeted at homeless persons, they have been heralded as low-barrier and inclusive – and by their location are likely to assist persons with housing insecurity problems among others.²¹ The recent *Lancet* Commission report on global mental health²¹ included mention of homelessness as both a cause and consequence of poor mental health.

The advent of Housing First has been a rare success story at the programmatic and systems levels in the US, Canada and Western Europe.²⁷ Begun in New York City as a small but determined counterpoint to 'treatment first' approaches making access to housing contingent on adherence, Housing First has achieved an impressive evidence base and extensive adaptations to new populations such as homeless youth, families and opioid users.²⁷ By reversing the usual care continuum of first requiring medication adherence, abstinence and proof of 'housing worthiness', Housing First is the prime exemplar of an evidence-based, cost-saving enactment of the right to housing. Importantly, it is not 'housing only', i.e. support services including mental healthcare are essential to its success.²⁸ Early reliance on assertive community treatment in Housing First support services was eventually expanded to include less-intensive case management supports for clients whose mental health recovery had proceeded further.²⁷

Another evidence-based programme known as critical time intervention (CTI) has proven effective in preventing home-

lessness pending discharge from institutional care.²⁹ Using time-sensitive intensive supports before and after discharge, CTI connects the patient or client with housing and support services to ease return to the community and avert falling into homelessness.²⁹ Like Housing First, CTI has focused on persons with mental disorders but has since been adapted for other at-risk groups, such as clients leaving substance misuse treatment settings or prisons.

In the USA, there are a few signs that housing as a social determinant of health is receiving greater recognition. The Obama-era Affordable Care Act offered states the opportunity to expand Medicaid eligibility to millions of low-income households, including coverage for mental healthcare.³⁰ Although federal rules prohibit use of Medicaid funds to pay for housing (with the exception of nursing homes), some states have creatively used Medicaid funds for all housing-related services short of rent, including move-in costs and follow-up supports.³⁰ Unfortunately, capital funding for building and developing new housing units remains woefully inadequate, and it is too often left up to the private sector to act on a profit motive incentivised by government subsidies and tax incentives.¹⁵ Given the current national political situation in the US, positive change at the federal level is unlikely, but states and cities continue to independently seek ways to move from shelters to housing.³⁰

The healthcare landscape in the UK offers opportunities for service integration under coordinated national healthcare, and the link between housing and health is evident in recent cooperation between the National Housing Federation and the Mental Health Foundation in providing supported accommodation for persons with mental disorders.³¹ In Western Europe, the establishment of FEANTSA (European Federation of National Organizations Working with the Homeless; www.feantsa.org) in 1989 with support from the European Commission has brought together representatives from 30 nations for programmatic and research initiatives (many using Housing First). Consideration of mental problems as cause and consequence of homelessness is a key component of FEANTSA's work, with psychiatrists actively involved in research at several sites, e.g. France's multi-city randomised trial of Housing First.³²

Psychiatrists and physicians as agents of change

In what ways can healthcare providers help? For housing-related risk assessment, family or general care physicians may make use of brief screening items inquiring about recent moves, evictions and rent arrears³³ as a means of ascertaining a patient's housing instability. Regrettably, there are limited programmes available to which to refer patients with 'positive' screens, but raising awareness and knowing a patient's life challenges can only improve care. Calls for medical training to include 'structural competency'³⁴ point to the broader importance of practitioners becoming versed in patients' life circumstances linked to poverty to contextualise their health problems. According to Metzl and Hansen,³⁴ structural competency is the practitioners' trained ability to recognise that patients' problems defined clinically as symptoms, attitudes or disease also represent the downstream implications of upstream decisions about housing affordability, healthcare availability, food delivery systems and other infrastructure supports.

Some physicians have called for the right to prescribe housing as a means of solving this underlying problem, with the added advantage of reducing medical costs.³⁵ Prescribing housing as a form of 'preventive neuroscience' has received support from the O'Neill Institute as a cost-saving humane investment in children's brain development.³⁶ Such attention to social and environmental determinants of health is hardly misplaced, as they account for 90% of health status, with only 10% attributable to medical care.³⁰

Homeless men and women have few encounters with physicians, much less psychiatrists and other formal mental healthcare providers. Those with diagnoses of severe mental illnesses might have an assigned psychiatrist to prescribe anti-psychotic medications, but these are brief encounters at best. Even in wealthier nations, psychiatrists working in the public sector are relatively fewer in number, overworked, underpaid and rarely able to address the hidden crisis of mental ill health wrought by homelessness and housing instability. In low-income nations, the service gap is even wider.²²

A recent US report on the alarming lack of access to mental healthcare even for the well insured points to a broad-based crisis in mental health services.³⁷ Ignoring laws ensuring parity, insurers provide much lower coverage for mental health treatment than would be tolerated for cardiac or cancer care, and out-of-pocket costs can run as high as \$400 per private psychiatrist visit.³⁷ The prospects for a homeless man or woman who is feeling anxious, depressed or suicidal are indeed dismal. Although many homeless and other low-income individuals in the US are enrolled in Medicaid, an acute scarcity of psychiatrists who accept Medicaid patients renders such coverage virtually unattainable in many parts of the US.³⁷

A caveat about the medico-scientific approach moving forward

Attempts to incorporate social determinants thinking into public policy discourse on the mental health benefits of stable housing still have some way to go in jurisdictions where the medico-scientific approach holds sway. As a case in point, witness the recent report by the prestigious US National Academy of Science, Engineering and Medicine (NASEM) on the health benefits of permanent supportive housing (PSH), a major source of housing and supports for formerly homeless persons with severe mental illness.³⁸ Acknowledging that research on the topic was severely limited owing to the recency of PSH and its many poorly defined iterations, the NASEM report nevertheless concluded that the health benefits of such housing were minimal, with the possible exception of persons with HIV/AIDS having improved outcomes.³⁸ The report argued for the need to identify ‘housing-sensitive’ health conditions to point future researchers in the right direction.³⁸

Such delimiting of what is important to ‘housing-sensitive’ medical conditions exemplifies the narrowness of the medico-scientific model set against a social determinants model combined with human rights. In response to such reductionism, the British Psychological Society recently proposed the Power Threat Meaning Framework as an alternative to the medicalisation of mental illness,³⁹ proposing that greater attention be given to the implications of power and inequality.

Homelessness represents an existential crisis that threatens mind and body alike. The concept of ontological security, having its modern origins in the writings of sociologist Anthony Giddens, offers phenomenological insights into the benefits of stable housing that domiciled persons easily take for granted. As noted by this author,⁴⁰ going from the streets to a home enhances one’s ontological security, as such a transition affords a sense of safety, constancy in everyday life, privacy, and a secure platform for identity development.⁴⁰ As with Maslow’s hierarchy,⁴¹ fundamental human needs must be met in order to satisfy higher-order needs such as belonging and self-actualisation.

Conclusion

Despite a plethora of research linking mental and physical health to housing stability, the salience of structural barriers is too often submerged in ‘blaming the victim’ for her or his plight. Physicians and healthcare providers receive little training in social determinants and often view them as off-limits or distracting from attention to signs and symptoms. Yet psychiatrists and other mental health professionals can become agents of change by paying greater attention to the social determinants of mental health and seeking structural competence in their practice. It is difficult to overestimate the benefits of having a stable, safe home as fundamental to mental health and well-being.

1.3.22 Placing poverty-inequality at the centre of psychiatry

Peter Byrne Adrian James

Correspondence

Peter Byrne (peter.byrne@nhs.net)

date

2020-10

Abstract

We examine epidemiological evidence for the central role of inequalities (principally economic) in driving the onset of mental disorders, physical ill health and premature mortality. We locate the search for solutions in current UK contexts, and include known and likely effects of the COVID-19 pandemic. Prevention of mental disorders and adverse outcomes such as premature mortality must begin with efforts to mitigate rising poverty-inequality.

Contents

 - *Solutions beyond this issue*
 - *From public education to public engagement*
 - *Declaration of interest*
 - *Supplementary material*

We can't go on like this. As clinicians in the UK and elsewhere, we are asked to treat rising numbers of people with mental health problems – definitely not the 'worried well' but patients with life-changing mental disorders. Rates of adult mental disorders and addictions are high, and that 'disease burden' bears no relation to the resources allocated to address it internationally.¹ Childhood mental disorders appear to be increasing, with rates of diagnosed illness of 15% in one large Danish cohort.² We see higher rates of psychological and physical morbidity in older people and, despite many examples of good professional practice, older adults' teams do not receive the resources needed to manage these.³ Even if we receive the long-promised extra funding to treat people with mental disorders across their lifespan, our recent gains with #ChoosePsychiatry will not deliver the numbers of psychiatrists we will need, let alone the nurses and other health and social care professionals. And so we look to prevention. Stopping these disorders from occurring, or reducing their severity, will reduce the distress of becoming unwell and alleviate the considerable costs to carers and wider society. Prevention is the first duty of the health system and those who work in it, on moral, ethical and sustainability grounds.

Where do we start with prevention?

Many would begin with adverse childhood experiences (ACEs). The original concept arose from a prospective study of childhood obesity,⁴ but their wider predictive value merits study. Hughes et al⁵ demonstrate increased relative risks in adults with four or more ACEs: doubled risks of heart disease (95% CI 1.66–2.59), alcohol misuse (1.74–2.78), and cancer (1.82–2.95); tripled rates of chest diseases (2.47–3.77) and anxiety (2.62–5.22); a four-fold increase in ‘low life satisfaction’ (3.72–5.10) and depression (3.54–5.46); and a 30-fold increased risk of a suicide attempt (14.73–61.67). For selective or targeted prevention, we look at the other end of the (shorter) life of someone with severe mental illness (SMI);⁶ we might start with smoking, obesity, alcohol and substance misuse. All four shorten life expectancy and healthy years expectancy (life before multimorbidity begins) and make our task of improving quality of life in SMI even harder. Then there is a sixth area, fair access to medical care: current national strategies to improve physical health outcomes in people with SMI and treatment of all mental disorders focus on this. Older citizens, who began life as ‘baby boomers’, have acquired the nastier metaphor of a ‘ticking time bomb’ in terms of likely health and social care costs. The prevention of many dementias (vascular dementia, alcohol-related brain damage, head injury) is achievable.⁷ Seven challenges then, maybe for seven Royal College of Psychiatrists-led intercollegiate Committees? No, there is a better way. Behind all seven of these, Michael Marmot’s ‘causes of the causes’, prevention has one major focus: *poverty-inequality*.

What are the consequences of poverty-inequality?

‘Inequality exists in the stresses and strains on family life, which shape the environment in which children grow up. It is the divergence in life expectancy between deprived and affluent areas, and the growing burden of poor mental health among disadvantaged groups’.⁸ In his accessible book, *The Health Gap*, Marmot⁹ concludes that ‘the (health) gradient involves everyone, rich, poor and in between’ (p. 26). Poverty is not inevitable, and ‘in the US, after transfers and taxes, child poverty is higher than Lithuania – 23% compared with 15% – despite having similar levels of poverty pre-tax’ (p. 137). Life expectancy, and specifically why this is falling in the UK (and was falling before COVID-19) among older and poorer citizens, is key to understanding why we need fundamental change. Marteau and colleagues¹⁰ studied the UK government’s ambitions to reverse this rising mortality: ‘the leading causes of years of life lost in England are tobacco use, unhealthy diet, alcohol consumption, and physical inactivity. All of these behaviours are socioeconomically patterned’. The scientific literature has reached a consensus on the health harms of poverty-inequality. In their study of multimorbidity in the ethnically diverse London borough of Lambeth (where a third of a million are registered with a general practitioner (GP)), Ashworth et al¹¹ concluded that: ‘acquisition of multimorbidity is patterned by socio-economic determinants’, with depression and asthma as early drivers of poor physical health. The US and the UK have similar high levels of inequality, and their inhabitants can expect to lose 7–9 *healthy* years (free from physical disability) by the age of 50 if they are poor, compared with their fellow citizens at the least deprived end of the gradient.¹² All the evidence points to poor mental health, from common mental disorders through to SMI, as the means whereby poverty wrecks *physical* health.

But rich people get mental disorders too

Yes, they do. But they get better from depressive episodes faster and relapse less, in contrast to people on lower incomes, who have higher prevalence rates and worse outcomes.¹³ We also concede that most people who grow up in poverty do not develop a life-changing episode of depression, let alone SMI. But the antecedents of SMI are complex, and our understanding of why people develop psychosis is changing, building on the seminal work of Jim Van Os on the toxic effects of urbanicity¹⁴ – with consistent evidence of the cumulative effects of social disadvantage. Work with case-control groups in south London showed consistent odds ratios (ORs) for subsequent psychosis in people below the poverty line of 4.50 (95% CI 2.89–7.00) and 2.95 (1.89–4.61), for 1-year and 5-year *pre-symptom onset*, respectively. These ORs were the single highest predictors of psychosis, other than the related but confounded OR of 12.05 (7.13–20.35) for being unemployed on presentation to psychiatric services.¹⁵ Outcomes in adults with first-episode psychosis are complex and improving slowly in our professional lifetimes (with adequately resourced early intervention services); even at 5-year follow-up, Mattsson et al¹⁶ showed financial strain and social networks to be strong, independent predictors of outcomes.

Lessons from history

We cannot ignore poverty as a predisposing, precipitating and maintaining factor in most of our patients' disorders. Early in the neuroleptic era, we knew that poorer people had worse outcomes in schizophrenia, stayed in hospital longer, and were socially isolated even if they achieved discharge,¹⁷ but our textbooks called this 'social drift' despite prior debunking of the drift hypothesis.¹⁸ Hindsight is easy, certainly, but perhaps we should look to psychiatry's institutional bias. We still speak of a problem of *stigma* (negative societal attitudes) rather than acknowledging the reality that people with SMI have lower status conferred on them and face institutional obstacles to achieving their life goals, and calling this out as subcitizenship.¹⁹ At the time we started writing this, we welcomed the stated intention of the UK government to reverse a decade of austerity, signalled first in October 2018²⁰ and often repeated during the first weeks of the spring 2020 lockdown. In advocating a broader role for busy psychiatrists in opposing regressive social policies, we are echoing the 'wake-up call' to colleagues from 2008: '[it is] fully consistent ... to think of psychiatry as being the only specialty in which its practitioners are fully trained doctors, incorporating psychology and social-based knowledge and skills as major components of training'.²¹ Not 'social workers with stethoscopes' but clinicians with public health knowledge who understand the environments in which our patients live. And die.

What we know about the effects of COVID-19 (so far)

COVID-19 has changed how every health professional practises. Each health specialty must play its part in mitigating and preventing further adverse outcomes. The virus leaves a trail of delirium, depression and anxiety, perhaps post-traumatic stress disorder in those who survive,²² and further misery for those bereaved. COVID-19 has revealed and exacerbated inequalities. Examination of death rates in the first 20 283 hospital deaths with proven COVID-19 in England and Wales shows major differences between the richest and poorest regions: 'people living in more deprived areas [for example, the London boroughs of Newham and Brent, in the context of an early first peak in London] have experienced COVID-19 mortality rates more than double those living in less deprived areas. General mortality rates are normally higher in more deprived areas, but so far COVID-19 appears to be taking them higher still'.²³ At the time of writing, recording of the proportions of deaths among Black, Asian and minority ethnic (BAME) groups was incomplete, but preliminary figures, not least those for deaths among our BAME colleagues working in health and social care, have shown an excess. Health gradient differences are among the lessons of the pandemic: the age-standardised mortality rate of deaths involving COVID-19 in the most deprived areas across England was 55.1 deaths per 100 000 population, compared with 25.3 deaths per 100 000 population in the least deprived areas.²³ We have yet to learn the full extent of excess deaths from COVID-19 among our patients across age groups, regions and specialties. It is too late for them, but we will not dodge the hard questions. As mental health professionals, we cannot remain as observers; we must now act on poverty-inequality.

Solutions in this issue

This issue opens with a contribution from two people with lived experience of SMI. Smoking remains a challenge in mental health services, and you will read about tobacco poverty and how to achieve more 'quits'. *Housing First* shows the evidence for changing how we approach this issue. We feature the Glasgow perspective on how we might progress, as well as an article on the cruelty of 'reforms' to the safety net benefits system. There is a biomedical perspective too.

What have we left out?

To name just five areas, we have not raised here the related premature mortality of people with personality disorders and intellectual disabilities, often worse even than that in people with SMI,⁶ nor the excellent work by patients, carers and professionals to reduce high-dose prescribing of psychoactive medications in intellectual disability.²⁴ Health inequalities drive the UK's obesogenic environment, which is relevant to premature mortality in general but specifically to COVID-19 deaths. Cuts to addictions services are considered elsewhere, alongside the opioid crisis that has crossed the Atlantic.²⁵

Solutions beyond this issue

As we mature as clinicians, our goals of intervention adjust to realities and hard-won experience. We do not see patients as a collection of neuroreceptors (including subtype and putative phenotype); we devise complex formulations to persuade patients towards self-management and empowerment, consolidating their (real not virtual) social networks and support systems. To achieve this, we will need to practise *psychosocial education*. Communicating complex information about the drivers of mental disorders might be easier if our patient has just one, but aetiology (causes of the causes) is shared. Beyond your wards and clinics, other health professionals also need to know what we know. Do our GP letters communicate the individual drivers of someone's misery (inadequate housing, precarious income, indeterminate status to remain, no locally available stop smoking services, the pressures of raising children when a parent has mental health or substance issues, etc.), or is it easier to write about medications and risk? It is a great start to identify what we can do better where we work^{9,26} – and we cannot dispense social prescribing unless we understand our local communities.

From public education to public engagement

Do you know who leads on inequalities in your local organisations? Are there aspects of your practice where inequalities are making outcomes worse, and are you in a position to influence mitigation for these? Regional structures and local alliances have the potential to achieve results beyond the ephemeral 'levelling up' of current public discourse. Of course there will be political voices (of all shades and volumes) to keep us quiet, but we are 'following the science'. The Royal College of Psychiatrists has joined with many partners in Equally Well (www.equallywell.co.uk) to use the available evidence to reverse rising SMI mortality. We hope this special issue of the *BJPsych Bulletin* will get people thinking and talking. What will *you* do to achieve a wider societal dialogue? Our College and others are building resources to tackle poverty-inequality, but we need all the help we can get.

Peter Byrne is a Consultant Liaison Psychiatrist at the Royal London Hospital; Associate Registrar in public mental health, Royal College of Psychiatrists; and Visiting Professor at the Centre for Health Policy, University of Strathclyde. **Adrian James** is President of the Royal College of Psychiatrists.

P.B. devised and wrote first drafts of this article to frame a special issue of the *BJPsych Bulletin* on poverty. A.J. commented on these drafts and enhanced the content on BAME inequalities and prevention.

Declaration of interest

P.B. remains the lead for public mental health at the Royal College of Psychiatrists, and represents the College in the Equally Well collaborative, hosted by the Centre for Mental Health; he is also a former Trustee of the Mental Health Foundation.

London-based neuropsychologist Vaughan Bell recently mused on Twitter: 'I'm always slightly mystified why the situation in Northern Ireland gets ignored by the wider UK mental health community. Thirty plus years of armed conflict, highest prevalence of mental health problems in the UK, shockingly low level of investment in services' (@vaughanbell, 2 Feb 2020; Tweet reproduced here with permission). I confess, I myself have wondered.

Inequality is indeed writ large in the mental health of Northern Ireland's populace. The statistics are alarming: deaths by suicide have doubled since the ceasefire heralded by the Good Friday Agreement in 1998 and are now the highest in the UK; there is a 25% higher prevalence of mental health problems in Northern Ireland compared with England; and Northern Irish people are prescribed more psychotropic medication than any other European population.

¹

Claire Mckenna talks to Ciaran Mulholland, clinical director of Northern Ireland's Regional Trauma Network about the legacy of 'the Troubles' and why psychiatry is inherently political

Professor Ciaran Mulholland took time out to talk to me during a 2019 conference on ‘Psychiatry and Conflict’ in Belfast, where he was speaking in his role as clinical director of Northern Ireland’s unique Regional Trauma Network. Set up in 2017 as a fitting legacy for the 3700 killed and 55 000 injured in the conflict, it aims to provide a world-leading mental health service, across a network of voluntary and statutory sectors, for victims of all forms of trauma in Northern Ireland.

A legacy of conflict and deprivation

Mulholland’s first posting as a consultant adult psychiatrist was in 1998, the year the worst of the violence stopped. His base was the socially deprived area of Newtownabbey on the Northern outskirts of Belfast: “‘There was a lot of paramilitary activity in the area. There were also parts of the catchment area where many ex-soldiers, ex-policemen and ex-security forces were living, who clearly had their own experience [...] A lot of what I dealt with was trauma related, where the individuals in some way have been impacted by the Troubles.’”

Newtownabbey is a microcosm of Northern Ireland’s more deprived communities. Many moved there to get away from the violence in Belfast in the 1970s, some involuntarily: “‘That means the local community is quite atomised and not as cohesive as you might get in some parts of Northern Ireland, which is one of the reasons Newtownabbey has quite high rates of psychiatric problems.’”

Northern Ireland has higher rates of mental illness than the rest of the UK across all types of mental health conditions. Why have so many people not seen the dividends of peace reflected in their mental health? Mulholland says the causes are complex: socioeconomic deprivation is strongly associated with mental illness; there is a long legacy of underfunding of mental health services (half the proportion of health funding compared to England); there is a tribal political structure, leading to impasses in policy decision-making; and the psychological ripples of the Northern Ireland civil war continue to reverberate 23 years after it ended.

And then there are those stark suicide statistics: 143 people died by suicide in Northern Ireland in 1996. When last recorded in 2015, the figure had more than doubled to 318. It’s tempting to attribute the lower rates in wartime to a protective ‘Blitz-spirit’, which bonds people together through shared adversity. Mulholland thinks this could be a factor in more deprived communities, but we have to be careful not to over-interpret.

He points out that during the years of the Troubles, paradoxically, policing by paramilitaries kept drug misuse in Northern Ireland lower than anywhere else on these islands – which is now not the case. There is also some evidence that, for people in their 50s or 60s, who lived through the worst years of violence, their untreated trauma was a factor in their suicide decades later. Most people who die by suicide in Northern Ireland don’t have contact with mental health services, so tackling it can’t be addressed by mental health services alone.

PPE: politics, psychiatry and economics

We’re talking in the Harland Bar, named after the local shipyard, in the shadow of the four hulking steel prows of Belfast’s Titanic building. It seems an apt place to meet, for a man whose political life has been bound up with the struggles of the blue-collar worker: “‘Well, I mean, I am a socialist, you know. I’m on the left and my version of socialism is avowedly anti-sectarian. So, I’ve not needed to be in either camp. I’ve a very clear, distinctive view about there being a third tradition in Northern Ireland, which is kind of around labour and socialist politics.’”

Northern Irish psychiatry is a small community, where reputations travel by word of mouth. Mulholland seems to plough his own furrow, more or less. Genial and unassuming in manner, the only signifiers of non-conformity are the Dr Martens boots he wears with his suit. There is no evidence of the reputed (possibly apocryphal) Trotskyite student streak.

Mulholland says that doctors in Northern Ireland have always had strong links with the socialist tradition. The nascent socialist and labour movement was stymied by the eruption of the civil war in 1968–1970. Sectarianism has dominated the political discourse ever since. He describes the influence of these socialist roots on his professional life: “‘It was just central to my work from the day I began working as a doctor, even before I trained in psychiatry. Perhaps that was of assistance to me that I wasn’t as focused on the biology as a causative factor and as a sole explanatory factor, as maybe some other doctors were.’”

In the Northern Ireland context, he thinks socialism has a unique ability to straddle the sectarian divide: “‘I think socialism properly speaking is neither Unionist nor Nationalist and seeks to unite people [...] And it’s around issues like health and education. That’s how you unite people in terms of what they have in common as opposed to dividing them.’”

Although for some people socialism is conflated with the ‘Red Peril’, Stalinism, et cetera, Mulholland is at pains to stress that fundamentally it’s about creating a more equal society: ‘That’s [Stalinism], not my version of socialism. It has to be democratic or it’s not socialism’.

Mulholland sees the current resurgence of socialism (among young people in particular) as a renunciation of individualism. He detects a growing public awareness that collective purpose is needed to reduce social inequality and to improve our mental health: “‘I think it’s the impact of the global crisis of 2007, 2008, 2009 [...] that led to people who hadn’t previously questioned the system, how it operated, asking profound questions. And I think that’s now magnified by other developments, for example the question of the future of the planet, the environment [...] if you study that particular threat carefully, and you think about what the alternatives are, it does suggest transformational change is required.’”

What is at psychiatry’s cutting edge?

No, it’s not the sexy neuroscience. ‘I suppose I’ve always been interested in prevention and early intervention’, Mulholland explains, ‘in the sense that if psychiatry has a cutting edge it’s about: How early can we intervene?’

If circumstances hadn’t changed suddenly in 2012 he might have stayed in his first consultant job in Newtownabbey. He collapsed at work, was rushed to theatre with a haemoglobin of 3 and was diagnosed with a rare form of stomach cancer. There was no Damascene moment, but after 9 months off, with time to take stock, he came back to find a small pot of money available to do some innovative work.

One of the earliest advocates in Northern Ireland for early intervention in psychosis services, he now works as a consultant psychiatrist with STEP (Service, Treatment, Education and Prevention), Northern Ireland’s only early intervention service for the ‘at-risk mental state’, which he helped set up in the Northern Trust area. He is also one of the clinicians who has done most to fertilise the ground for mental health research in Northern Ireland. He co-leads the mental health special interest group in the Northern Ireland Clinical Research Network.

His research interests primarily focus on first-episode psychosis, prevention of transition to psychosis and the impact of trauma on mental health. Northern Ireland has higher rates of psychosis than most places in the UK (excepting parts of London with a high African–Caribbean population).

There is a burgeoning evidence base that early intervention can improve outcomes for young people with psychotic illness and even prevent transition from at-risk mental states in some cases. Though as Mulholland says, it can be quite difficult to prove a negative.

The Belfast fixator

Northern Irish medicine has some grim claims to fame because of medics’ unique war-zone experience. The ‘Belfast fixator’, for example, was designed here by an orthopaedic surgeon to heal injuries from beatings and explosions.

Four out of ten adults in Northern Ireland have been directly or indirectly affected by Troubles-related trauma, Mulholland says. According to data collected between 2004 and 2008, 8.8% of the population met criteria for post-traumatic stress disorder (PTSD) at some point in their lifetimes (higher even than in other, more intense conflict zones such as Lebanon and Israel).¹ The methodology of that paper has been pored over since, but he backs up its findings: “‘It is clear and demonstrable that other places have higher rates of trauma with lower rates of PTSD. Some other factors must be at play [...] one of the areas which we are compared to, for example, is Israel [...] but there is evidence that Israeli society is particularly cohesive. That’s a protective factor and perhaps our society is not quite so cohesive and that’s how rates [of PTSD] have crept up.’”

How then does a trauma history affect the trajectory of severe mental illness such as bipolar disorder and psychosis? When Mulholland was training, the dominant paradigm was a biomedical one, but he says, “‘I was always interested

in the idea that actually psychological trauma was more central to the aetiology and the course of schizophrenia than was allowed for. And it was around that time in the 1990s [...] that evidence began to emerge from groups all over the world, that psychological trauma can actually cause psychosis.”

Although this is more widely accepted now, he allows that there is much work to do to develop causal models of psychotic illness.

The Northern Ireland Regional Trauma Network, of which he is clinical director, was set up with a research focus from day one. Randomised controlled trials looking at epigenetic factors in the intergenerational transmission of trauma and psychological treatments of trauma are in the offing.

Mulholland discusses the emerging evidence that psychological trauma causes brain damage, particularly to the hippocampus and amygdala. He says there is evidence that damage can be repaired with medication and psychological therapy: ‘So a psychological insult causes brain damage and psychological therapy causes brain repair. I think that’s very exciting and it opened up an entirely new way of looking at the brain’.

How does he respond to critics who, on the basis of the association between trauma and mental illness, question the validity of a biological contribution to psychiatric disorders? He suggests that we avoid ideological entrenchment: “‘I would have an issue with the individuals who practise biological determinism [...] but I think equally now we have strident voices where it’s psychological determinism, where it’s your psychology that determines everything, and that’s clearly not always the case.’”

Media and mental health

Mulholland has long had an interest in the portrayal of mental health in film and media. He helped organise a symposium on ‘Film and the politics of mental health’ in 2016, with a focus on two countercultural figures, Franco Basaglia and R.D. Laing. I wonder whether I’ve caught a glimpse of the radical psychiatrist within, but he remains elusive.

Mental health anti-stigma messages sometimes seem at saturation point in the media, but it’s not the ‘worried well’ Mulholland wants to target: “‘I think it’s one role of psychiatrists to ensure that there’s greater understanding that there is such a thing as a mental illness. I think that actually is important. You could say it’s a concept or a construct and it is in a sense, of course, but I think it’s important for us to make the case that sometimes there is demonstrable pathology, which means that a person’s way of being is different, which meets all the criteria for illness and that ought to be addressed.’”

In a socially conservative society like Northern Ireland he thinks this is especially crucial. The BBC’s Countryfile programme shone a spotlight on mental health problems among gay farmers last year. Mulholland was involved with the episode, which interviewed a Northern Irish farmer who had suicidal feelings as a result of repressing his sexual identity.

Since then he has been working with the BBC on a Horizon programme (screened in spring 2020), about prominent 1990s comedian Tony Slattery. In particular, he wants to highlight the genesis of mental illness through trauma: “‘He [Slattery] received a diagnosis of bipolar affective disorder after his parents died. He went into the media and began to talk about a traumatic experience at the age of 8 and once he began to talk about it, he wanted to explore it further. So we worked with the producers of Horizon and made a programme all around this, about his life trajectory, his life course, but going beyond that to examine bipolar disorder as a concept – what the biological underpinnings of bipolar disorder might be and the role of trauma in bipolar disorder.’”

Not another brick in the wall

Early-life adversity remains the fulcrum of Mulholland's interests. Northern Ireland has higher levels of multiple deprivation (defined as an inability to access three or more basic necessities) than the rest of the UK. The most deprived areas are also those most affected by the Troubles.² He references the zeitgeisty book *The Spirit Level*,³ which made a compelling case that socio-economic inequality, rather than poverty per se, drives poor mental health: "So in the United States and the United Kingdom, where neoliberal ideas were most to the fore, appear to have higher rates of mental problems compared to more cohesive societies like the Scandinavian countries where there are lower rates of social division."

We discuss economist Lord Layard's seminal 2006 report, which led to the Improving Access to Psychological Therapies (IAPT) programme in England. Among the criticisms of Layard was his framing of anxiety and depression as discrete illnesses that, when individually treated could return people to economic productivity, rather than formulating these problems as people's responses to the difficult socioeconomic circumstances in which they find themselves.

Mulholland demurs: "I think in the main it's [IAPT] been an excellent initiative that has brought psychological therapies to large numbers of individuals who've benefited and who wouldn't have received such treatment. I think Northern Ireland would benefit from a similar initiative."

In the manner of Sophie's choice, I ask him to pick one thing that would have the biggest impact on mental well-being in Northern Ireland. A glimpse of the radical psychiatrist emerges at last: "Our society is dysfunctional. It's a function of the level of division in society that we are literally divided by walls, physical walls [the incongruously named 'peace walls' that separate Catholic and Protestant communities], but we're also divided by metaphorical walls in various ways. There's clear evidence that those who live close to the physical walls, the 'peace lines' that separate our communities, have higher rates of mental health problems. 'So, in Northern Ireland [...] in my working lifetime, the number of consultant psychiatrists has doubled. Where's the demonstrable impact on the rates of mental health problems? Can we prove that we are effective? I think there's a real challenge there. Whereas we can demonstrate that if you make real changes to societal structures, that *will* have an impact on rates of mental health problems."

Long live the (democratic, peaceful) revolution.

1.3.24 Safeguarding the physical health of people with severe mental disorders during the COVID-19 pandemic

Shuo Zhang Jayati Das-Munshi Graham Thornicroft

date

2020-10

Contents

- *Safeguarding the physical health of people with severe mental disorders during the COVID-19 pandemic*
– *Declaration of interest*

The coronavirus disease 2019 (COVID-19) pandemic is putting unprecedented stress on global healthcare systems. Psychiatrists have also seen great changes to their day-to-day practice with a move towards telephone and video consultations alongside general practice and secondary care colleagues. As we move towards operating in these new ways for the foreseeable future, it is likely that COVID-19 will further exacerbate multilevel risk factors for excess mortality in people with severe mental disorders (usually understood to include people with psychosis, bipolar disorder or major depressive disorder).

People with SMD already have a 2–3 times higher premature mortality rate, accounting for a 10–20-year reduction in life expectancy, mediated through increased exposure to risk factors for non-communicable diseases, such as smoking, harmful use of alcohol, sedentary behaviour, iatrogenic effects of medications and inequitable access to healthcare

services.¹ Those with SMD also often receive poor quality care, including health promotion and prevention, screening and treatment.

Individuals at higher risk for severe COVID-19 infection and mortality are people aged over 60; with underlying conditions such as obesity, hypertension, diabetes, cardiovascular disease, or chronic respiratory disease; and those who smoke.² For other infectious diseases, people with SMD are likely to be at increased risk of: (a) exposure to the disease; (b) accessing less effective healthcare; and (c) increased vulnerability for significant morbidity and mortality.¹

Although there are overlaps with pre-existing multilevel risk factors,³ there are some important differences. For individuals with SMD, disorder-specific factors of COVID-19 such as early symptoms being common and non-specific could delay diagnosis, and it is possible that people with SMD may be less able to self-monitor and raise concerns if their condition deteriorates. Furthermore, COVID-19 has the potential to mimic signs and symptoms seen in severe clozapine-associated complications, such as neutropenic sepsis and myocarditis, which can be difficult to clinically differentiate from severe COVID-19.² We anticipate that health-related behaviours, such as tobacco use and associated higher prevalence of underlying lung disease in the SMD population, will increase the risk of COVID-19 complications and deaths from pneumonia.

Individual vulnerabilities are exacerbated by health system factors such as absence of relevant shared guidelines for the management of COVID-19 from physical health and mental health bodies, diversion of resources from mental health settings, high rates of COVID-19 illness within the health workforce, and the challenges of infection control management in mental healthcare settings, exacerbated by global shortages of personal protective equipment (PPE).

People with SMD have continued higher exposure to sociocultural risk factors including experiences of stigma and discrimination, living in deprived neighbourhoods, and limited family and community resources.³ At present the impact of these factors within the context of the COVID-19 pandemic is unclear.

We suggest the following measures to address individual, facility and health system determinants of health.

Individuals should be supported with infection prevention, for example the direct provision of education about hand-washing, social distancing and the signs and symptoms of COVID-19 along with health promotion strategies such as smoking cessation or harm reduction, reducing drug and alcohol use, and optimising conditions such as diabetes mellitus, chronic respiratory conditions and cardiovascular health. People with SMD should maintain contact with mental healthcare teams and receive ongoing review of mental health needs. At present although there has been some specific guidance on supporting people with cognitive impairment and dementia,⁴ it remains unclear what the impact of the pandemic may be on people with SMD, a group who may be especially vulnerable because of pre-existing social isolation, which may be further exacerbated by social distancing measures.

Staff at mental health community and residential facilities should have equal access to PPE and training on infection control in order to reduce the risks of infection. Urgent reviews of visitor policies, and assurance of sick pay for self-isolating staff are also needed.

Further consideration is needed to optimise effective delivery of care when mental and physical health staff reduce routine face-to-face meetings, and to minimise disruptions in the supply of medication and routine monitoring of medications such as clozapine and lithium. People with SMD may need additional support in accessing services when community health centre staff adopt new ways of working, such as telephone or video consultations.

People with SMD should be offered the same level of treatment for physical healthcare in line with the principles of non-discrimination, the Right to Health, and the fundamental demand of the United Nations Sustainable Development Goals,⁵ namely to 'leave no-one behind'.

1.3.25 Poverty and mental health: policy, practice and research implications

Lee Knifton Greig Inglis

Correspondence

Lee Knifton (lee.knifton@strath.ac.uk)

date

2020-10

Abstract

This article examines the relationship between poverty and mental health problems. We draw on the experience of Glasgow, our home city, which contains some of Western Europe's areas of greatest concentrated poverty and poorest health outcomes. We highlight how mental health problems are related directly to poverty, which in turn underlies wider health inequalities. We then outline implications for psychiatry.

Doctors have often played leading roles in social movements to improve the public's health. These range from the early days of John Snow isolating the role of contaminated water supplies in spreading cholera, through to advocating harm reduction, challenging HIV stigma and, more recently, highlighting the public health catastrophe of mass incarceration in the USA.¹ Almost all examples are rooted in poverty. There is now increasing recognition that mental health problems form the greatest public health challenge of our time, and that the poor bear the greatest burden of mental illness.²

Our article draws on data from Scotland, and especially Glasgow, which contains some of the areas of greatest need and widest health inequalities in Western Europe. However, the relationship between poverty, social stress and mental

health problems is not a new phenomenon and was reported by social psychiatrists half a century ago in Langner & Michael's 1963 New York study³ and consistently since then. Poverty is both a cause of mental health problems and a consequence. Poverty in childhood and among adults can cause poor mental health through social stresses, stigma and trauma. Equally, mental health problems can lead to impoverishment through loss of employment or underemployment, or fragmentation of social relationships. This vicious cycle is in reality even more complex, as many people with mental health problems move in and out of poverty, living precarious lives.

Poverty and mental health

The mental health of individuals is shaped by the social, environmental and economic conditions in which they are born, grow, work and age.⁴⁻⁷ Poverty and deprivation are key determinants of children's social and behavioural development^{8,9} and adult mental health.¹⁰ In Scotland, individuals living in the most deprived areas report higher levels of mental ill health and lower levels of well-being than those living in the most affluent areas. In 2018 for example, 23% of men and 26% of women living in the most deprived areas of Scotland reported levels of mental distress indicative of a possible psychiatric disorder, compared with 12 and 16% of men and women living in the least deprived areas.¹¹ There is also a clear relationship between area deprivation and suicide in Scotland, with suicides three times more likely in the least than in the most deprived areas.¹²

Inequalities in mental health emerge early in life and become more pronounced throughout childhood. In one cohort study, 7.3% of 4-year-olds in the most deprived areas of Glasgow were rated by their teacher as displaying 'abnormal' social, behavioural and emotional difficulties, compared with only 4.1% in the least deprived areas. By age 7, the gap between these groups had widened substantially: 14.7% of children in the most deprived areas were rated as having 'abnormal' difficulties, compared with 3.6% of children in the least deprived.¹³ National data from parental ratings of children's behaviour show a similar pattern: at around 4 years of age, 20% of children living in the most deprived areas of Scotland are rated as having 'borderline' or 'abnormal' levels of difficulties, compared with only 7% living in the least deprived areas.¹⁴

These findings reflect a broader pattern of socioeconomic inequalities in health that is observed internationally.¹⁵ The primary causes of these inequalities are structural differences in socioeconomic groups' access to economic, social and political resources, which in turn affect health through a range of more immediate environmental, psychological and behavioural processes.^{16,17} A wide range of risk factors are more prevalent among low income groups for example, including low levels of perceived control¹⁸ and unhealthy behaviours such as smoking and low levels of physical activity,¹¹ although these are best understood as mechanisms that link the structural causes of inequality to health outcomes.¹⁷

Excess mortality and mental health in Glasgow

Glasgow has some of the highest Scottish rates of income deprivation, working-age adults claiming out of work benefits, and children living in low-income families.¹⁹ Moreover, the city also reports poor mental health, relative to the Scottish average, on a host of indicators, including lower mental well-being and life satisfaction, and higher rates of common mental health problems, prescriptions for anxiety, depression or psychosis, and greater numbers of patients with hospital admissions for psychiatric conditions.¹⁹

These statistics are consistent with Glasgow's overall health profile and high rates of mortality. Life expectancy in Glasgow is the lowest in Scotland. For example, men and women born in Glasgow in 2016–2018 can expect to live 3.6 and 2.7 fewer years respectively than the Scottish average.²⁰ Within Glasgow, men and women living in the most deprived areas of the city can expect to live 13.5 and 10.7 fewer years respectively than those living in the least deprived areas.²¹

The high level of mortality in Glasgow can largely be attributed to the effects of deprivation and poverty in the city, although high levels of *excess* mortality have also been recorded in Glasgow, meaning a significant level of mortality in excess of that which can be explained by deprivation. For example, premature mortality (deaths under 65 years of age) is 30% higher in Glasgow compared with Liverpool and Manchester, despite the similar levels of deprivation between these cities.²² Crucially, this excess premature mortality is in large part driven by higher rates of 'deaths of despair'²³ in Glasgow, namely deaths from suicide and alcohol- and drug-related causes.²²

It has been proposed that excess mortality in Glasgow can be explained by a number of historical processes that have rendered the city especially vulnerable to the hazardous effects of deprivation and poverty. These include the lagged effects of historically high levels of deprivation and overcrowding; regional policies that saw industry and sections of the population moved out of Glasgow; the nature of urban change in Glasgow during the post-war period and its effects on living conditions and social connections; and local government responses to UK policies during the 1980s.²⁴ On the last point, Walsh and colleagues²⁴ describe how the UK government introduced a host of neoliberal policies during this period – including rapid deindustrialisation – that had particularly adverse effects in cities such as Glasgow, Manchester and Liverpool. While Manchester and Liverpool were able to mitigate the negative effects of these national policies to some extent by pursuing urban regeneration and mobilising the political participation of citizens, there were fewer such efforts made in Glasgow, which contributed to the diverging health profiles of the cities.

These researchers have also suggested that this excess mortality may partly reflect an inadequate measurement of deprivation.²⁴ However, that does not capture the reality of living in poverty. One aspect of this lived experience that may be important is the experience of poverty-based stigma and discrimination.²⁵ Stigma is a fundamental cause of health inequalities,²⁶ and international evidence has demonstrated that poverty stigma is associated with poor mental health among low-income groups.²⁷ Individuals living in socioeconomically deprived areas may also experience ‘spatial’ stigma, which similarly has a range of adverse health effects for residents²⁸ and, crucially, may be unintentionally exacerbated by media and public health professionals’ reports of regional health inequalities.²⁹ Given the continued focus on Glasgow’s relatively poor health it is possible that the city is more vulnerable to such stigmatising processes. However, we stress that additional research will be required to test whether stigma is an important aspect of the lived reality of poverty, particularly as several psychosocial explanations have already been offered for the excess mortality, with varying levels of supporting evidence.²⁴ The notion of intersectional stigma is also gaining traction and requires further research.

Understanding the life-course impact of poverty on mental health is also important. Childhood adversity is one mechanism through which poverty and deprivation have an impact on mental health. Adverse childhood experiences, such as exposure to abuse or household dysfunction, are relatively common in the population. Marryat & Frank examined the prevalence of seven adverse childhood experiences among children born in 2004–2005 in Scotland, and found that approximately two-thirds had experienced at least one adverse experience by age 8.³⁰ Moreover, the prevalence was greatest in low-income households: only 1% of children in the highest-income households had four or more adverse childhood experiences, compared with 10.8% in the lowest-income households. Adverse childhood experiences are also strong predictors of mental health in adulthood: individuals who have experienced at least four are at a considerably greater risk of mental ill health, problematic alcohol use and drug misuse.³¹ It has also been suggested that experiences of childhood adversity and complex trauma may contribute to Glasgow’s – and Scotland’s – excess mortality, particularly that which is attributable to violence, suicide and alcohol and drug-related deaths.³² The implications are significant for psychiatry. Not only does it offer a broader explanation of causation; it also highlights the importance of supporting early interventions for young people’s mental health and supporting the families – including children – of those experiencing mental health problems.

Implications

When faced with the scale of the challenge the response can be daunting. This is especially so at a time when we see increasing poverty and socioeconomic inequalities within our society and challenging political conditions. The complexity and enduring nature of the problems necessitate a multilevel response from psychiatry across practice, policy, advocacy and research, which we explore in this section. We argue that this response should address three broad areas.

Reinvigorate social psychiatry and influence public policy

The demise of social psychiatry in the UK and USA in recent decades has deflected focus away from the social causes and consequences of mental health problems at the very time that social inequalities have been increasing. Now is the time to renew social psychiatry at professional and academic levels. There is considerable scope to form alliances with other areas – especially public mental health agencies and charities. Psychiatry as a profession should support those advocating for progressive public policies to reduce poverty and its impact. If we do not, then, as Phelan and colleagues outline, we will focus only on the intermediate causes of health inequalities, rather than the fundamental causes, and this will ensure that these inequalities persist and are reproduced over time.³³ Activism with those who have consistently highlighted the links between poverty and mental health problems, such as The Equality Trust, may effect change among policy makers.

Tackle intersectional stigma and disadvantage

We must understand, research and tackle stigma in a much more sophisticated way by recognising that mental health stigma does not sit in isolation. We need to understand and address what Turan and colleagues define as intersectional stigma.³⁴ Intersectional stigma explains the convergence of multiple stigmatised identities that can include ethnicity, gender, sexuality, poverty and health status. This can then magnify the impact on the person's life. In this context, the reality is that you have a much greater chance of getting a mental health problem if you experience poverty. And if you do, then you will likely experience more stigma and discrimination. Its impact on your life will be greater, for example on precarious employment, housing, education and finances. It is harder to recover and the impact on family members may be magnified. Intersectional stigma remains poorly researched and understood,³⁵ although the health impact of poverty stigma is now emerging as an important issue in studies in Glasgow and elsewhere.²⁵

Embed poverty-aware practice and commissioning

We conclude with our third idea, to ensure that poverty-aware practice is embedded in services through commissioning, training and teaching. This means that recognising and responding to poverty is part of assessments and care. Income maximisation schemes should be available as an important dimension of healthcare: how to access benefits, manage debt, access local childcare and access support for employment at the earliest stages. This needs to be matched by a major investment in mental health services focused on low-income areas, to address the inverse care law.³⁶ These principles are already being put into action. For example across Scotland, including Glasgow, several general practices working in the most deprived areas (referred to as Deep End practices) have recently trialled the integration of money advice workers within primary care, which has generated considerable financial gains for patients.³⁷

(BJPBulletin@rcpsych.ac.uk)

date

2020-10

Abstract

Inequality is a significant and reversible risk factor for mental disorders which demonstrates the essentially political nature of psychiatry. The *BJPsych Bulletin* is pleased to make space for those at the frontline of this inequality. Two experts by experience explain how financial concerns exacerbated their distress and the benefit of social interventions.

Psychiatry's great appeal is also its Achilles' heel. It embraces a multitude of perspectives which can appear mutually incompatible, drawing accusations of vagueness and incoherence. This themed edition of the *BJPsych Bulletin* will, I hope, demonstrate that such criticisms are wrongheaded. It has been a pleasure to work with Peter Byrne to produce this edition on inequality, a recognised but still under-appreciated driver of mental illness about which he is passionate and persuasive. Although epidemiological studies can feel rather detached or aloof, they have identified some of the most significant and well-replicated risks for developing mental disorder, something that cannot be said for the majority of experiments in neuroscience, despite its glossy allure. Nevertheless, accommodating psychiatry's various perspectives involves somehow tethering known risk factors to plausible biological mechanisms, whether one considers the suffering a disorder or not. For clinicians, it is the individual patient who must be the focus, but too often our concern with odds ratios and objective data can come across as alienating. These different and incommensurate levels of analysis remind me of the various forms of government – by the one, the few or the many – and that psychiatry is inextricably political. Inequality is a reversible cause of mental disorder, and inequality is a political choice. If doctors find it hard to be heard in the political realm, how much harder must it be for those who suffer the consequences of inequality? I am especially pleased to include in this article contributions from two experts by experience, Nikita Egan and Ben Russell, both from

Equally Well UK (<https://equallywell.co.uk/>), a collaborative – led by Centre for Mental Health in partnership with Rethink Mental Illness – that champions parity of esteem. Their moving accounts of illness and alienation underscore why we do what we do and, I hope, establish the Bulletin's increased focus on co-production and, in our own small way, sharing the levers of power. Over to you, Nikita and Ben.

Nikita Egan, Expert by Experience, Equally Well UK

'We as a species are not very good at asking for help. In doing so, we are admitting, to ourselves at least, that we aren't as independent as we might have hoped – that we're fallible. If we consider this natural discomfort felt when asking for help, is it any wonder that applying for benefits such as UC [universal credit] and PIP [personal independence payment] can often seem like a humiliating ordeal?

'It was a previous CPN [community psychiatric nurse] who advised me to apply for PIP, stating that I shouldn't see it as a benefit, but more to put me on an equal playing field with my peers who didn't face a daily struggle with their mental health. When the form did arrive it seemed condescending, but also forced me to look inwards to my own daily difficulties. When the form was complete, I asked my CPN to read it. Did she think I'd exaggerated? Did she not really think I should apply? Thoughts like this were a daily monologue in my head, but having read horror stories from other applicants, I didn't hold out much hope anyway. Being awarded the higher rate for daily living and lower for mobility was such a contradictory feeling, especially as I didn't have a face-to-face assessment. Is this my life now, living on benefits? Accepting handouts?

'The time to apply for UC didn't arrive until 2018 when my marriage ended. I had nothing except my PIP and no choice but to apply online for UC. In my head all I could think of was 'going on the dole'. As I filled in my disability, details of the emotions of the PIP application process came flooding back.

'The face-to-face assessment was terrifying, especially finding out that my date and time were the same as the letter given to 12 other people. The paranoia was terrible, and so many obscure ideas ran through my mind. I began to panic as I scanned the room; everyone else seemed to have a physical impairment. As it turned out the assessment was with a compassionate nurse. My form and records had been checked; I just had to confirm some details and give a copy of my prescription.

'PIP and UC – based on the decision that I have limited capacity to undertake paid work – allow me to pay my rent and bills, and also to enjoy an albeit thrifty life with my children. Many others are not as lucky, and don't have the support to make and endure application processes.

'Personally, I don't think of myself as living on benefits. I think of myself as living, however I can.'

Ben Russell, Expert by Experience, Equally Well UK

'It's difficult to focus cause I'm being harangued from all sides. I run from room to room to escape, but they follow me. I turn around suddenly, hoping to catch them in the act, but there's no one else there. I am alone. I realise, all of a sudden, that I'm ill again. I hear a hissing sound and spin around and see a fox standing there with blood-red eyes and its hackles raised. I scream and *run* to the next room, but the fox is already in there. In fact, it's in every room I run to waiting for me. It's difficult because knowing I'm ill doesn't stop me being ill. I go into town hoping that the fresh air will do me good, but there are people following me. If they catch me, they'll do experiments on me, so I run back to my flat and lock the door behind me. I don't know how long I've been ill for, but there's a mound of envelopes in my letterbox. More than likely bills. But I can't function, let alone pay them. I also don't remember the last time I ate. Nothing makes sense.

'I've also not been paying my bills. The mortgage company send me threatening letters, as do the council. I'm also unable to work. My phone is vibrating on the coffee table. There're seven missed calls. I answer warily, ready to be berated some more. It's my nurse. She says that she's been trying to contact me for days. I tell her that I'm not right in the head. An indeterminable amount of time passes before my nurse comes to my flat. She says that I need to be in hospital, but I'm worried about my flat. I get personal independence payments, but they're not enough to cover my mortgage. I was working as a hod carrier, but then I became unwell with my mental health and no longer have a job. My nurse is insistent anyway. I go to hospital. On the ward, my family are contacted. They arrange to help pay my

bills, which is the luckiest thing, because I was about to lose my flat. The important thing, they said, was getting well. And so many people in my position don't have that chance. The crisis team also help me get in touch with my creditors and arrange payment plans.'

Many thanks to Nikita Egan and Ben Russell for agreeing to share their experiences. Their contributions are invaluable.

1.3.27 Freda E. Martin, MD, FRCPsych, FRCPsych (Canada)

Dora Black

date

2020-10

Contents

- *Freda E. Martin, MD, FRCPsych, FRCPsych (Canada)*

Formerly Chair, Department for Children and Parents, Tavistock Clinic, London, and Executive Director, CM Hincks Treatment Centre, Toronto, Canada

Freda Martin, who died in Toronto on 2 August 2019 at the age of 87, was one of the early pioneers of family therapy, first in the UK and then in Canada. In 1962, while working at the Tavistock Clinic, London, in collaboration with Janet Knight, she published an important paper describing the assessment of disturbed children involving the whole family.¹ At that time, the standard assessment of such children involved the mother being seen by a social worker, while the child saw the psychiatrist. Fathers were either not seen at all or seen usually on only one occasion with the mother. Freda Martin, with Rosemary Whiffen and John Byng-Hall, influenced both by John Bowlby and the family therapy movement in the USA, was able to demonstrate how not just assessing but treating the whole family as a unit often illuminated the family dynamics in a manner impossible to achieve when family members were seen individually.

Freda came to the Tavistock Clinic with an unusual background. Arriving there in 1960 as the first psychiatrist with a Jungian, rather than a Kleinian, analytic training, she was not aligned with the existing predominantly psychoanalytic factions. This enabled her to be eclectic in her clinical work and to espouse her belief in the importance of multidisciplinary teamwork, involving psychiatrists, psychologists, social workers and psychotherapists.

Initially, she met much hostility at the Tavistock Clinic from those who found it difficult to accept that an analyst could embrace such views. She persisted, first as one of a number of colleagues and later as Chair of the Department for Children and Parents.

In 1975, she returned to Canada, eventually becoming Executive Director of the CM Hincks Treatment Centre in Toronto. Here she was able to introduce clinical approaches derived from attachment theory. According to a colleague, she brought to Canada the importance of early intervention to promote physical and emotional well-being in all children, as well as her belief in the importance of postgraduate training for all disciplines, which she regarded as equally necessary for helping children and families. Today these ideas are accepted and practised, even in centres formerly devoted to only one treatment mode for disturbed children.

She initiated postgraduate multidisciplinary training and research into what previously had been a purely clinical setting. The renamed Hincks Dellcrest Centre Gail Appel Institute, now part of the Hospital for Sick Children, Toronto, came into being in 1986. It required new, expanded premises. Freda Martin persuaded the Board to construct a seven-floor building on the clinic car park. It was opened by John Bowlby.

She continued to develop new approaches to treatment applying them, for example, to the successful treatment of anorexia in adolescents. In a seminal paper published in 1990,² she described what she called ‘run-away’ effects at various systemic levels (physiological, individual, family, social), which triggered dieting behaviour in perfectionistic personalities.

Creating a link with the University of Toronto, where she was an assistant professor, enabled her to create fellowships to train social workers and psychologists, educators and psychotherapists in family therapy and infant mental health.

Freda Martin (née McQueen) was born in Niagara Falls, Canada, on 11 April 1932 to Andrew, an engineer, and Lily. She studied medicine at the University of Toronto Medical School, qualifying in 1956. In 1959, she came to the Maudsley Hospital, London, for postgraduate psychiatric training. She was appointed a senior registrar at the Tavistock Clinic in 1960, shortly afterwards becoming a consultant and then Chair of the Department for Children and Parents.

Freda met her husband Kenneth Martin, an adult psychiatrist who worked mainly in private practice, at the Maudsley. They had two children. Freda and her family loved to relax in the family ‘cottage’ by Devil Lake, where they sailed, canoed and entertained friends.

After leaving her full-time post in 2005, Martin became involved in advising the provincial and federal governments about the importance of teaching parents and educators about early physical and emotional development. She set up and evaluated 3-year ‘learning through play’ courses all over Canada. Later, she worked in Jamaica and Latvia with senior professionals using this material to train parents, carers and nursery staff. These activities were funded by the Canadian International Development Agency. After full retirement, she took singing lessons and enjoyed singing in a choir. Very recently she helped children to read as well as reading to fellow residents in her retirement home.

Freda is described by family members and her many devoted colleagues as outstandingly creative, decisive, forthright and brisk. She was not afraid to speak her mind, although she was always regarded as kind and supportive to staff and students.

The daughter of a close friend described her as a ‘bullshit detector’. When this same friend was terminally ill, Freda, in the words of her friend’s daughter, ‘enabled mum to articulate and process her own death’, with support and love, helping the family in their grief.

Kenneth died in 2012. Freda is survived by her two children, Andrew and Peter, as well as by two grandchildren.

1.3.28 Are UK care homes ready for the telemedicine revolution?

Meta McGee Claire Potter Joseph Kane

date

2020-10

Contents

- *Are UK care homes ready for the telemedicine revolution?*
 - *Declaration of interest*

The restrictions implemented by coronavirus disease 2019 (COVID-19) have reawakened discussion surrounding the use of telemedicine in routine clinical practice.¹ Nursing home residents have emerged as a particularly vulnerable group, not only with respect to the virus itself, but to the effects of social distancing² and disruption to the services in place to support them. In working to stop the spread of COVID-19 within their facilities, many homes have found it difficult to sustain the non-pharmacological mainstays of management of delirium and behavioural and psychological symptoms of dementia.² Telemedicine, a proposed solution to these difficulties, has been demonstrated to be both valid and acceptable to patients with dementia and care home staff³ but it does not appear to be part of routine practice in the UK.⁴

We therefore aimed to determine nursing homes' capacity and enthusiasm for telepsychiatry assessments. Over a 2-week period in June 2020, we contacted senior staff at the 70 nursing and 'elderly mentally infirm' homes falling within the Belfast Health & Social Care catchment area and administered a short survey via telephone. Two questions; 'how would you rate your facilities' current capacity to participate in mental health assessments via video link?' and 'how interested would you be in establishing the capacity to participate in mental health assessments via video link?', were answered using a five-point Likert scale.

Participating nursing homes (56/70; 80%) reported that reliable WiFi connections and appropriate equipment (such as a tablet device, or desktop or laptop computer with webcam) were available in 41/56 (73%) and 40/56 (71%) facilities, respectively. Staff at 21/56 (38%) reported that they already felt they had the capacity to facilitate such consultations (answering '5' on the Likert scale); 16/56 (29%) felt they had little (5/56; 9%) or no capacity (11/56: 20%) to currently do so. Nursing home staff answering '3' (10/56; 18%) or '4' (9/56; 16%) on the Likert scale indicated some capacity to participate in remote consultations, although they felt they would not be able to do so on a routine basis. Respondents were 'very interested' in establishing capacity to use remote consultations in 44/56 (79%) of surveys.

Most nursing homes possess the appropriate equipment to facilitate telemedicine, and the majority (84%) demonstrate an enthusiasm for doing so. The failure to adopt telepsychiatry may therefore be more closely related to factors within mental health services, such as our access to appropriate equipment, than those within nursing homes. A survey of American psychiatrists working in nursing homes reported widespread support for telemedicine, but only 13% felt they had access to appropriate equipment.⁵ It would appear, however, that obstacles to telemedicine go beyond hardware; in spite of most respondents' access to equipment, we observed considerable variation in their perceived capacity to engage with remote consultations, perhaps suggesting a lack of comfort or familiarity with the medium. We suggest that before telemedicine becomes part of, as has been suggested, 'the new normal', that more detailed exploration is conducted regarding the attitudes and skills of professionals on both sides of the webcam.

1.3.29 The affective neuroscience of socioeconomic status: implications for mental health

Yu Hao Martha J. Farah

Correspondence

Yu Hao (hhao@sas.upenn.edu)

date

2020-10

Abstract

We review basic science research on neural mechanisms underlying emotional processing in individuals of differing socioeconomic status (SES). We summarise SES differences in response to positive and negative stimuli in limbic and cortical regions associated with emotion and emotion regulation. We discuss the possible relevance of neuroscience to understanding the link between mental health and SES. We hope to provide insights into future neuroscience research on the etiology and pathophysiology of mental disorders relating to SES.

 - *Declaration of interest*
 - *Supplementary material*

Low socioeconomic status (SES) is a potent risk factor for mental disorders, particularly mood and anxiety disorders.^{1–3} Life's challenges weigh more heavily on people with fewer financial resources and less education, and the impact of

SES on emotional well-being is substantial. For example, Guhn et al⁴ found an adjusted odds ratio for mental health conditions 25–39% higher for children of low-income families compared with others. A Canadian government survey⁵ found that disabling mental health problems are twice as common among those without a high school diploma compared with college graduates.

In this article we review what is known about the affective neuroscience of SES and sketch some of the implications this field of science might have for mental health. We begin with basic definitions and distinctions. ‘Affective neuroscience’ is the study of neural mechanisms underlying the experience, expression and regulation of emotion. Given that the brain is shaped by a combination of genes and environment, explanations in terms of the brain and the environment are not mutually exclusive. SES is a complex construct, or more accurately an interrelated set of constructs, that captures differences in material and social wherewithal. It has been measured in terms of financial attributes (e.g. income, wealth), neighbourhood characteristics (e.g. rates of unemployment and crime near one’s home), educational and occupational background and self-reported social standing, among other approaches. Although these measures are all distinct from one another,⁶ they are normally moderately correlated.⁷ Here we will seek broad generalisations within this relatively small literature, referring therefore to SES in general rather than making distinctions among more specific measures. Similarly, we will generalise across life stages at which participants’ SES was measured. All of these distinctions undoubtedly have scientific and clinical relevance, which should also be examined. Nevertheless, for a preliminary review, we choose to begin by aggregating findings as much as possible.

Many useful insights into the aetiology and pathophysiology of mental disorders have come by studying the brain. Here we explore the possible relevance of neuroscience to understanding the link between mental health and SES. Recent attempts to link SES and psychopathology through the brain have adopted different concepts from psychology and neuroscience as explanatory frameworks. These include the effects of stress on the brain,⁸ the role of self-regulation in mental health⁹ and the distinction between adversities consisting primarily of deprivation (prevalent in low SES) and those consisting primarily of threat (such as accompanies abuse¹⁰). These frameworks are not mutually exclusive, and the goal of our review is neither to adjudicate between them nor to develop a fourth alternative. Rather, we aim to gather the most comprehensive collection to date of research findings related to SES, brain and affect, and attempt a provisional integration that will enable empirical generalisations and highlight consistencies and inconsistencies.

The neuroscience studies reviewed here are basic science research, carried out with normal people of varying SES. Note that in some studies SES is not the focus of the study but included as a covariate. In some of these cases the range of SES is restricted and the power to detect SES effects is therefore attenuated. *Figure 1* depicts the systematic review process. *Fig. 1* Flowchart for the systematic review. Relevant studies were identified through searches of the database PubMed throughout 13 March 2020. The search required that studies used at least one of the following socioeconomic status (SES) keywords in the full paper: socioeconomic status, poverty, income, neighbourhood quality, neighbourhood disadvantage, educational attainment, social class, social standing. Identified studies also used at least one of the following social and affect-related keywords in the entire paper: emotion, threat, fear, angry, sad, happy, reward, social interaction, hostility, rejection. In addition, the keyword of neuroimaging method was included: fMRI. This search identified 166 results, which were screened for the inclusion criteria.

The resulting functional magnetic resonance imaging (fMRI) studies manipulated emotional states experimentally inside the scanner with emotionally evocative stimuli or tasks. The most common methods involve photographs of faces expressing different emotions or of affectively valenced objects and scenes, and signals that money has been won or lost in a game. Less frequently, studies have used other kinds of stimuli or experiences to evoke emotion and these will also be described.

Subcortical and cortical bases of negative affect

Textbook coverage of affective neuroscience invariably begins with subcortical systems, particularly the amygdala and ventral striatum. These appear to respond automatically, without the need for conscious awareness of the emotion (e.g.^{11,12}), and play crucial roles in the experience and expression of emotion. Many other regions, cortical and subcortical, also participate in emotion and there is no simple mapping of specific emotions to specific brain areas.¹³ Emotion is best thought of as a construction of the brain as a whole.¹⁴ Nevertheless, many studies take the amygdala as a starting point in the investigation of emotion and the brain, especially negative emotion.

Brain responses to negative facial emotions

Although the amygdala plays a role in a range of emotions, its most consistent role is in negative emotions. The amygdala is most readily activated by viewing facial expressions of fear and anger. Our review identified a substantial number of studies that have compared low- and high-SES individuals under these experimental conditions. In the majority of studies, lower SES by at least one measure was associated with stronger amygdala reactivity to negative facial emotions. Young adults whose parents were of lower SES showed greater amygdala activation when viewing angry faces compared with control conditions in two studies.^{15,16} In another study, negative facial expressions elicited greater amygdala reactivity for young adults from lower-SES families, taking into account parenting quality and maternal mental health.¹⁷ Emotional faces more generally evoked greater right amygdala activation in adults of lower SES.¹⁸ The same study showed that SES was associated with strength of coupling between right amygdala and right insula.¹⁸ In a study of first-time mothers viewing the faces of either happy or distressed infants, the right amygdala was more active to depictions of distress in mothers of lower SES.¹⁹

Three other studies yielded partial support for a relationship between amygdala reactivity to negative facial emotions and SES. The support from these findings was qualified by participant gender in one case (only for women²⁰), ethnicity of depicted face in another (only for Black emotional faces in a study with Mexican American participants²¹) and history of violence exposure in a third (only in non-exposed participants²²). In only one study testing the relationship between amygdala reactivity and SES was a significant relationship not found, and this study had relatively little variance in SES among the participants (all were recruited through an antipoverty programme²³). Finally, in a memory study with emotional faces as retrieval cues, testing the hippocampus as a region of interest (ROI), there was less activity in the posterior hippocampus in lower-SES individuals when they watched angry faces.²⁴

Brain responses to other negative stimuli

Apart from facial emotional cues, other stimuli that have been used to evoke negative emotions include unpleasant sounds, social rejection and loss of money. In one study unpleasantly loud auditory stimuli were used to evoke emotional states in participants of varying SES, violence exposure and ethnicity, generally with a warning tone but occasionally without.²⁵ When trials without a warning cue were considered, family income was negatively associated with hippocampal activity, consistent with greater effect of unexpected negative stimuli with lower SES. SES showed the opposite effect with cued noise, with higher neighbourhood deprivation (i.e. lower SES) showing lower activity in the hippocampi and amygdalae, perhaps related to reduced preparatory regulatory effects.

Two studies have used the sound of babies crying, contrasted with white noise, with participants of varying SES. The crying was rated as more annoying,²⁶ but effect of SES on neural response to the cry in non-parent adults was complex and difficult to interpret; there was generally more activation in the insula and several other regions in women from low-SES backgrounds, with the opposite pattern in men. Another study of mothers hearing baby cries found less activation associated with lower SES in frontal and temporal cortical regions, but differences in classic emotion-related areas were not found.²⁷ Although baby cries communicate urgency and distress, they may function less as generic signals of threat or harm and more as triggers for complex, evolved systems of parenting behaviour.²⁸

Social rejection is another kind of experience that evokes negative emotion. The so-called ‘social pain’ that results from rejection is not typically associated with amygdala activity, but has a more distinctive functional anatomy including the dorsal and ventral anterior cingulate, anterior insula and also the ventromedial prefrontal cortex (vmPFC) and orbital

cortex regions (see meta-analyses^{29–31}). Gonzalez et al³² assessed responses to exclusion in the classic ‘cyberball’ rejection task in young adults of varying neighbourhood SES, and tested whether SES was associated with dorsal anterior cingulate cortex (dACC) and insula responses. The insula was not reliably activated by exclusion in this study overall, nor as a function of SES, but lower SES was associated with a larger dACC response. Related to social rejection is negative social evaluation. Muscatell et al³³ had participants read negative versus neutral or positive personal assessments of their performance in an interview, and *a priori* regions of interest were the dorsomedial prefrontal cortex (dmPFC) and amygdala. Although amygdala activity did not differ with subjective social status (and it was not stated whether the task evoked amygdala activity in this condition for participants in general), dmPFC activity was evoked by negative evaluations and was higher in lower-SES participants.

Finally, the aversive experience of losing money, a secondary reinforcer, which differs in some ways from primary aversive stimuli such as pain,³⁴ has been assessed during fMRI in two studies with participants of varying SES, neither of which found effects of SES.^{35,36}

Summary

There is a trend, across various forms of negative emotional state, for lower-SES individuals to have more brain activity in at least some emotion-related areas. This includes evidence from tasks using emotional facial expressions, loud noises and social rejection. This generalisation, although reasonably broad, does not extend to all of the literature. In particular, two studies using infant cry sounds show SES effects, but these effects are complex and cannot be interpreted as simply more activity in emotion-related areas, and two studies of monetary loss failed to show effects of SES at all.

Subcortical and cortical bases of positive affect

The anatomy of positive affect overlaps with some of the areas mentioned above in connection with negative affect, consistent with the complex, emergent nature of emotion in the brain. Studies of positive affect use depictions of happy faces and scenes and the occurrence of desirable outcomes such as the winning of money or points in games. The region most often associated with positive affect is the ventral striatum, which consists primarily of the nucleus accumbens and part of the caudate nucleus, although other cortical regions are also engaged, including the medial and orbital frontal cortex, cingulate cortex and anterior insula.³⁷

The literature on the neural correlates of positive emotion and SES is relatively small. One study, already mentioned in connection with negative emotion, is also relevant to positive emotion. In this study, mothers viewed happy as well as unhappy baby faces, and some of the areas activated by the happy faces, including the left amygdala and the right insula, differed by SES and specifically were less active in the lower-SES mothers.¹⁹

Silverman et al³⁸ exposed participants to affectively valenced pictures of people, objects and scenes and contrasted neural responses to positive images (e.g. an amusement park) relative to neutral images (e.g. furniture). They found lower activity in response to the happy pictures in lower-SES participants in a variety of areas, including the striatum.

Other studies have induced positive emotional states with monetary gains during simple games. The focus of most studies on SES and reward has been on reward anticipation, rather than the receipt of the reward itself. Reward anticipation is a motivational state sometimes associated with ‘wanting’, in contrast to the response of ‘liking’.³⁹ Response to receipt of a reward has either not been shown to differ by SES^{35,40} or the study design has not allowed reward receipt to be examined separate from reward anticipation because of block rather than event-related design.³⁶ In contrast, reward anticipation generally evokes more activity for lower-SES participants. Romens et al⁴⁰ found heightened response to the anticipation of reward in medial prefrontal cortex (mPFC) in lower-SES girls, and no locations of reduced response. Gonzalez et al⁴¹ found a similar relationship in striatal and other regions. Quevedo et al³⁵ covaried SES in a study of the effect of attachment style on reward, and although the range of SES was relatively narrow, they found that maternal unemployment and lower family income during childhood were associated with higher striatal activity and amygdala activity respectively, during reward anticipation. When anticipating a larger but lower-probability reward, lower-SES adolescents show more mPFC activation.⁴²

Summary

Positive stimuli may evoke smaller responses in people of lower SES, although the evidence is limited, while reward anticipation may be accompanied by greater activation.

Networks for emotion and emotion regulation

Emotion regulation refers to self-induced changes in intensity and duration of emotional experience, typically for the purpose of reducing negative experience. These changes can be accomplished by either conscious, explicit strategies or automatic, implicit processes.⁴³ One of the most effective explicit emotion regulation strategies is cognitive reappraisal, by which we volitionally reinterpret the meaning of stimuli in order to alleviate negative feelings. A recent review suggests that explicit emotion regulation engages the dorsolateral, ventrolateral and dorsomedial frontal and parietal cortex.⁴⁴ Kim et al⁴⁵ showed disturbing pictures to participants of varying SES and instructed them to reduce negative emotion through cognitive reappraisal, for example viewing a picture of a bruised and beaten woman and reappraising it as a picture of an actress playing the role of a violence victim. They found that individuals of low SES recruited less prefrontal activation than their higher-SES counterparts and showed less reduction in amygdala activity during reappraisal, consistent with this emotion regulation strategy being used less effectively by these participants. However, gender seems to moderate the effect of SES on prefrontal activity related to emotion regulation:²⁰ in males but not females when considered separately, activation in dorsolateral and ventrolateral prefrontal cortical regions (dlPFC and vlPFC) during cognitive reappraisal was positively correlated with SES.

Another form of emotion regulation is implicit, involuntary emotion regulation, which does not require effortful use of a strategy or conscious monitoring of emotional state, but is simply evoked automatically.⁴⁶ Implicit emotion regulation is omnipresent in our encounters with emotional stimuli, with ventral ACC and vmPFC engaging automatically to modulate subcortical activity.⁴⁴ By its nature, implicit regulation is not carried out following instructions, so it can be difficult to determine in any given task whether these ventral anterior activations represent regulatory activity. In any case, less functional coupling between the amygdala and vmPFC has been found in low-SES individuals when processing negative emotion.⁴⁷ In the same intensively studied group of participants (see also^{20,45,47}), Liberzon and colleagues⁴⁸ found less prefrontal activity in lower-SES participants in a task designed to evoke implicit emotion regulation, although in this task the finding was localised to lateral rather than medial regions.

Studies of participants at rest provide additional evidence concerning limbic–cortical interactions. Functional connectivity between the amygdala and the vmPFC was found to be weaker in participants of lower SES, and this difference in brain activity accounted for SES disparities in vulnerability to stressful life events.⁴⁹ Connectivity of the amygdala and hippocampus to prefrontal regions was also reduced in lower-SES children, and these differences fully mediated the relationship between SES and later depression.⁵⁰ Finally, connectivity between the ventral striatum and ventral PFC is reduced in low SES, and this fully mediated the relationship between SES and anxiety.⁵¹

Conclusions

We offer this preliminary review of the literature as a starting point, to be refined as the literature grows and our understanding of SES and affective neuroscience advances. It is limited in part by the small size of the literature. Our search method uncovered only 27 studies, and many of these involved small samples ($n < 50$ for half of the studies) or a restricted range of SES. In addition, affect and SES are both complex constructs, and each has been operationalised in numerous different ways in the studies reviewed here. Is it sensible to group the sight of a frightened face, the sound of a crying baby and the loss of small sums of money into a common category of ‘negative emotion?’ We did so here provisionally, to help organise our review at a very general level, recognising that important differences may be glossed over. The studies reported here were also heterogeneous in terms of participants’ ages. Finally, the studies measured SES in different ways, for example in childhood or adulthood, and according to income, educational attainment or neighbourhood deprivation. In attempting this first broad review of SES and the neural bases of emotion, we do not distinguish between different measures of SES, and we report findings as positive if any measure of SES shows a statistically significant effect.

For the reasons just mentioned, any conclusions from this review must be considered very provisional. Nevertheless, some trends can be discerned, and these may be relevant to the SES gradient in mood and anxiety disorders. Socioeconomic disadvantage shapes the brain's response to emotional stimuli, such that negative stimuli appear to evoke a stronger response and positive stimuli may possibly evoke a weaker response. This amounts to an overall bias towards the negative and away from the positive for lower SES, which would be expected to indicate a greater susceptibility among low-SES individuals to depression and anxiety. In contrast, anticipation of reward appears to evoke more activity in people of lower SES, which in one study mediated the relationship between socioeconomic disadvantage and adolescent depression symptoms.⁴⁰ Greater reactivity to the promise of reward may contribute to disorders of impulse control.⁵² Finally, in at least a few studies functional networks that may serve to regulate emotion are weaker in people of lower SES, and these differences too have been found to mediate risk for psychopathology.

Given the disproportionate mental health burden borne by those of low SES, it makes sense to deploy the full range of approaches to understanding and addressing this inequity, from the sociological to the neuroscientific. High priorities for future research will be to expand the evidentiary base relating SES, brain function and psychological symptoms, and to establish how social and economic factors external to the individual may give rise to the neural and psychological vulnerabilities reviewed here. In aiming to understand the interrelations among psychology, biology and social context, it should be possible for mental health and well-being to be more widely enjoyed throughout society.

1.3.30 Mental health, smoking and poverty: benefits of supporting smokers to quit

Vicky Salt Ciaran Osborne

Correspondence

Vicky Salt (vicky.salt@ash.org.uk)

date

2020-10

Abstract

Smoking rates among people with common mental health conditions remain around 50% higher than those in the wider population; this is a significant cause of the 10–20-year reduced life expectancy of

people with mental health conditions. However, the effects of smoking go far beyond physical health. Research estimates that smokers with mental health conditions could be spending as much as £2200 a year on tobacco, pushing an estimated 130 000 people with a common mental disorder into poverty. The Government has set a target for England to be smokefree by 2030; however, without a dramatic increase in support, smokers with mental health conditions risk being left behind. Action on Smoking and Health provides the secretariat for the Mental Health & Smoking Partnership. The Partnership aims to reduce the inequality in smoking rates between people with mental health conditions and the wider population. It brings together Royal Colleges, third-sector organisations, trade unions and academia to review progress and highlight areas for further action.

The challenge

People with mental health conditions die on average 10–20 years earlier than individuals in the wider population.¹ High smoking rates are one of the key reasons for this health inequality.² Smoking rates remained largely static among people with mental health conditions during the 20 years from 1993 to 2013, at around 40%.³ Although new figures suggest that this prevalence is starting to decline, smoking rates among people with common mental health conditions remain around 50% higher than those in the wider population.^{4,5}

However, the effects of smoking go far beyond reduced life expectancy; it influences employment prospects,⁶ reduces earnings,⁶ increases care needs⁷ and causes poverty.⁸ Higher smoking rates are associated with every indicator of disadvantage, but most adult smokers want to quit.⁹ Smokers with mental health conditions are aware of the risks to people around them from second-hand smoke and see this as a motivator to quit; clinicians must offer support to enable them to do so.

The challenge of The Mental Health and Smoking Partnership is to help tackle these inequalities.¹⁰ The Partnership was established in 2016 following publication of *The Stolen Years: The Mental Health and Smoking Action Report* by Action on Smoking and Health (ASH), with the ambition of reducing smoking prevalence to 5% or less among people with mental health conditions.¹¹ The report sets out the sector-wide action needed to reduce smoking rates among people with mental health conditions, from reviewing the training of the mental health workforce to building the research base on peer support and expert-by-experience-led interventions.

Three years on, the Government has published the Tobacco Control Plan for England,¹² NHS Long Term Plan¹³ and Prevention Green Paper,¹⁴ committing to reducing smoking prevalence among people with mental health conditions.

However, change is not happening quickly enough. The recent Green Paper *Advancing our Health: Prevention in the 2020s* sets an ambition to end smoking in England by 2030, defined as a prevalence of 5% or less.¹⁴ To achieve this, using the latest publicly available data,¹⁵ it is estimated that the annual rate of decline from 2014–2030 among people with mental health conditions needs to be an ambitious 1.82 percentage points a year, more than double the previous rate of decline. Unless we dramatically increase the support available, this target will not be met, and people with mental health conditions will be left behind.

Tobacco, health and poverty

In his landmark 2010 report, *Fair Society, Healthy Lives*, Michael Marmot made clear the moral dimension of tackling health inequalities: ‘Inequalities are a matter of life and death, of health and sickness, of well-being and misery. The fact that in England today people from different socioeconomic groups experience avoidable differences in health, well-being and length of life is, quite simply, unfair and unacceptable’.¹⁶

Half of all lifetime smokers will die from their addiction, that is, more than 96 000 people every year in the UK. For every smoker who dies, an estimated 30 others will be living with smoking-related diseases.¹⁷ This should be reason enough to act.

However, there are also short-term, immediate benefits to quitting smoking. Smoking decreases disposable income (defined as household income after tax and National Insurance contributions), which can be returned to the household when smokers quit. Smokers in social housing spend, on average, 14.6% of their disposable income on tobacco, compared with 6.9% among owner occupiers and 5.8% of those living in privately rented accommodation.¹⁸ This has substantial economic consequences, with more than 1 million people – including 263 000 children – living in poverty as a direct result of income lost to expenditure on tobacco. The proportion of social housing tenants living in poverty increases from around a quarter (28.3%) to two in five (42.8%) once the costs of smoking are considered.⁸

Research commissioned by ASH and Public Health England has shown the extent to which people with mental health conditions are economically disadvantaged due to smoking.¹⁹ Higher rates of smoking are found among people with a mental health condition living in poverty (*Table 1*). Looking at the number of cigarettes smoked and taking into account purchases of illicit and cheap tobacco, researchers estimate that smokers in poverty spend an average of around £1200 a year on smoking, at 2015 prices.¹⁹ However, adjusting for underreporting of the amount of tobacco smoked, smokers with a mental health condition below the poverty line could be spending over £2200 a year on tobacco.¹⁹ *Table 1* Smoking prevalence according to mental health disorder and poverty¹⁹ Type of disorder reported Smoking prevalence in whole population Smoking prevalence among those in poverty Common mental disorder 34% 46% Currently taking psychoactive medication 34% 46% Longstanding mental disorder 40% 52%

Using the conservative estimate of £1200, researchers estimate that around 130 000 people with a mental health condition are pushed into poverty by expenditure on tobacco. *Table 2* shows a breakdown of smokers with common mental disorders, those taking psychoactive medications and those with longstanding mental disorders across the UK, who are pushed into poverty by expenditure on tobacco.¹⁹ *Table 2* Population estimates of the number of UK adults with a mental disorder who are in poverty and who smoke, and who are drawn into poverty by their expenditure on smoking¹⁹ Common mental disorder (CIS-R score >12) Currently taking psychoactive medications Longstanding mental disorder Smokers with disorder who are in poverty a Smokers with disorder who are in poverty b Numbers with disorder drawn into poverty by smoking a Smokers with disorder who are in poverty a Smokers with disorder who are in poverty b Numbers with disorder drawn into poverty by smoking a UK 1 217 733 904 647 135 304 553 801 405 28 255 38 071 110 425 420 100 062 England 1 021 983 759 225 113 554 464 778 340 133 46 478 601 835 357 034 83 977 Scotland 103 011 76 527 11 446 64 848 34 284 46 856 66 235 98 784 64 Wales 58 913 43 767 65 462 6 793 19 607 26 793 4 694 20 582 48 41 North-

ern Ireland³³ 82525 128375815 38311 257153819 91911 8172779¹²³

The effects of expenditure on tobacco are compounded by lower earnings among smokers in employment, with non-smokers earning on average 6.8% more than smokers. Smokers are also significantly less likely to be in employment than never-smokers. Long-term smokers are 7.5% less likely to be in employment than never-smokers.

People with mental health conditions are more likely to be unemployed, to receive benefits and to be living in relative poverty than those without mental health conditions.^{2,20} It is well documented that debt and financial stress can exacerbate mental ill health and that people with mental health conditions are more likely to experience debt problems.²¹ The interactions between smoking, poverty, debt and mental health suggested by these studies are important reasons to support smokers to quit.

Effects on mental health

Further motivation to support smokers with mental health conditions to quit comes from the positive influence this can have on mental health. Quitting smoking is associated with reduced depression, anxiety and stress, as well as improved positive mood and quality of life compared with continuing to smoke.²² For some people with mental health conditions, smoking can feel like ‘self-medicating’, and people say that it is an important way for them to deal with stress. However, this relief is temporary, linked to relieving withdrawal from nicotine and in the long term it can exacerbate symptoms.²³ The effect of smoking cessation on anxiety and depression appears to be at least as large as that of antidepressants.²²

Not only does smoking cessation improve physical health and reduce the chances of developing a smoking-related disease, supporting smokers to quit can also lift them out of poverty, return valuable disposable income to households and improve mental health.

It is also crucial that we remember that a majority of smokers want to quit.⁹ This is true among all smokers, including those with mental health conditions.²⁴ An even larger majority (71%) of smokers wish they had never started.²⁵

Providing support to quit

This raises the question: are services doing enough to support smokers with mental health conditions to quit? In 2016, the Five Year Forward View for Mental Health set a target for all in-patient mental health services to be smokefree by 2018.²⁶ This commitment was reiterated in the Tobacco Control Plan for England, which stated that it would include ‘providing integrated tobacco dependence treatment pathways’¹² in line with National Institute for Health and Care Excellence (NICE) guidance: *Smoking: Acute, Maternity and Mental Health Services* (PH48).²⁷ There are no specific targets for community mental health services, yet ASH’s survey of community mental health practitioners, discussed below, shows that there is a need to focus on the support provided by community mental health teams.

¹ CIS-R, revised Clinical Interview Schedule; HBAI, households below average income.

² Poverty based on 60% median gross income within survey.

In-patient settings

This 2018 target has been missed. A 2019 survey of mental health trusts in England found that nearly one in five (18%) did not have a comprehensive smokefree policy in line with NICE guidance.²⁸ Over half (55%) of trusts reported not always asking patients about their smoking status on admission, and 57% of trusts said that staff accompany patients on escorted leave to smoke every day, a practice which is: ‘...outdated. It reduces the resources available to deliver clinical care²⁹ and causes direct harm to patients.’¹²

Further, although all trusts reported that they offer nicotine replacement therapy (NRT) to patients, only 49% offered varenicline (Champix).²⁸ This is likely to be due in part to historic misunderstandings about the effects of varenicline on mental health. However, evidence shows that varenicline is not associated with negative outcomes for people with mental health conditions.^{30–32} As reflected in the Royal College of Psychiatrists’ position statement on prescribing of varenicline: ‘varenicline is a generally safe and well-tolerated medication which has been proven to increase rates of smoking cessation in psychiatric and non-psychiatric populations’.³³

However, prescribing rates for varenicline are falling fast, particularly for people with mental health conditions. Primary care data for over 200 000 smokers shows that smokers with mental health conditions were 31% less likely to be prescribed varenicline than NRT, despite varenicline being more effective.³² Smokers with mental health conditions who were prescribed varenicline were 19% more likely to have successfully quit at 2-year follow-up, compared with those prescribed NRT.³²

These policies must be addressed to ensure that all smokers are being offered the best support available to quit, in line with NICE guidance. Smokers with mental health conditions are often more heavily addicted,² and ensuring they have access to the most effective pharmacotherapy is essential to supporting quit attempts.

ASH’s survey also showed significant variation in approaches to vaping, from allowing a range of devices to be used across trusts, to prohibiting the use of e-cigarettes. National guidance from PHE,³⁴ the Royal College of Physicians³⁵ and the Royal College of Psychiatrists³³ highlights that vaping is substantially less harmful than continuing to smoke. Under UK regulations, the Medicines and Health Care Products Regulatory Agency (MHRA) oversees notification of new nicotine-containing e-cigarettes and e-liquids, and operates a yellow card reporting system for any adverse reactions.³⁶ A report is not proof that a reaction was caused by vaping, just that the reporter suspected it might have been. From 20 May 2016 through to 9 January 2020, the MHRA had received 84 yellow card reports on 245 adverse reactions, including 27 serious respiratory events.³⁷ In 2019, over 3.6 million people in England were estimated to be using e-cigarettes.³⁸

E-cigarettes are the most popular aid to quitting smoking in England,³⁹ and research has shown that using an e-cigarette along with behavioural support can be twice as effective for quitting smoking compared with using NRT.⁴⁰ Further, vaping is much cheaper than smoking. Research suggests that smokers who switch to e-cigarettes spend around £417 a year on vaping, substantially less than the estimated expenditure on tobacco of £1200 a year.⁴¹ These benefits should not be underestimated, and trusts should review policies in line with the latest evidence^{37,42} and national guidance.⁴³

Smokers also want greater provision and variety of support. In a focus group with 12 participants with experience of in-patient services or with family in in-patient services, no participant felt that the support offered on admission to a smokefree in-patient service was sufficient.⁴⁴ They noted that smokefree often felt like a ‘checkbox exercise’ rather than part of their care, with references to clear failings in the support options available: ‘*Handing someone a card with a number should not, in my opinion, count as actively giving someone smoking cessation support – that’s what I’ve had. But they can say they’ve given you some support; the fact that you couldn’t use the phone at the time doesn’t seem relevant*’.

To reduce the inequality in smoking rates between people with mental health conditions and the wider population, it is essential to improve the support offered in in-patient services. There are examples of trusts leading the way on this agenda, offering excellent support and engaging with smokers to ensure that they are addressing the broader social aspects of smoking and not just physiological withdrawal. Public Health England’s videos on implementation of NICE PH48 illustrate some of these examples.⁴⁵ If we are to achieve a smokefree 2030 for people with mental health conditions, these examples must become the norm.

Community services

A similarly patchy picture of support is seen in community services, which support the majority of people with mental health conditions.⁴⁶ Although there is less evidence here, a small-scale, self-selecting survey conducted by ASH of 103 mental health nurses (representing 33 trusts) and 171 psychiatrists (representing 48 trusts) found that over 55% reported receiving no training on supporting smoking cessation.⁴⁷ Only around a quarter of respondents said that they 'always' or 'usually' delivered very brief advice on smoking.

Prescribing medications for smoking cessation was reported to be similarly uncommon in community settings. Three-quarters (76%) of qualified nurses said that they never prescribed smoking cessation medications (NRT or varenicline), as did three-fifths (59%) of psychiatrists.⁴⁷

What works?

This absence of support is concerning, especially as there is a strong evidence base around what works to support smokers to quit. Smokers are three times more likely to quit successfully with the support of a specialist stop-smoking service than when attempting to quit unaided.^{48,49}

The Smoking Cessation Intervention for People with Severe Mental Ill Health (SCIMITAR) pilot⁵⁰ and randomised controlled trial (SCIMITAR+)⁵¹ were built on this evidence base. The SCIMITAR trials tailored the support set out in NICE guidance for people with mental health conditions, showing that such an approach is both effective and cost-effective. SCIMITAR compared the effectiveness of combined behavioural and pharmacological support for smoking cessation with usual care.⁵¹ Trial-condition participants received face-to-face behavioural support delivered by a trained mental health professional and prescriptions of their choice of smoking cessation medications, the most commonly chosen being NRT. Adaptations for people with severe mental health conditions – including extended pre-quit sessions, 'cut down to quit', and home visits – were offered in the trial arm. Compared with usual care, this intervention more than doubled quit rates at 6-month follow-up and showed significant improvements after 12 months.⁵¹

Participants in the SCIMITAR trial reported that the intervention being delivered by mental health nurses was important to them. It was important that they felt this support was being delivered by someone who would understand their mental health diagnosis without judgement and with professional expertise.

An ASH/Rethink focus group participant highlighted clearly the unique part a mental health nurse could play in supporting smokers: *'Community mental health nurses visit people in their own homes, and they see how that person is managing. Smoking's expensive ... if it's the difference between paying your electricity bill and buying a packet of fags... If this person is struggling, the community mental health nurse is in a good position to advise and act as a sign-post ... and link with GP services and the local chemists that offer smoking cessation'*.⁴⁴

This illustrates the value of training mental health professionals to deliver smoking cessation advice and support. However, studies have shown that mental health staff may not see addressing smoking as part of their role. One study found that only 48% of respondents felt that addressing smoking was within their remit as a mental health professional,⁵² and one in five were not sure whether quitting smoking would have a positive effect on recovery or thought quitting smoking could have negative effects.⁵²

The persistence of these myths undermines the potential for mental health services to support smokers to quit, and highlights the need for smoking and smoking cessation to be included in the training of mental health professionals.

Making change happen

Population-level interventions that have driven down smoking rates nationally have largely failed to reach smokers with mental health conditions. Although the specific commitment to supporting people with mental health conditions to stop smoking in the NHS Long Term Plan is welcome, the pace of change is currently slow.¹³ Transformation funding through the NHS Long Term Plan will not be in place nationally until 2023–2024.¹³ Although this additional funding and national commitment is welcome, it will not, on its own, help enough smokers with mental health conditions to quit.

Smoking rates among people with mental health conditions will not reach the national ambition of 5% or less by 2030 without a trained workforce that sees smoking and smoking cessation as part of their role. The current lack of training in smoking cessation among the mental health workforce, as evidenced by trust and community surveys, is a problem that must be tackled if staff are to be able to deliver on these commitments.

Smokers expect doctors to ask them about smoking and deliver advice. If clinicians are not asking about smoking, it sends the signal that this is nothing to worry about. All psychiatrists should be able to deliver very brief advice, an evidence-based brief intervention on smoking that asks about smoking status, advises that support is available that will increase the chances of successfully stopping, and signposts smokers to further support. This is not designed to support someone through their quit attempt; it is about raising the issue and motivating smokers to try to quit.

Smokers with mental health conditions are likely to be more heavily addicted and therefore can find quitting harder.² Ensuring that smokers with mental health conditions have access to the right pharmacotherapy to support them to quit is essential. Mental health trusts must ensure that the most effective treatments, including combination NRT and varenicline, are on their formularies and that they are being prescribed to patients in line with NICE guidance.^{27,53}

Psychiatrists have a key role in reducing smoking among people with mental health conditions and in turn need appropriate training to deliver this. Although people can become immune to statistics about disease and death caused by smoking, reminding them about the effects that smoking has on well-being and quality of life is always worthwhile.

The number of people with mental health conditions pushed into poverty by smoking demands urgent action. Although quitting smoking will not solve poverty for everyone with a mental health condition, giving people the support they need to quit is a big step in the right direction.

1.3.31 Child psychiatry: a model for specific goals for in-patient treatment linked to resources and limitations in out-patient treatment

Simon R. Wilkinson

Correspondence

Simon Wilkinson

(simonrwilkinson@gmail.com)

date

2020-12

Abstract

I present a rationale for two different types of in-patient child psychiatric unit: 24/7 intensive units and 24/5 child and family units. Intensive units address safety requirements. The developing personality of young people is at the centre of in-patient approaches on the child and family units. This requires attachment-informed practice. Families must always be involved and placement of units must facilitate their participation. The primary skill characterising these units is use of the milieu for therapy and combining this with family therapy. In other words, nurses and allied professionals need to be the dominant force in unit development, under the reflective guidance of consultants and clinical psychologists.

- * *Supplementary material*

Sitting beside a nurse from a county in California at an international conference I realised for the first time that areas in the USA provide third-world levels of child psychiatric treatment. She was the only clinical worker for children and adolescents with psychiatric problems for a county with a total population close to 100 000. She arranged for patients to fill out forms, which were then sent to an adult psychiatrist, who prescribed medication over the phone. My concern is that general UK provision has for a long time been critically vulnerable because of the extremely low staffing levels and lack of obligation to provide a comprehensive service within each health trust. I do not believe that the UK model of service provision is conducive to making a leap forward with services tied to a tiers model. Yet there is no evidence of what ingredients might promote a healthier service. Even though we have evidence that in-patient treatment can give benefits,¹ we have no conceptualisation of how the complex interconnected processes on an in-patient ward might be working. Instead I will present here an analysis of how need can be formulated to suggest an alternative service model which can identify the elements that need addressing. Although I have been working within the well-endowed Norwegian health service, and there is no chance of the UK approaching the same level of provision in the near or distant future (we have over ten times the resources compared with the UK and other wealthy countries²), analysis of

what is required is no different. Having worked outside the taken-for-granted world of UK child psychiatry, a different perspective can be generated which maybe leads to new possibilities.

Safety first – 7 days a week (24/7)

The top priority has to be given to ensuring safety, when, by virtue of the young person's mental state, the patient or their VIPs (I will use 'very important person' to cover the adults responsible for ensuring the patient's care – biological parents, foster parents, etc.) have been in danger. This has to be available 24/7 and it requires a mix of out-patient provision and emergency out-of-hours service in liaison with a unit available to admit patients 24/7. The issue of whether it is desirable to provide more than 09.00–17.00 h out-patient provision to enable both VIPs and patients easier access to specialist services needs to be debated. Or could emergency services be staffed with child and adolescent psychiatric expertise? (In Oslo there is a psychiatric emergency department which is staffed until 23.00 h, covering the time after out-patient departments cease their obligation to evaluate emergencies at their closing time. Some privileged populations in the UK have access to services with such out-of-hours specialist cover.) Why is it not expected that all emergency departments should be catering for the second highest cause of mortality among our adolescents after accidents?

Rather than going into the pitfalls of evaluating potentially suicidal behaviour, as only one potential reason for acute referral, I will only remind us here that those with greater experience refer fewer patients for admission because of potential suicide. This underlines why highest-quality expertise is needed in the front line.

It is not the Axis I diagnosis that determines the need for admission, but the necessity of an alternative 'containment' of the patient to that available at home. Two factors operate here: the state of the child and the processes at home. The ICD-10 system's Axis V diagnoses of the psychosocial context were included as of prognostic importance and needed to be addressed in treatment plans. Context matters as much as the young person's 'state' – and it is entwined in the same complex causal system, such that states evolve to 'traits' depending on the maintaining influence of context processes. No admission should occur without the possibility of integrating approaches to the child's state, as well as addressing precipitating and maintaining factors in the context of the episode. The younger the patient, the more important the context factors in treatment. Here, planning for young people differs from that for adults. Out-of-region 'refuse recirculation' is detrimental to patient recovery and welfare and can be expected to be associated with need for more frequent readmissions. Every such unit needs to be able to work with family, school and local resources – and that means fathers as well as mothers.

The critical elements concern ensuring highest expertise during out-patient evaluations, with ideally similar levels of expertise available 'out of hours', and an in-patient resource that is equipped to address the patient's state as well as the context factors. The level of staffing needs to be high – and, importantly, consist of a stable group of nurse therapists (use of locums is countertherapeutic to the teamwork required). A higher level of staffing and greater stability of staff leads to reduced needs for restraint or emergency medication.¹ Staffing needs to include other therapists working in the patient 'milieu'² who are expert in childcare issues, such as residential social workers. They need to be used to working with complicated family dynamics, where abuse of power – both verbal and physical – may well be a problem. Safety is primarily ensured by these staff, to a greater degree than by doctors and clinical psychologists, who provide the back-up understanding of the treatment needs and reflection on the treatment dynamic as it evolves. The high

¹ The Norwegian adaptation of the Quality Network for Inpatient CAMHS (QNIC), known as KvIP (www.akuttnettverket.no/kvip-barn-og-unge), has found that an emergency sedation regime has not proved necessary, and it was recently removed from the list of standards. This is attributed to the higher levels of stable qualified staffing.

²

In Norway the staff are collectively known as milieu therapists, and include both nurses, childcare workers and other professionals, besides the non-milieu psychologists and child psychiatrists.

staffing levels enable the intensive approach required, and this suggests that the proposed 24/7 acute admission units should be called intensive units, as in UK adult psychiatry. Because transfer of patients between units and therapists creates lacunae of security, such intensive units should be able to keep treating their patients who require longer than an acute admission. This most vulnerable group of patients needs help to set up their transfer back to the context from which they were admitted, so that a return to their out-patient department will succeed without the patient isolating themselves in connection with the transition. An adequate model for practice needs to include an ambulant service from the intensive unit to anchor the patients in meaningful activities at home – school, clubs, sports, etc. – so that any tendencies to isolation can be mitigated.

Working with personality – 5 days a week (24/5)

There is another group of patients who can also benefit from admission, albeit not the intensive kind with a focus on security. Often these have been referred for diagnostic evaluation and treatment. But in principle there is little to suggest that an admission should be used for diagnosis, given the skills that need to be available on an out-patient basis (in my practice the costs of 1 year's admission was the equivalent of 4–5 full-time out-patient clinicians). What cannot be done there? Out-patient clinicians cannot easily evaluate problems arising at bedtime and during the night! Usually such referrals for diagnosis are a 'cop out'. Any referral precipitated by lack of progress in out-patients requires that the covering letter identifies the barriers preventing progress – and how these might be more successfully addressed during an admission. In my experience this does not happen. Additionally, on admission, objective criteria should be decided as to how far treatment needs to have come before transfer back to out-patient provision can occur successfully.

Do we know what the barriers are likely to be? They are not the Axis I diagnoses, as all of these can potentially be treated outside institutional services. I have my experience to go on from Norway, and it may be very different in the UK. My guess is that the barriers are universal, but seldom acknowledged. The elephant in the room, the dimension not talked about in child psychiatry, is personality, both that developing in the patient and in the VIPs. Progress in treatment depends on working with both the patient and the VIP and establishing an alliance with them that facilitates their ability to take chances in doing things differently. But this is easier for some than others. The more insecure a VIP or patient the greater their need to do things to feel in control of the situation. These individuals can be impulsively dramatic. And they take fewer chances to do things differently – for the VIP to read the child's signals differently, to understand their vulnerabilities in new ways, or for the child to respond to their fears as much as to fight their way out of a corner, to take chances to tell others what they are going through. In such control-focused meetings things continue to happen impulsively with little reflection, according to well-worn strategies. As Peter Cook replied to Dudley Moore when asked what he had learnt from his mistakes: 'I could repeat them exactly'. This tendency to impulsiveness associated with lack of change can easily suggest to the therapist that they are missing something and that a diagnostic admission is required. Instead I suggest there is a need for an admission to a totally different sort of unit than the intensive unit. There will be no sole focus on the Axis I diagnosis, Axes II–V being at least as significant for the admission – and assuming that Axis VI scores (Children's Global Assessment Scale, CGAS) are at least under 40. Admitting patients with primarily personality problems to an intensive unit is expected to be counterproductive.

A child and family unit can have a lower staffing level. It is not apparent to me that it should be a 24/7 unit, as there are advantages of the patients being at home at weekends. Therefore a 24/5 unit would be better. It needs to be able to address the impulsive responses to which the patients and their VIPs are disposed, fuelled from their implicit memories. The milieu staff would interact with patients in the 'here and now', allowing response patterns characteristic of the dispositional representations³ of the patients' personalities to be revealed, and would set up situations to create optimal learning opportunities. The staff would be grounded in understanding of personality, a field with which child psychiatry is only slowly coming to grips. My suggestion is that adapting Clarkin's⁴ conceptualisation of personality and informing it with knowledge about child development will give us personality as reflecting factors present at birth or by the end of the first years of life (Clarkin used the short-hand 'temperament', as if it were an obviously genetic factor) in interaction with attachment strategies, and influenced by experiences of trauma and loss. This would have given us the personality dimensions suggested, but not adopted, for DSM-5.

The advantage of such a unit operating 24/5 is that the focus is continually on patterns that recur in the home environment. Has the treatment week led to different patterns at the weekend? During the week it is necessary to work with the patient, but also with parental responsiveness and the parent's ability to identify precipitating and maintaining factors in their child's disturbance. Each weekend is not a break from treatment, but a time for renewal and update of

the treatment contract, refreshing and refining the focus for all concerned. With clarity preceding admission in what needs to have changed before out-patient treatment can resume, the approaching discharge timing will be clear to all involved 'en route'. If issues of security arise during the weekends then a temporary move to an intensive unit may be required, but the priority is a thorough analysis of the sequences that precipitated the situation by the staff from the 24/5 unit.

These units will often find they are working in the no man's land between child-protection services and medicine. Child psychiatric services will always need to have close liaison with social services and make use of consultation from child-protection services – and provide corresponding consultation to child-protection services.

A plea

From my position across the water it is indefensible to be bussing young patients out of region. Every patient should be getting eventual need for admission met within easy travel distance of home so that family approaches can be integrated with the in-patient treatment. If a unit is designated as an intensive unit it should not be allowed to close its doors to local acute admissions. It should be under an obligation to provide the 24/7 service required even if it means temporary beds. Any other arrangement rewards keeping patients longer than required to enable the unit to avoid the crushing work of new admissions; and frees the out-patients from pressure to ensure a rejuvenated service for the returning patient. Tier 4 expertise should be available primarily on an out-patient basis. An admission is not to a hierarchically superior service, but to one of two possible treatment units providing distinctly different provision, where the role of the milieu staff has primacy in the treatment strategy.

Simon Wilkinson, MD, FRCPsych, has run the adolescent in-patient units at the National Centre for Child Psychiatry, Oslo, Norway. He has retired from clinical practice although is still employed by Oslo University Hospital and Akershus University Hospital to provide psychotherapy supervision for junior doctors in training.

Abstract

Aims and method

To explore the experiences of emergency workers dealing with incidents in which section 136 of the Mental Health Act 1983 is invoked by the police. Data from interviews with police officers and ambulance workers in a London locality were subject to interpretative phenomenological analysis.

Results

Participants felt they were the first port of call and that training should be improved to help them deal with those experiencing mental health crises in the community. Police participants noted time pressures trying to gain individuals' trust and described section 136 detention as sometimes feeling like a betrayal of the individual. Most participants had negative experiences of admissions to the 136 suite; several suggested ways of improving the admissions system. Several went beyond their expected duties to ensure that distressed individuals were supported before accessing mental healthcare services.

Clinical implications

Improving training of emergency workers in dealing with mental health crises would also help with aftercare decision-making. Learning identified from the participants' experiences lends support to collaboration between emergency and mental health services, an important step towards improving the section 136 process so that detainees can access help without unnecessary delay.

Section 136 of the Mental Health Act 1983 for England and Wales (amended in 2007) permits police officers to legally detain someone who is in a public place and is believed to be at risk to themselves or others and to be requiring immediate care or control.¹ Detainees are taken by police and the ambulance service to a designated place of safety for assessment, with arrangements for treatment and aftercare.^{1,2} According to the Act, a ‘place of safety’ could be a police station, a unit in a psychiatric hospital or another suitable residential place willing to temporarily accommodate a detained person.^{2,3}

Implementing section 136 not only requires quick thinking but can pose a challenge for emergency workers with limited or no training in mental health.^{1,4,5}

Two papers^{6,7} exploring police officers’ experiences of section 136 highlighted participants’ concerns about vulnerable individuals being turned away from in-patient mental health services. There is a paucity of research on the experiences of ambulance and paramedic workers. This study aims to fill this gap by exploring emergency workers’ experiences of section 136 and how they make sense of them.

Method

Participants

Emergency workers were purposively sampled on the basis of the roles they undertake and their experiences of implementing section 136. Four individuals from a police force and three from an ambulance complex in a London locality participated. This sample size is consistent with the interpretative phenomenological analysis (IPA) literature, which suggests the appropriateness of relatively small samples, for whom the research questions are significant.^{8,9,10}

Characteristics of the participants (who were allocated anonymised identifiers such as PO1) are presented in *Table 1*.
 Table 1 Participant characteristics at time of interview
 Participant identifier Role Gender
 Police 1 (PO1) Police officer Male
 Police 2 (PO2) Police officer Female
 Police 3 (PO3) Police officer Male
 Police 4 (PO4) Police mental health liaison officer Male
 Ambulance worker 1 (AMB1) Ambulance worker Female
 Ambulance worker 2 (AMB2) Ambulance worker Male
 Ambulance worker 3 (AMB3) Paramedic Female

Ethics

This research received ethical approval from the London South East National Health Service Research Ethics Committee in 2011, reference number 11/LO/1002. Participants were given a detailed information sheet and completed a written consent form.

Data collection and analysis

Police officers ($n = 4$) and ambulance workers ($n = 3$), not known to each other, participated in separate interviews (data were collected between 2012 and 2014). In keeping with the IPA approach, open-ended questions were used inviting participants to tell their stories in their own words, with prompts where necessary.^{8,11}

The following are examples of questions asked.

Ambulance workers: ‘Please could you tell us about your recent experiences of taking someone under a section 136 from a public place to a place of safety?’. Prompt: ‘How do you feel about dealing with incidents of this nature?’.

Police officers: ‘Please could you tell us about a recent experience of sectioning someone?’. Prompts: ‘What factors are involved in making this decision? Did you feel that your action(s) were justified?’; ‘Have your encounters with individuals in these kinds of situations affected, if at all, the way you view people with mental illness?’.

Interviews took place at police stations or ambulance complexes and lasted around 50 min. The third author (L.S.) took summary notes of the interviews to supplement the audio transcripts. Responses were digitally audio-recorded and transcribed into text verbatim by the first author (M.G.).

A framework underpinned by the IPA literature was developed and used to inform the analysis process.^{5,8,10} Questions were asked of the data by M.G. to aid the process of identifying themes: (a) What experiences are being shared and how are respondents making these meaningful to one another?; and (b) What are the consensus, conflicts/contradictions and how these are being managed?^{12,13}

Themes were deemed to be prominent if they occurred in approximately one-third to half of participants' accounts.^{9,11} For example, most participants referred to their experiences of interacting with individuals in distress, how they felt about engaging and showing empathy. This was deemed to be a shared experience and characterised by the theme: 'Making yourself human as first responders'.^{14,15}

Quality checks were undertaken by M.G. and L.S., which involved comparing a random selection of themes alongside verbatim quotes. This was done to ensure that themes closely reflected the participants' experiences and it fits with the epistemological approach.^{9,16}

The findings are presented under the thematic headings below. Quotes from the participants are interwoven with interpretative commentary that encompasses emotions evoked as well as the language and text they relate to.

Results

Making yourself human as first responders

Participants described themselves as the '*first responders*' and spoke of how they approached and communicated with the individuals involved. Some were sensitive to the way a uniform or emergency vehicle can be perceived. Communication was seen by these participants as 'Essential for people who may be suffering from some sort of psychosis, sort of gaining trust, turn your radios down, taking off your hat. Essentially try and be the only person talking to them' (PO3).

Police participants reflected that detaining and removing someone against their will could generate feelings of betrayal towards the person they were trying to build trust with. The main challenge for them was in encouraging individuals to accept help voluntarily. Some of the police officers felt that they did their best to demonstrate that their role is not only about enforcing the law, but also supporting individuals in difficult and sensitive circumstances: "It takes a good few hours to build rapport with her, which can be difficult if someone is going through an episode. You don't want them to feel humiliated or mocked. Because you want them to know you are there to help' (PO1)."

Participants tried to make sense of the barriers and pressures that made it difficult for them to establish a rapport: "Making yourself more sort of human to them. But the problem is your lifeline is your radio and so by turning it down you are not hearing what's happening outside' (PO2). 'We are under pressure from our radio, from our supervisors. So, it sounds awful but it is time-consuming. In this day and age we do not have 2 hours spare, which sounds awful to say. But you end up having to build that rapport up, say "come on you know what, the best thing to help you is to voluntarily go with the ambulance". And probably 7 out of 10 it works' (PO2)."

The excerpt below is a good example of the police officer involving a family member to support a distressed individual. It brought about a sense of reassurance for the parties involved in ensuring that the person was supported in keeping themselves safe: "Like, the lady, she was holding a knife to her throat. We ended up calling her son to say "look, your mum, she's voluntarily said she can come to hospital. This is what's happened. We just want you to be aware because I think she could do with a loving face, like have someone from the family there"" (PO3)."

The 136 suite

The place of safety or ‘136 suite’ was salient for the participants as the transition point into in-patient mental health-care. All of the participants spoke less favourably of their experiences of trying to get individuals admitted into the suite. Strong feelings were voiced regarding the potential welfare of detainees in situations where there were delays. Ambulance workers felt for individuals who had little or no choice but to wait inside an emergency vehicle: ‘I find once you get to [hospital X], I’ve waited 2 hours before to get into the 136 suite and that can cause issues with the patient’ (AMB2).

When considering what the waiting might involve, the ambulance workers reflected that ‘We’re not allowed in the building. So, we just literally sit outside in the ambulance or in the police van’ (AMB2).

Unlike ambulance workers, police officers were able to enter the 136 suite and liaise with staff there. Ambulance worker participants often speculated on what goes on inside the facility, which may have generated some friction between the ambulance workers and mental health workers at the 136 suite. They wondered what happened to individuals who were admitted and how they got on: ‘Once we take someone to [hospital X], we don’t see what happens’ (AMB2).

The exchange below illustrates the police liaising with mental health workers at a 136 suite. There is a sense of the parties colluding with each other, together with somewhat blurred boundaries around responsibility. The liaison between police and hospital staff amplifies a sense of being in an awkward position and of feeling overwhelmed, in a situation in which there are no clear answers regarding care decisions: “‘It went back and forth, our inspectors got involved. Hospital staff basically turned around to us and said that if we left the hospital they would let him walk out of the hospital and into the street, where he would then become our responsibility again [...] And that if he was to attack someone it would be on the basis that the police left him and that they washed their hands of him [...] We explained that we had no powers, essentially the only thing we had was a breach of the peace, inside the facility whilst he was there [...] This went on for about 2 hours, this debate’ (PO1).”

Most of the participants’ experiences at the point of entry to the 136 suite were negative. However, there was a unique example in which an individual under a section 136 was able to access the care they needed, in a timely and seamless manner: “‘I think I had a positive one. We had a gentleman who was out on the street. The police were already there when we arrived on the scene. And it was called in by friends of his because he was behaving erratically [...] When we got there he was in the back of a police van, but his behaviour was quite self-harming, even though he was quite chatty [...] And then what we’ve got in place was that a paramedic travelled with the police in the van to ensure the safety and the care for the patient. And actually we did take him straight to the 136 suite on this incident and he was booked straight in. So that worked really well. But that was during the day. It was early. It was a weekday. So everything was in place on that incident’ (AMB1).”

Training and quest for collaboration

When participants reflected on their skills in dealing with individuals experiencing mental health problems, there was a unanimous view that training and opportunities were somewhat limited. The participants reflected on specific areas that they felt could influence their practice, given their involvement in section 136 detentions. For example, ambulance workers felt that they would benefit from a better understanding of substance misuse and mental illness: “‘I’d like to have more training [...] Historically, our training has been a bit ad hoc [...] I think it’s got to be around drugs and alcohol, what that impact is on how we are assessing a patient. Because as you can imagine, probably 75 per cent will have drugs and alcohol on board’ (AMB2). ‘There is no training on what you might want to look for, how it might present itself and different types of mental health, erm, issues. I don’t think there were any role-plays or anything like that, which I think could possibly be helpful’ (PO3).”

Ambulance workers put forth some practical suggestions that they felt would benefit professionals and detainees, with an emerging consensus towards a more collaborative approach. One respondent referred to the potential of a bed management system that he had found successful in general accident and emergency (A&E) settings: “‘A bed manager in A&E is always well versed on what beds are available. So ITU beds, neonate beds [...] Why isn’t that available in psychiatric healthcare?’ (AMB2).”

The same respondent speculated as to whether such a system could be applied in the 136 suite to ease the transition into hospital care: “So, we’re on a job with someone who is going to get 136’d [...] So rather than waste half an hour with the police trying to ring the 136 suite, because they are obviously busy preparing for two to come in, why don’t we get someone to just say “There’s no beds. Your nearest bed is there”. Bang! Why can’t we do that?” (AMB2).”

Further suggestions were put forth to minimise waiting times and ensure that detainees were promptly received and attended to at the 136 suite: “It needs some immediate action. It’s not something that can be delayed [...] Can we go early with the information that we’re going to be taking a patient there?” (AMB3).”

In some cases, there was a sense of commitment and willingness to go beyond the remit of their roles, for example: “If we’re going to be spending this long with patients [...] waiting to convey them to the 136 suite, if we can find out more information on the scene then let’s do it” (AMB2).”

Discussion

This research is the first of its kind to collectively explore and combine findings from police and ambulance workers’ experiences of detaining individuals under section 136 of the Mental Health Act (England and Wales).¹ This piece of work highlights that lived experience plays a key role in service development in a range of settings. Two key aspects of experience emerged from the findings: (a) therapeutic engagement in a crisis and (b) drawing on the expertise and experiences of the parties involved in a section 136 admission.

Personal engagement

Professionals felt that how they approached and engaged with individuals had made some difference in those people’s willingness to accept help. Police participants felt pressured by their agency to prioritise other emergencies over mental health incidents.^{17,18} It is not entirely clear how much time emergency workers can devote to situations in which mental health problems are suspected. This was a source of conflict for study participants. Therapeutically engaging and gaining trust were seen by participants as an important first step and in the detainee’s best interests as a way of enabling them to access immediate support.

Accessing the 136 suite

A pressing concern for participants was the inordinate amount of delay regarding decisions on granting access to the 136 suite (the place of safety). In some cases, detainees were having to wait for longer than necessary inside an emergency vehicle or were refused entry, which generated further distress. The findings also point to friction between the emergency and mental health services regarding responsibilities of care. The collusion between the parties can have implications for the waiting time for detainees in need of immediate care and support. These findings were similarly noted in Burgess *et al*⁵ and Riley *et al*⁶ and is at odds with key recommendations from the Royal College of Psychiatrists’ section 136 national guidance. According to these guidelines: 136 suites should agree to accept an individual before the emergency services begin their journey and have the necessary staff on hand to receive individuals without delay or recourse to emergency professionals.^{2,17} In contrast, another finding conveyed an emergency worker’s experience where the section 136 journey for the detainee in question was smoother and well supported. This finding highlights what one can learn from personal experiences and consider how these can inform future practice. A prominent aspect to this study was that emergency workers wanted to be more involved in the section 136 process and to work jointly with staff at the 136 suite. This was evidenced by their efforts to seek out practical solutions for the dilemmas they experienced. The participants felt that this way of working would enhance the quality of the experience for detainees accessing mental healthcare.^{10,19}

Training

This study has shown that ambulance and paramedic workers play a pivotal role in dealing with individuals experiencing mental health problems in a community setting. Yet, training for this group of professionals is somewhat limited. There was a general consensus regarding the improvement of training to enable emergency workers to feel more confident in recognising how mental health problems can present, dealing with crises and engaging with individuals affected.^{6,14,19}

Given this, future work needs to prioritise interdisciplinary training to enable the various agencies to appreciate the roles and limitations of their services. These different agencies can learn a lot from each other.²⁰ In keeping with suggestions in previous work, involvement of patients and carers could enhance the quality of the training for emergency workers, by bringing in their lived experiences.^{7,20} This is another important area, which would benefit from being further explored in future research.

Strengths and limitations

Interpretative phenomenological analysis (IPA) captured emergency workers' experiences of the section 136 process and how they were affected by it. Situating the study in a catchment area of a National Health Service mental health trust in London could be seen as both a strength and a weakness, since the views expressed only reflect those who took part in the study. It is possible that the views of emergency workers with different characteristics in other areas of England and Wales will vary. Further research in other geographical areas could help to ascertain whether this perspective of section 136 detainment could be understood more widely.

We thank participants and organisations in the study catchment area.

Contents

- *Systemic racism and mental health services: the time is now*
- *Declaration of interest*

The killing of George Floyd refocused global attention on racial injustice. UK Covid-19 death rates are highest among Black, Asian and minority ethnic (BAME) groups,¹ with systemic racial inequality a central cause.² Although BAME people face many inequalities, Black people's unique experiences require particular attention.³

In mental healthcare, we must consider links between psychiatric symptoms and experiencing racism, systemic racism within services and medico-legal interfaces. The *Delivering Race Equality in Mental Health Care* (DRE) agenda⁴ was prompted by the 1998 death of David Bennett, an African–Caribbean patient, following in-patient restraint. DRE prioritised reducing fear of services, developing culturally appropriate therapies, and engaging BAME groups and patients in training, policy development, service planning and provision.

A DRE progress review⁵ advocated dedicated community development workers, engagement projects, training, clinical trailblazers and measuring progress. Patients, professionals, campaigners and academics attributed continued race inequality in mental healthcare post-DRE to institutional racism, inadequate training, poor system design and lack of an empowering culture.⁶

In our experience, DRE is not prioritised. Core training competencies of 'cultural diversity', evaluating institutional prejudices, respect for diversity and evaluating biases are neglected. Despite a strong position statement,⁷ racism is absent from MRCPsych examinations. Static e-learning modules replace interactive, in-person training that could stimulate engagement, discussion and reflection. Black leadership and collaboration with Black community stakeholders are lacking in mental health trusts serving largely Black populations.

Mental health service leaders must role-model, reflecting on personal and workplace unconscious biases.⁸ We should each ask of our own organisation, how equitable is provision? Do Black patients have equal access to psychological therapies and specialist services? Are their perspectives represented? Do we foster dialogue with local communities? Do Black staff experience disproportionate bullying and harassment? Can they speak up if safeguards are lacking? Identifying and ameliorating clinical inequalities should drive research, so that treatments meet Black patients' needs.⁹

'We do not need another review, or report, or commission to tell us what to do' about race inequality in the UK,¹⁰ nor in mental healthcare. To address mistrust, services must acknowledge and address inequalities experienced by Black patients. We welcome RCPsych's appointment of presidential race equality leads and hope they will forge multidisciplinary alliances to mainstream anti-racism across mental health professionals.

It should not have taken a death to trigger the biggest race equality focus in mental health services' history, nor should it have been so rapidly forgotten. Black stakeholders must be empowered to occupy positions of influence, but it is not Black staff or patients' responsibility to effect change; organisations must be accountable. In a mostly White-led profession, tackling systemic racism will inevitably cause discomfort. Mental healthcare, with its recognition of transference and countertransference, and prioritisation of supervision, reflection and psychotherapeutic skills, is well-placed to lead the difficult discussions the health service needs. Silence is not neutral. The time is now.

1.3.34 Critical psychiatry: an embarrassing hangover from the 1970s?

Duncan B. Double¹

2020-12

Abstract

Critical psychiatry is associated with anti-psychiatry and may therefore seem to be an embarrassing hangover from the 1970s. However, its essential position that functional mental illness should not be reduced to brain disease overlaps with historical debates in psychiatry more than is commonly appreciated. Three examples of non-reductive approaches, like critical psychiatry, in the history of psychiatry are considered.

 - *George Engel's biopsychosocial model*
 - *Conclusion*

The Critical Psychiatry Network has promoted critical psychiatry for the past 20 years.¹ It is a small group of psychiatrists and although psychiatrists in general may be aware of its critique, it remains a minority perspective. In this sense, critical psychiatry still seems marginal to mainstream practice. This may be because of its association with so-called anti-psychiatry. Although the first modern use of 'anti-psychiatry' was probably by David Cooper in his book *Psychiatry and Anti-Psychiatry*,² the term has generally been applied by mainstream psychiatry to denote criticism that it does not accept. For example, Martin Roth, when he was the first president of the Royal College of Psychiatrists, identified an international movement against psychiatry that he regarded as 'anti-medical, anti-therapeutic, anti-institutional and anti-scientific'.³

Psychiatry's response to anti-psychiatry

Anti-psychiatry, perhaps most associated with the names of Thomas Szasz and Ronald Laing, now tends to be seen as a passing phase in the history of psychiatry.⁴ In this sense it was an aberration, a discontinuity with the proper course of psychiatry. However, it is difficult to accept that there was no value in the approach and what may be more beneficial is to look for the continuities, rather than discontinuities, with orthodox psychiatry. In fact, anti-psychiatry is not a single perspective; for example, Szasz equally rejected both mainstream psychiatry and Laing's views.⁵

Part of how psychiatry was able to move on from anti-psychiatry was by trying to make psychiatric diagnoses more reliable; for example, through the American Psychiatric Association's publication of the DSM-III. Another way was by avoiding ideological disputes engendered by anti-psychiatry, by encouraging eclecticism in practice that includes psychosocial as well as biological factors.⁶ The challenge to a narrowly biomedical model, which was of such concern for anti-psychiatry, was thereby averted.

Mainstream psychiatry now tends to regard anti-psychiatry as a 'straw man' argument. It was sustained by the counter-culture of the 1960s and without this support it has waned away. Social cultural critiques, with which anti-psychiatry was aligned, are no longer academically respectable. Critical psychiatry, by apparently resurrecting anti-psychiatry ideas, may therefore seem like an embarrassing hangover from the 1970s.

Historical foundations of critical psychiatry

The history of psychiatry can be understood as a conflict between two factions of somatic and psychic approaches rather than a simple chronological development. Critical psychiatry is part of this debate. The essential position of critical psychiatry is that functional mental illness should not be reduced to brain disease. Its challenge to reductionism and positivism, including mechanistic psychological approaches, creates a framework that focuses on the person and has ethical, therapeutic and political implications for clinical practice. This editorial focuses on conceptual issues, as the more practical aspects of critical psychiatry could be said to follow from its theoretical position. This is not meant to detract from these central practical concerns of critical psychiatry, such as the political and socioeconomic origins of mental illness.

The argument of critical psychiatry is that psychiatry can be practiced without taking the step of faith of believing that functional mental illness is owing to brain pathology. This anti-reductionism is primarily explanatory rather than ontological and does not undermine the importance of organic factors. Functional psychiatry could be said to be doomed to a kind of descriptivism rather than being able to become a mechanical natural science. Historically critical psychiatry may actually be more integrated with mainstream psychiatry than is commonly appreciated.

Modern psychiatry has its origins in the Enlightenment of the 18th century.⁷ The problem of knowledge began to shift away from philosophy toward science. Critical engagement of reason with itself created a descriptive approach to madness. Psychiatrists were originally called alienists, identifying mental alienation.

Descartes had separated the soul from the body, and, reacting against this Cartesianism, anthropology established itself as an independent discipline, concerned with the study of man as a psychophysical unity. In this context, medical psychology had its origin with two major variants of anthropological thinking.⁸ A medically orientated anthropology represented by Ernst Platner, among others, was one version, and can be seen as the root of biomedical psychiatry. Physiological knowledge of humans seemed to create the possibility of a natural scientific psychology. The other version was Immanuel Kant's pragmatic anthropology, which may be seen as the origin of critical psychiatry. Kant believed that a natural science psychology was impossible to realise in practice. Applying a physico-chemical mechanistic approach to life cannot accommodate the purposiveness of living beings. Organisms, unlike machines, are self-organising and self-reproducing systems. Kant was clear that it is futile to expect to be able to understand and explain life in terms of merely mechanical principles of nature.

Building on this proto-psychiatry, the first half of the 19th century saw the development of anatomoclinical understanding. Relating symptoms and signs to their underlying physical pathology was a major advance for medicine and still underlies our modern understanding of disease. Pathology emerged as a distinct discipline with autopsy findings of lesions in organs and tissues being related to clinical examination at the bedside. Histological studies established cellular abnormalities for disease.

Applying this anatomoclinical method to psychiatry was not as successful because it was not always easy to relate mental conditions to underlying brain pathology. The enthusiastic search for anatomical localisation in psychiatry led to fanciful notions later in the 19th century. For example, Theodor Meynert (1833–1892) delineated various ‘fibre-systems’ in the brain and deduced functions for these ‘pathways’. Meynert’s research may have appeared so successful because it seemed to give a material explanation of the basis of mental illness. Despite his skills in brain dissection, his theories were not based on empirical findings. They were eventually attacked and labelled as ‘brain mythology’, particularly after his death.

It was eventually established that dementia paralytica was a late consequence of syphilis. Senile dementia was also seen as having a physical cause such as Alzheimer’s disease. Focal abnormalities in the brain were identified and physical causes of learning disability were recognised. However, most psychopathology is functional, in the sense that there are no structural abnormalities in the brain.

Wilhelm Griesinger (1817–1868) was dedicated to the idea of the pathology and therapy of mental diseases as a mechanical natural science, although he remained aware of the gap between this ideal and reality. Nonetheless he set the trend for this positivist biomedical understanding that has dominated psychiatry since the middle of the 19th century. His aphorism that ‘mental diseases are brain diseases’ could be seen as the origin of modern biomedical psychiatry with its wish to find a physicalist basis for mental illness. Such a positivist reduction of mental illness to brain disease is what causes such concern for critical psychiatry.

This historical narrative is necessarily selective and schematic. It is more of a genealogy, attempting to make the origins of critical psychiatry intelligible. Psychiatry and its critical version had their origins at the same time in medical psychology. Incorporating the anatomoclinical way of understanding disease into psychiatry, particularly following Griesinger, has eclipsed a more critical understanding of mental illness. There have, nonetheless, been non-reductive approaches in modern psychiatry that amount to a critical position. For reasons of space, this editorial will consider just three examples: Ernst von Feuchtersleben, Adolf Meyer and George Engel.

The forgotten psychiatrist Ernst von Feuchtersleben

In the same year, 1845, that saw the publication in German of the book that gave Wilhelm Griesinger his reputation in psychiatry, Ernst von Feuchtersleben produced his psychiatric textbook⁹ based on his lectures. Following Kant, he recognised that the mind–brain problem is an enigma, which can never be solved. He was aware of the somatic bias in medicine and one of the aims of his lectures was to encourage young physicians to study its psychical element. As far as he was concerned, all physicians should have a clear understanding of the relationship between mind and body.

Feuchtersleben took a holistic approach to medical psychology. Materialism, in the sense of reducing mind to body, as far as he was concerned, explains nothing because such reductionism leads to the loss of meaning of human action. Mental illness is deduced rather from the relationship of mind and body without necessarily being able to explain this relationship. There is a limit to the natural scientific understanding of mental life.

Philipp Carl Hartmann, his teacher and Chair of General Pathology, Therapy and Materia Medica at the Vienna Medical School, influenced Feuchtersleben.¹⁰ Hartmann’s understanding of disease as a dynamic process was a corrective to the physicalist perspective. Although both Hartmann and Feuchtersleben of course recognised that mental activity has a physical basis, they were clear that physiology is not able to derive the activities of the mind completely from the laws of the physical world. Despite the success of Feuchtersleben’s book, biomedical approaches became more dominant and his psychosomatic viewpoint had no impact in the second half of the 19th century.

Adolf Meyer's psychobiology

Adolf Meyer was regarded as the Dean of American psychiatry in the first half of the 20th century. His approach, called psychobiology,¹¹ has an integrated understanding of mind and brain. Meyer began his career as a pathologist and moved into the clinical field, standardising procedures for history-taking and mental state examination. Psychopathology needs to be studied functionally in experiences and social interactions rather than organically at the level of neurobiology. Psychobiology was not an aetiological psychiatry, in the sense of providing psychoanalytical mechanisms or Kraepelinian disease entities.

Meyer viewed mental activity and brain activity as a single biological response. Mental dysfunction, as much as brain disease, is a medical condition resulting from pathological processes. As far as Meyer was concerned, functional mental illnesses are failed adaptations, rather than distinct brain diseases. He was fond of calling a 'neurologizing tautology' any attempt to reduce mental illness to brain disease.

Meyer's ideas never really take hold as a systematic theory of psychiatry. This was partly because of his pragmatic compromising attitude. He was prepared to accommodate all perspectives in psychiatry even if he disagreed with them. He recognised this himself in a heartfelt note he wrote a few years before he died, saying, 'I should have made myself clear and in outspoken *opposition*, instead of a mild semblance of harmony'.¹²

George Engel's biopsychosocial model

George Engel's biopsychosocial model¹³ to integrate biological, psychological and social factors in medicine and psychiatry was a deliberate challenge to biomedical reductionism. Engel acknowledged the historical significance for his integrated and holistic model of the work of Adolf Meyer. He recognised the difficulties in overcoming the power of the prevailing biomedical structure, whose dogmatism he thought needed to be neutralised. As far as he was concerned, doctors had become insensitive to the personal problems of patients and were preoccupied with procedures. This was a crisis for the whole of medicine, not just psychiatry. An integrated understanding of the whole person, including emotional needs and life issues, forms the basis for patient-centred medicine.

The biopsychosocial model accepts the inherent uncertainty in psychiatric and medical practice. By contrast, the biomedical perspective seems to have an advantage because of its perceived potential for certainty in the understanding of mental disorder. The biopsychosocial model can be seen as too vague by comparison.

Further, the biopsychosocial model is often used in an eclectic way in current psychiatric practice. It is commonly said that biological, psychological and social must all be taken into account in psychiatric assessment, as though all three are more or less equally relevant in all cases and at all times. This ill-defined basis for practice may create theoretical inconsistency, such as viewing more minor psychological disorder as psychosocial, whereas more severe mental illness is identified as biological in origin. It may also lead to the combination of psychotherapy and biological treatments without any systematic theory to support such a strategy. This eclecticism has been critiqued¹⁴ and does seem to have outlived its usefulness.

In fact, Engel's original version of the biopsychosocial model was not eclectic and eclecticism has more to do with the mainstream response to anti-psychiatry.¹⁵ The conflict created by the split between biomedical and biopsychosocial models has encouraged the compromise of eclecticism to avoid ideological argument.

Conclusion

To be clear, critical psychiatry is encouraging the integration of mind and body, not their separation. The brain is the origin of the mind and minds are enabled but not reducible to brains. In other words, mental disorders show *through* the brain but not necessarily *in* the brain. Critical psychiatry argues that believing that functional mental illness is a brain disease is more like a faith that doctors are obliged to believe rather than a scientific position.

As demonstrated with three examples, this essential position of critical psychiatry has been expressed in the history of modern psychiatry. At the same time as Griesinger was steering psychiatry toward a positivist understanding of mental illness, Feuchtersleben based psychiatry on Kant's critical philosophy. Meyer's psychobiology provides a legitimate

theoretical framework for critical psychiatry, although any neo-Meyerian position must take into account Meyer's tendency to compromise and cannot simply be a restatement of his legacy. Engel's biopsychosocial model also provides a valid anti-reductionist position for critical psychiatry, although it should not be associated with the eclecticism it has come to acquire in current psychiatry.

In summary, critical psychiatry should not be seen as an embarrassing hangover from the 1970s. It can be understood as a non-eclectic, biopsychosocial, neo-Meyerian approach to psychiatry based on Kant's critical philosophy. This position should not be overly polarised in an argument against the biomedical model and recognises that other models, such as the psychodynamic and psychoanalytic, also emphasise psychic aspects. An integrated mind-brain understanding needs to be enriched by a biology that accepts the limitations of a mechanistic interpretation of mental illness and life in general. Critical psychiatry has relevance for modern psychiatry.

Abstract

The HCR-20 has taken on a life of its own. In forensic services it has been elevated from helpful aide-mémoire into a prophetic tool worthy of Nostradamus himself. Almost every outcome is interpreted through it. Despite the evidence of its limited utility, the difficulties of predicting rare events, the narrative fallacies and other heuristic biases it creates, and the massive opportunity costs it entails, commissioners and services alike mandate its use. Yet in routine practice the problems are not acknowledged, multiple conflicts of interest lie unobserved and other opportunities are neglected.

Violence risk assessment is a core part of forensic psychiatry. It has evolved from an unstructured clinical and anecdotal exercise, through the use of actuarial tools and is now dominated by a variety of structured professional judgement (SPJ) instruments. Of these the Historical Clinical Risk Management-20 (HCR-20) is pre-eminent. It has itself evolved: first published in 1995, it is now in its third iteration. Initially it was used as an aide-mémoire to assist clinicians and others to systematically assess what were believed to be risk factors for violence across time: historical (ten items), clinical and risk management (five each). In 2001 further materials were added, including scenario planning.

The HCR-20 is the most widely used violence risk assessment tool in the world,¹ and in the UK it has become the ubiquitous gold standard for the risk assessment of violence in forensic services. NHS England commissioners of secure services for forensic patients mandate an HCR-20 assessment, updated every 6 months, even when there is no history of violence. As can be the case with many expert judgements,² any outcome can be seen through its lens. In cases of disaster, ‘the HCR-20 was completed incorrectly’, ‘the recommendations were not followed’, ‘it was not updated on time’ and, most seriously, ‘there was no HCR-20’. When there is success then the merits of the risk assessment and assessor are praised. Fearing blame in the event of failure, my psychologist colleagues spend dozens of hours reading through volumes of notes and the outputs are so long as to be unreadable. Explanations of previous violence are formulated, estimates of risk made and future risk scenarios hypothesised. The tool is over-relied on to guide patient management through complex systems of care, a task it cannot achieve. Curiously, updates are frequently done after clinical decisions about management have been made. But the limitations are not acknowledged and they are legion. Some are relevant to violence risk in general and others specifically to SPJ tools and the HCR-20 in particular.

Limitations to SPJ tools

- There is no grade 1 randomised controlled trial (RCT) evidence for the effectiveness of SPJ tools in reducing violence; the only RCT tested the Short Term Assessment of Risk and Treatability (START) and gave a negative result.³
- Most items in structured risk assessment instruments, especially the Psychopathy Checklist –Revised (PCL-R), and many in the HCR-20 do not predict violence.⁴
- Random combinations of risk factors are as useful as those assembled in standardised instruments.⁵
- The HCR-20 ignores pertinent facts regarding the importance of adherence to specific drug treatments and risk.⁶
- The area under the curve (AUC) measure of utility bears very little relevance to use in clinical practice and ignores the difficulty of prediction when base rates are low.⁷ It is a concept rarely used in other areas of medical practice, where positive predictive value (PPV) is the usual measure.
- As with any attempt to predict rare events⁸ (p. 170) the PPV of the HCR-20, as with other risk tools, is poor and it produces many more false- than true-positive findings.⁹
- High-quality negative evidence regarding the utility of multiple risk tools is not noticed, is refuted and as yet has had no impact on commissioners or services.^{9,10}
- Intellectual and financial conflicts of interest in the publications on various SPJ tools are not mentioned.¹¹ Those who submit research papers on the HCR-20 and other risk instruments rarely, if ever, declare an interest in receiving fees from training in its use. Yet it is a ‘product’, like a pharmaceutical agent, and one for which they stand to gain financially if it is promoted. Similar conflicts may exist for those who conduct serious adverse incident reviews recommending improved use of risk assessment if this is also a service they provide on a commercial basis.
- The narrative explanations of risk formulations and future risk scenarios are accepted. They are not seen as rhetorical devices requiring empirical validation, unlikely to be correct in systems too complex for analysis. To make sense of the world humans require stories that examine concrete events, ignoring chance and the things that did not happen. Any recent salient event is a candidate to become the kernel of a narrative explanation.¹²
- Narratives combined with recent or high-profile events feed heuristic biases, including representativeness, availability and, most important, affect.^{13,14} In forensic services our patients have often violated basic human norms: rape, incest, murder, mutilation and losses of control.¹⁵ At times we will be disgusted. This is rarely acknowledged and instead there is a serious risk that an emotionally driven sense of disgust¹⁴ will result in the immediate generation of opinions for which the supporting evidence is subsequently found, with risk assessment becoming confused with the assessment of outrage¹⁶ and becoming a moral exercise.¹⁷
- Whatever our organisations may tell us, it feels as if there is only punishment for failure and so an increasing tendency to risk aversion is inevitable.¹⁸
- The definition of violence used in the HCR-20 is so broad (including verbal threats) as to be meaningless in the services we work in.

The consequences of ignoring these limitations

Ignoring these difficulties is not just a failure of a tool. It has enormous consequences for patients, professionals, the public and those who pay for our services. The patients we care for face prolonged detention and the opportunity cost of professional time that could be spent delivering interventions. The patients we do not care for face delays in accessing care, often untreated and in inadequate facilities in prison. As professionals we become preoccupied with avoiding failure instead of achieving improvement and it often feels like the risk that is being managed is the risk to ourselves and to, or even from, our organisations. An explicit analysis of risk will be an important part of a patient's treatment, but in the context of deficiencies in treatment and access to care, an HCR-20 will not protect us, or our organisations, from litigation or public criticism. Instead of trying to determine what the prospective risk is given the facts and the base rates, we anticipate how failure will be perceived in hindsight. Those that fund our services complain that too many are detained,¹⁹ while removing funding from objective research.²⁰ Inquires²¹ continue to recommend interventions that do not work – case management,²² risk assessment and community treatment orders²³ – and themselves can fuel narrative fallacies.²⁴ Through our overvalued ideas regarding risk assessment, forensic services are left caring for a tiny percentage of mentally disordered offenders, who we dare not part company with, and at vast expense.²⁵

What can we do?

The argument is not that risk assessments should be abandoned, only that we should be much more circumspect about their power, utility and explanatory value, and recognise how narratives may mislead as well as explain. This is now the position in the related field of suicide risk assessment. In stark contrast to the requirements for secure services and the use of the HCR-20, the National Institute for Health and Care Excellence (NICE) advice is: 'Do not use risk assessment tools and scales to predict future suicide or repetition of self-harm'²⁶ (p. 8), for the simple reason that we cannot stratify risk using the tools available. The information they provide regarding the likelihood of the outcomes we are really concerned about is of no practical use.²⁷ But it is very hard for systems to change and for professionals to give up their sincerely held beliefs. This is the case throughout medicine. It takes an average of 17 years to translate research findings into practice.²⁸ Although short structured assessments would be helpful, our attempts to stratify risk of violence are not useful and should be abandoned, as should narrative explanations of the past and hypothesising future scenarios. It is not particularly useful to say that a man who has been violent in the past might be violent in future if intoxicated, threatened, feeling disrespected or aggrieved, lost to follow-up, non-adherent to antipsychotic or mood stabilising medication and in contact with a vulnerable potential victim.

Some hope that technology will provide a solution. But it took the resources of Deep Mind's artificial intelligence (AI) capabilities, combined with a vast sample of over 700 000 patients, to develop a system to predict the highly specific outcome of acute kidney injury within the tight window of 48 h in highly monitored in-patient environments.²⁹ So why do we think that we can predict violent behaviour over timescales of weeks, let alone months or years, on the basis of human analysis, or that in future AI will be able to make longer-term predictions about far more complex human behaviours? Even if such analytic systems are developed, it is questionable whether clinicians, patients or the legal system would accept them. It is likely that highly discriminatory variables would be key factors in AI algorithms – gender, age, ethnicity, residence in a high crime area, peer group criminality – and there would be fears that the scenarios of *The Minority Report* would emerge.³⁰ Instead the approach adopted by NICE regarding suicide and self-harm should be taken, with the emphasis on the delivery of effective treatments, ensuring services are adequately resourced and developing better habits regarding quality.³¹

A hint of change?

A quick search using Google Trends shows that online interest in the HCR-20 has fallen dramatically, from a peak in September 2007 to date. The Gartner Hype Cycle,³² with its phases of a technology trigger, a peak of inflated expectations, a trough of disillusionment, a slope of enlightenment and then a final plateau of productivity, is held as an example of the boom, bust and then stabilisation of new technologies. But perhaps this is what is happening already?

Edward Silva is a consultant forensic psychiatrist at Ashworth Hospital, Mersey Care NHS Foundation Trust, Liverpool, UK. He has worked in secure services since 1998 and has been involved in the use of SPJ tools throughout as part of the routine clinical care of many detained patients.

1.3.36 A model for specific goals for in-patient treatment linked to resources and limitations in out-patient treatment

Virginia Davies¹

Correspondence

Virginia Davies

(virginia.davies@ouh.nhs.uk)

date

2020-12

Abstract

The author reflects on the Norwegian inpatient service descriptions contained in Wilkinson's article, considering the challenges laid out in his piece from the perspective of a child and adolescent psychiatrist working in a hospital crisis setting, as well as within the context of child and adolescent mental healthcare staffing across the UK.

Contents

- *A model for specific goals for in-patient treatment linked to resources and limitations in out-patient treatment*

As a paediatric liaison psychiatrist, I was dubious about how an article that concerns itself with goals for in-patient care would speak to my own experiences and practice. I need not have worried; Wilkinson's paper¹ is rich in reflections about the core issues at play in child and adolescent psychiatric practice and has relevance for all child and adolescent psychiatrists.

Wilkinson writes from the vantage points of retirement and from being 'over the water'. Having spent his working life practising in the well-funded healthcare system of Norway, he brings a huge amount of digested clinical encounter to his analysis of how in-patient services are most usefully oriented, around safety and the developing personality. He argues for two different types of in-patient unit, which might be considered as future service development objectives within the UK. Both rely on considerable expertise and stable staffing. His 'safety first' model requires most child and adolescent psychiatric expertise at the emergency and out-patient levels, with less direct psychiatric input during

¹

in-patient admission. He acknowledges that we are a long way from a point where we might manage this, but how far off are we?

In the UK, the number of consultant child and adolescent psychiatrists per head of child population is significantly, perhaps scandalously, lower than for other specialties. As of September 2019, provision ranged from 2.8 consultant child and adolescent psychiatrists per 100 000 children in Kent, Surrey and Sussex to a high of 10.7 per 100 000 children in North Central and East London. This compares with 29.3 consultant paediatricians per 100 000 children across England. Most UK general hospitals do not have not a single consultant child and adolescent psychiatrist in their employ. Accordingly, the majority of emergency departments catering for under-18s have no departmental consultant child and adolescent psychiatrist either.

Wilkinson's powerful charge really resonated with me for this reason: 'Why is it not expected that A&E departments should be catering for the second highest cause of mortality?' It is clear what he means by 'catering for'; he has earlier described using in-house 'child and adolescent psychiatry expertise'.

He notes the value of front door expertise: 'those with greater experience refer fewer patients for admission because of potential suicide'. Experienced staff also take less time to come to a decision and tend to provide greater psychological containment, be this in the care of a child with a perturbing mental health presentation or one with a serious physical ailment. Junior psychiatrists, emergency department staff of all grades, and patients and their families all know this. So why are we not stacking more experience to the fore as per Wilkinson's 'safety first' model?

In discussing why local in-patient work is so vital for the 'safety first' cohort, Wilkinson describes the task thus: 'It is not the axis 1 diagnosis which determines the need for admission, but the necessity of an alternative "containment" of the patient to that available at home. Two factors operate here: the state of the child and the processes at home.' Working in an emergency setting, a very large proportion of those we refer for admission fall into the second bracket. This is the reason I have watched the stripping back of family therapy provision within in-patient settings with a deal of dismay.

Wilkinson highlights the need for high and stable levels of staffing in the 'intensive' (24/7) units needed for the 'safety first' cohort. This brings us back to the central importance in recovery at any state or stage of relationships and attachment. How many of our child and adolescent in-patient units have 'a stable group of nurse therapists'? How many even have enough staff each shift? He comments on the reduced need for restraint and sedation in Norwegian units, an enviable outcome of such stable staffing.

Going on to consider the needs of a second cohort of patients, he describes how counterproductive it is to admit those with developing personality issues to the same type of unit as that used for the 'safety first' cohort. He proposes instead a weekday unit, with greater direct involvement by psychiatry, who are less directly involved in day-to-day patient care in the 24/7 'intensive' units. The benefit of a 5-day unit is the testing out and information gathering that can be garnered by weekends at home.

In the UK, psychiatric admission for those with personality issues is generally to the same unit as the 'safety first' cohort. The idea of the 24/5 unit, with its strong emphasis on attachment, trauma and loss, sounded like an extension of what our current dialectical behaviour therapy teams offer, but with the added containment for the rest of the system of not having responsibility for the child or young person during their most risky stages. Our 'ordinary' in-patient units already focus on axes 2–5. And I don't think most in-patient settings in their current form are failing to consider trauma and loss. But staffing issues are the real 'elephant in the room'. We have so much nursing 'churn' and such a paucity of senior staff capacity that both the intensive 24/7 unit model, with its reliance on stable nursing staff and high-level emergency and out-patient expertise, and the 24/5 'developing personality' unit model, with its reliance on intensive consultation and liaison with other agencies, especially social care, feel like impossible dreams for us here in the UK.

It would be easy to close by asking 'Please can I move to Norway?', but I suppose the challenge laid down to us in this paper is this: what can we do individually as citizens, or as a professional collective, to try to address this most gross injustice of utterly inadequate mental health services, emergency, out-patient and in-patient, for some of the most vulnerable members of our society?

Virginia Davies, MRCP, MRCGP, FRCPsych, is a Consultant in Paediatric Liaison in the South London and Maudsley National & Specialist CAMHS Paediatric Liaison Service at King's College Hospital Denmark Hill, London, UK.

1.3.37 Feasibility and utility of enhanced sleep management on in-patient psychiatry wards

Chloe Novak Emma Packer Alastair Paterson Ambrina Roshi Rosie Locke Patrick Keown Stuart Watson Kirstie N. Anderson

Correspondence

Kirstie N. Anderson

(kirstie.anderson@nuth.nhs.uk)

date

2020-12

Abstract

Aims and method

Sleep disturbance is common in psychiatry wards despite poor sleep worsening mental health. Contributory factors include the ward environment, frequent nightly checks on patients and sleep disorders including sleep apnoea. We evaluated the safety and feasibility of a package of measures to improve sleep across a mental health trust, including removing hourly checks when safe, sleep disorder screening and improving the ward environment.

Results

During the pilot there were no serious adverse events; 50% of in-patients were able to have protected overnight sleep. Hypnotic issuing decreased, and feedback from patients and staff was positive. It was possible to offer cognitive-behavioural therapy for insomnia to selected patients.

Clinical implications

Many psychiatry wards perform standardised, overnight checks, which are one cause of sleep disruption. A protected sleep period was safe and well-tolerated alongside education about sleep disturbance and mental health. Future research should evaluate personalised care rather than blanket observation policies.

Normal duration and timing of sleep is vital for mental and physical health and yet the majority of patients on a psychiatric ward experience sleep disturbance.¹ Sleep disturbance is an independent risk factor for suicide.^{2,3} Poor sleep is often attributed to the psychiatric disorder requiring in-patient treatment, but is also attributable to the ward environment. Noise, light and regular, typically hourly, overnight observations disturb patients independent of the psychiatric diagnosis.⁴ Primary sleep disorders, including obstructive sleep apnoea and restless legs syndrome, are increased in psychiatry patients and also disturb sleep.⁵ For a subgroup of patients, insomnia-specific cognitive-behavioural therapy can be effective within an acute psychiatry ward.⁶

Nursing observations are designed to enhance care and reduce risk, but may paradoxically increase sleep disturbance. To date, little research has focused on the effect of and need for regular overnight observations within psychiatry. Understandable concern about patient safety is one reason for frequent physical checks, despite no direct evidence that fixed timing checks reduces risk.^{7,8}

After review of current observation policy across a large mental health trust, a pilot scheme to enhance sleep was introduced (the SleepWell programme). This was a package including reduction of overnight noise and light, formal staff education about sleep and sleep disorders, a protected sleep period for those deemed safe and screening for sleep apnoea and restless legs syndrome for all in-patients. There was a service evaluation of adverse events, including harmful behaviours before and during the change in night-time observations, alongside detailed patient, staff and carer feedback over the assessment period. Cognitive-behavioural therapy for insomnia (CBTi) was made available to two of the seven wards that undertook the pilot. Issuing data of hypnotic medication was assessed before and during the pilot period.

Method

This was a service evaluation of a pilot scheme to enhance sleep and adjust overnight nursing policy. As such, formal ethical approval was not required, but the design, safety and existing trust operating procedures were reviewed before commencement, by the medical staff committee, the trust board and an existing trust safety programme ‘positive and safe’, which was aimed at reducing restrictive interventions while managing challenging or violent behaviour. Seven adult wards across one large mental health trust (Cumbria, Northumberland, Tyne and Wear NHS Foundation Trust) were used for the pilot. To ensure a range of patients they included a 16-bed male and two 16-bed female adult acute in-patient units based on two separate sites, a 26-bed long-stay rehabilitation unit with shared house, a 16-bed mixed neurorehabilitation ward, a 12-bed in-patient dementia service and an 18-bed psychiatric rehabilitation and recovery unit.

Staff training

Two designated staff representatives from each unit were identified as sleep leads to facilitate development and delivery of the necessary practice changes. Before implementation there was education about sleep and sleep disorders from K.N.A., and creation of an educational package labelled as SleepWell. The service evaluation was designed as a 6-month intervention, with 3 months to identify and educate sleep leads and then 3 months of the SleepWell programme in place with protected sleep during this time. Project supervision and clinical governance came within 'positive and safe', with monthly reports from all sleep leads.

Ward environment and protected sleep time

The ward environment was assessed for all pilot wards and all staff reported weekly during the 3-month pilot on night noise reduction measures. Eye masks and ear plugs were offered to all suitable patients. The trust estates department were involved for wards that required any adjustment to soft-closing bins and doors. Non-caffeinated drinks were offered to the patients in the evening. Set wake-up and bed times and reduction in large meals before bed was encouraged. An agreed addition to the assessment tool was developed to highlight those safe for protected sleep time after at least 72 h on the ward. This was set at 00.00–06.00 h. There was in addition screening for obstructive sleep apnoea, using the validated STOPbang screening questionnaire.⁹ A score of >3 indicates an >50% chance of having obstructive sleep apnoea. Screening for restless legs syndrome was undertaken with a single validated screening question with additional prompt to differentiate from drug-induced akathisia.¹⁰ The SleepWell pathway is shown in *Fig. 1*. This included asking all patients 'Is sleep a problem for you?'. On every pilot ward, information about the SleepWell project was displayed and all patients and carers were informed about the change in policy on admission (shown in Supplementary Appendix 1 available at <https://doi.org/10.1192/bjb.2020.30>). For those with persistent insomnia on two of the acute wards (with adequate and trained psychology provision), CBTi was offered on a weekly basis as a small group therapy and, following existing published protocols developed from the Oxford Ward Sleep Solution study, this is modified to allow for the in-patient setting and encompasses education about sleep, sleep hygiene, sleep scheduling and relaxation, but does not use sleep restriction.⁶ Fig. 1 SleepWell algorithm used on all wards. CBTi, cognitive-behavioural therapy; MDT, multidisciplinary team; SSRI, selective serotonin reuptake inhibitors.

Feedback and review of incidents and hypnotic prescribing

The quantity of hypnotics (zopiclone, temazepam, melatonin and promethazine) issued to each ward was examined across two time periods: January to March 2019 (the SleepWell pilot time period) and January to March 2018 (before the SleepWell intervention). The specific number of patients deemed safe for protected sleep time and the number who completed sleep disorder assessments were also recorded. Interviews with staff and patients across all wards provided feedback for qualitative analysis of the intervention. Incident rates are routinely recorded within the trust by incident report forms (IR1) via an electronic incident reporting system. The number and type were looked at during the time of the pilot and for a further 5 months after this period, and compared with a similar 8-month period before the SleepWell pilot. A comparison between incidents recorded over 24-hour periods and specifically during the protected sleep time was made. Ongoing review of the incident data continued after the service evaluation for an 8-month period in total, as all pilot wards elected to continue protected sleep time. No patient-identifiable data were used at any stage.

Results

Protected sleep time

After assessing those who needed more frequent observations for reasons of physical health or safety, an average of 50% of patients were able to have protected sleep time during their in-patient stay (range 44.3–60%); the data for the different wards is summarised in *Table 1*. The psychiatric rehabilitation and recovery ward was excluded from the data below because patients were not on hourly observations as standard, but instead had established protected sleep time of 00.00–07.00 h living within long-stay flats and houses. *Table 1* In-patients on the six wards during the 3 month SleepWell pilot where there was a change to night-time observations

Ward	Total number of patients on the ward	Number of patients on protected sleep	Percentage of patients on protected sleep
All wards combined	2501	1164	46.4%
Acute adult male	793	544	68.6%
Acute adult female	1201	260	21.6%
Acute adult female	2125	564	26.5%
Dementia service	105	50	47.6%
Neurorehabilitation	168	50	29.8%

Adverse events during protected sleep time

Incident data was compared between 1 January 2018 to 31 August 2018 and 1 January 2019 to 31 August 2019, which included the SleepWell protected sleep period. Far fewer incidents occurred at night in any of the different incident categories both in 2018 and 2019. No serious adverse event, suicide attempt or suicide occurred as a result of the overnight protected sleep period. The deaths that occurred were in-patients on the psychiatric rehabilitation and recovery and dementia wards and were attributed to an expected decline in physical health conditions. A single death occurred in an elderly patient overnight, but this was off-site in an acute medical ward and was attributable to perforated bowel. Across all seven pilot wards, the total number of patients absent without leave or absconding decreased during the SleepWell pilot. Serious incidents requiring security decreased and self-harm decreased during the night, although not during the day, as did inappropriate patient behaviour at night. Aggression and violence increased between 2018 and 2019, with most of the incidents reported on the male high-dependency unit (264 of 781 incidents). It should be noted that there was a trust-wide implementation of a no-smoking policy at the beginning of 2019, and an increase in aggression and agitation was noted (mostly related to wanting to smoke on the trust premises). The results are summarised in *Table 2*.

Adverse event	Number of incidents during 00.00–06.00 h	Jan–Aug 2018	Jan–Aug 2019
Aggression and violence	483	781	468
Absent without leave and absconded	173	174	43
Self-harm	156	193	26
Inappropriate patient behaviour	76	115	4
Substance use/misuse/prohibited items (excluding smoking)	54	103	6
Death	35	11	8
Security	87	76	65

Hypnotic issuing before and during the SleepWell pilot

Review of hypnotics use (*Table 3*) showed a 25% decrease in the quantity of hypnotics ordered to the wards during the SleepWell pilot period. There were specific decreases in zopiclone 7.5 mg and 3.75 mg tablets, promethazine hydrochloride 10 mg and 25 mg tablets and melatonin 2 mg modified release tablets. There was an increase in temazepam 10 mg and 20 mg tablets, but the total number of all prescriptions issued decreased. Specific ward issuing data highlighted that six of the seven wards ordered less hypnotics from pharmacy. *Table 3* Hypnotic issuing during the SleepWell pilot compared with a similar time period before the pilot

Drug description	Quantity of hypnotics issued	Jan 2018–Mar 2018	Jan 2019–Mar 2019
Zopiclone 7.50 mg tablets	796	421	21
Zopiclone 3.75 mg tablets	828	590	90
Promethazine hydrochloride 25 mg tablets	81	46	30
Promethazine hydrochloride 10 mg tablets	112	0	20
Temazepam 10 mg tablets	336	366	20
Temazepam 20 mg tablets	14	160	2
Melatonin 2 mg modified release tablets	278	240	7
Total	3178	2407	147

Sleep environment

The input from estates varied upon the different wards, but included blackout blinds and dimmer lights to ensure light levels throughout the night were kept to a minimum. Soft-closing doors were fitted on two wards. Loud-closing bins were identified and replaced. Eye masks and ear plugs were available on request for all wards. The Rehabilitation and Recovery Unit was structured in bungalows, with fewer noises and disturbances, and so little adaptation was therefore necessary. The volume of night nurse calls was reduced to a minimum and staff were encouraged to report any issues relating to noise/light promptly during weekly meetings.

Posters were put on walls to remind staff and patients about the need try to keep the noise levels to a minimum at night-time. Carers and staff were invited to feedback on changes and given information about sleep and sleep hygiene (included in the Supplementary Appendices).

Staff and patient feedback

Before

One key theme running throughout the feedback collected before the pilot was about the negative effect the ward environment had on patient sleep. The main environmental factors noted were noise, temperature, lighting, bedding and other patients.

After

Post-pilot feedback from ward staff was universally positive and many commented that the ward environment was more peaceful and settled. A focus on bed-time routines was perceived by staff as helping better sleep and, overall, this was well-supported by staff, although there was initial anxiety before implementation about not checking on patients and assessing risk caused some disagreement about which patients were safe to go onto protected sleep. More standardised sleep assessments were not possible within the framework of a service evaluation primarily assessing safety and feasibility. Making this a documented, multidisciplinary team decision helped to reassure staff alongside involving the night coordinators.

Patients who did comment preferred being on protected sleep time: some did not notice a difference and had not been woken, but others expressed feeling safer without people looking into the room, and those who had been readmitted described it as better than previous admissions. All carers were positive about the intervention, with none asking for more frequent observations to be restarted. No patients or carers had concerns about the protected sleep time. All in-patients were asked about the SleepWell programme and typical comments from patients from all of the wards are summarised in Supplementary Appendix 2 but included 'better than last admission', 'I feel safer now' and 'I don't worry about people looking into my room on a night'.

Screening for sleep disorders

The numbers documented as screened were small on the acute wards despite encouragement throughout the period of SleepWell. A total of 39 out of 125 and 37 out of 79 patients were assessed for obstructive sleep apnoea and restless legs syndrome on the acute adult wards, respectively, with nine positive screens for obstructive sleep apnoea (STOPbang score >3). Using the screening tools, no sleep disorders were identified on the rehabilitation wards or the dementia unit.

CBTi

CBTi was implemented on two adult acute wards (one male and one female), with 25 patients assessed as suitable based on length of stay, problematic insomnia and ability to attend therapy. Thirteen (52%) then accepted therapy and attended at least four sessions.

A total of 85 admissions came to the two wards during the 3-month assessment period; only 27 were suitable and approached, 18 accepted and 13 completed. The majority not suitable were either transferred or due for imminent discharge, but 15 had decline in mental state and were unable to engage in therapy. All treated had either paranoid schizophrenia, psychosis or depressive disorder, reflecting the typical case mix of the two wards. Mean insomnia severity index before treatment was 18 (range 6–28), and completion insomnia severity index was 14 (range 6–16).

Discussion

In this pilot study, a protected sleep time and improved education around sleep were safely incorporated into a personalised care plan for adult psychiatric in-patients. There were no serious adverse events or deaths related to the change in policy, ward demands for hypnotics were reduced and both staff and patient feedback was positive.

For psychiatry patients, sleep disturbance is an independent risk factor for suicide,^{2,3} and has been shown to independently predict lower quality of life, higher symptom severity and less benefit from treatment, with Kallestad et al suggesting that sleep should be seen as a 'stand-alone therapeutic entity, rather than an epi-phenomenon of existing diagnoses'.¹¹ However, there have been few systematic studies of the factors that adversely affect sleep on in-patient units. A large, questionnaire-based survey showed 66% of in-patients had poor sleep quality independent of gender or diagnosis.¹ Previous work from our acute in-patient, psychiatry wards demonstrated high levels of objective sleep disturbance and suggested that a number of environmental factors within the ward, including noise levels at night and hourly observations, were disruptive and therefore paradoxically may be worsening mental health and delaying recovery.⁴ Measures to stabilise sleep by using a high-intensity, modified version of CBTi has been shown to be possible and highly effective in acute psychiatry in-patients,⁶ although it was carried out maintaining overnight hourly observations.

The need to protect sleep as part of treatment has to be set against the importance of a safe level of observations for those at high risk of harm from mental or physical health problems. The National Institute for Health and Care Excellence guidelines define various levels of observation determined by a risk assessment, especially for severe self-harm, suicide, violence and absconding.¹² Within physical health units, this initial assessment is rapidly followed by a personalised care plan, allowing for a step down to a protected sleep period where possible. This is shown to balance prevention of acute physical health deterioration with a minimum of intrusive night-time observations. The National Institute for Health and Care Excellence defined the purpose of observation as to 'provide a period of safety... with observation levels set at the least restrictive level, for the least amount of time'.¹²

With specific regard to suicide risk, sleep deprivation owing to frequent checks may still be justified if it can be shown to reduce the frequency of suicide or severe self-harm. However, 91% of those who commit suicide do so while under intermittent observation,¹³ and the most recent review from the National Confidential Enquiry into Suicide⁸ emphasised the avoidance of routine, non-personalised checklists. A recent review of the timing of suicide data highlighted a far lower risk of suicide occurring overnight during the night periods of 23.00–07.00 h⁷ and challenged the perceived benefit of frequent observations. Despite these recommendations, frequent and typically hourly checks throughout the night remain widespread across acute mental health trusts throughout the UK.

Psychiatric nursing observations remain fundamental to the emotional and physical support of the patient, and current guidelines advise 'minimising the extent to which patients feel they are under surveillance, while encouraging communication, listening, and conveying to the patient that they are valued and cared for'.^{13,14} This guidance is somewhat in contrast to typical night-time observations, which require the staff member to clearly see the patient is breathing. This can involve opening the window hatch in the door or entering the bedroom and shining a torch on the patient's face, switching on a light or physically waking the patient.¹⁵ Patient and staff feedback highlighted complaints about the intrusive nature of checks and dislike of the observation policy. During the pilot, support for nursing staff was vital so that staff felt protected and supported to change a policy that might expose them to criticism. In practice, only

50% of patients were deemed safe to be placed on protected sleep, with others requiring more regular observation and input for physical or mental health needs. This still allowed a greater level of necessary engagement for night staff for patients requiring more support or observation for their safety. However, the detailed work required to reassure staff before implementing the policy took an average of 3 months alongside the monthly meetings during the project. It is of note that all wards elected to continue the protected sleep period after the initial service evaluation.

A wide range of incident data is collected across the trust, and the main aim of the pilot was to use this data to show that serious adverse physical or mental health events were not increased in those on protected sleep time, and that there were no serious adverse events in those patients on protected sleep as an important safety measure. It would remain important to have ongoing monitoring of safety for those on protected sleep time and a flexible protocol that allows for any patient to have increased frequency of observation if there was clinical concern. Longer-term assessments would be required to assess for a consistent change in behaviour or any sustained improvements in night-time agitation.

High rates of obstructive sleep apnoea are found in those with severe mental illness, with a prevalence of 25% reported across all psychiatric disorders and the highest frequencies seen in major depressive disorder.^{5,16} Risk factors for obstructive sleep apnoea include male gender, age >55 years, reports of sleepiness and obesity and the STOPbang questionnaire has recently been validated as an effective screening tool in the psychiatric population.¹⁷ An in-patient admission is an opportunity to assess physical health, with increasing recognition of the poor cardiometabolic health of many patients with psychiatric disease.¹⁸ Obstructive sleep apnoea screening should ideally be part of this screening or at least considered as a modifiable cause of poor sleep. Use of the STOPbang questionnaire in our pilot remained challenging, with small numbers of STOPbang scores recorded in records. This may reflect acutely unwell patients or the number of other assessments also required for this group; however, those who were screened were often at risk, which allowed further investigation and lifestyle advice.

Hypnotics carry a risk of diversion and respiratory depression in overdose. Those issued hypnotics while on a psychiatry ward in the UK will typically remain on them at discharge, with a substantial percentage still using them at 12 months.¹⁹ A recent review of the side-effects and benefits of a range of hypnotics highlights the limited evidence base of antihistamines in particular, and the potential for dependency. There is also a falls risk in the elderly.²⁰ The total number of hypnotics issued to the wards decreased by 25% during the 3-month pilot period. This may reflect some hypnotic prescribing being partly attributable to a noisy environment and the observations themselves. However, the analysis did not include patient-level data, so future work would be needed to look at individual prescriptions over longer periods of time. The change in prescribing may also reflect increased knowledge of non-pharmacological strategies to manage poor sleep and the improved ward environment.

There are several limitations to this small study. Standardised sleep assessments were not undertaken, partly because of the variable ward populations and need to assess initial feasibility of protected sleep time. It was not possible to assess any effect on duration of in-patient stay or whether different mental health diagnoses were more or less able to have protected sleep time. Although a small number were able to have CBTi, many were excluded because of short-stay rehabilitation, highlighting the need to communicate to community teams for follow-up therapy. No cases of restless legs syndrome were detected, which likely reflects the lack of recognition of this syndrome and the need for more training. This pilot was designed to evaluate patient safety first and foremost, but a future, much larger trust-wide research study is underway to address patient-level data regarding diagnoses, patient-level prescribing data and patient stay for those on protected sleep time compared with those not on protected sleep time. Although some categories of incident increased, including aggression, this was felt to relate to factors outside of SleepWell, including the particular patient group on the high-dependency male rehabilitation ward and the implementation of the trust-wide smoking ban. It should be noted that even within this increase, far few incidents of any type occurred during the 00.00–06.00 h time window.

In summary, this is the first pilot trial within a UK adult psychiatry unit to formally evaluate the feasibility and safety of a protected sleep period. A trust wide review of the observation policy is now underway, but any personalised care plan for a patient should include an evaluation of the patient's sleep. Improving and stabilising sleep disturbance should be part of routine in-patient psychiatric care, with a personalised assessment of the risk versus the benefit of waking the patient at night.²¹

Award-winning investigative journalist Robert Kolker follows the success of *Lost Girls* with the incredible story of the Galvin family and the impact of schizophrenia on their lives.

Kolker follows the story of Don and Mimi Galvin who, along with their 12 children, represented the ‘perfect all-American family’ – that is until 6 of their sons developed schizophrenia. After a whistle-stop tour of the history of psychology and psychiatry, Kolker deftly navigates us from the first Galvin brother’s diagnosis in the 1960s through many pharmacological, genetic and psychological advances right up to our present-day understanding of schizophrenia. The book examines the conflicts within psychiatry over the years, poignantly portraying a family lost in the gulf of a speciality at war with itself.

Kolker deals sensitively and compassionately with the more challenging themes of sexual abuse, suicide and even murder, presenting the differing experiences of many of the family members in a thoughtful and considered way. A real strength of this book is that it also considers the experiences of ‘well’ family members, whose lives are so affected by their brothers’ illness. The hero of this story is undoubtedly Mimi Galvin: dismissed early on as the typical ‘schizophrenogenic mother’, she provides a lesson in love, loss and resilience and reminds us of the lengths to which a mother will go to protect her family.

Despite being marketed to the general public, the skilful mix of scientific detail coupled with engaging storytelling makes this book essential reading, particularly for psychiatry trainees. In addition to its clear educational value, for me this book served as a reminder of the importance of compassion in our services – not only to the patients themselves but to all those involved in their care.

You need look no further than the acknowledgements section to see the time, effort and genuine care that went into putting this story together with the help of the remaining Galvin family members. I believe this is something that, as psychiatrists, we can also bring to assembling and understanding our own patients’ stories.

1.3.38 Police involvement, characteristics and outcomes of place of safety referrals in the Scottish Highlands

Struan Simpson Jude Eze¹

Correspondence

Struan Simpson (struan.simpson@nhs.net)

date

2020-12

Abstract**Aims and method**

To characterise police involvement with those detained under place of safety legislation and determine factors associated with admission to hospital. Place of safety referrals over a 1-year period were identified retrospectively and evaluated.

¹ **Declaration of interest:** None.

Results

Place of safety legislation is generally used with regard to concerns about suicide. Individuals are often removed from high-risk areas and referrals to police are frequently initiated by individuals themselves. A diagnosis of mental illness or personality disorder predicted hospital admission. Presence of senior nursing staff at assessment, but not the seniority of the doctor, was associated with discharge.

Clinical implications

Closer multiagency working is required as police are currently being recruited to fill a void between mental health services and the population they serve. Junior doctors require more senior support in making complex, and often risky, emergency management decisions with this population.

Place of safety legislation permits police officers to remove individuals thought to be mentally disordered and in need of immediate mental health assessment to a facility where this assessment can be carried out. Such legislation exists in many countries, including the UK,^{1,2} Germany,³ South Africa,⁴ Australia⁵ and the USA.⁶ Powers and legislation vary between and within countries but in general police must suspect a mental disorder *and* perceive significant, acute or serious risk of danger or harm to the individual concerned or to others in order to permit removal to a place of safety. In Scotland this power is detailed under section 297 of the Mental Health (Care and Treatment) (Scotland) Act 2003¹ (this detention lasts for up to 24 h or until the individual has been assessed); similar powers in England and Wales are under section 136 of the Mental Health Act 1983.²

There have been efforts to reduce use of police stations as a place of safety, reduce overall use of the legislation and improve knowledge of the legislation.^{7–9} Practice, however, remains variable across Scotland¹⁰ and the rest of the UK.^{11,12} In Scotland the use of this legislation is rising, with 795 detentions in 2015–2016, up from 130 in 2006–2007.¹⁰

There is reasonable reporting of place of safety use and the characteristics of those subject to the legislation^{1,5,13–15} but little is known about the nature of police involvement and which factors, if any, are associated with hospital admission. This study in the Scottish Highlands aimed to characterise the nature of police involvement with those detained under place of safety legislation, the demographics of this population and aspects of the assessment process to determine factors that might be associated with admission.

Method

We conducted a retrospective study by review of medical case records, including Place of Safety forms (POS1, v7.0) completed by police constables, of all individuals brought under place of safety legislation to New Craigs Hospital, Inverness in the NHS Highland region (the designated place of safety for the NHS Highland health board) between April 2016 and March 2017. All place of safety referrals were included in the project, including repeat detentions for any one individual. Individuals who were already in-patients when the place of safety legislation was applied were excluded from the analyses regarding admission to hospital.

Referrals were identified by collecting POS1 forms from the medical records department and cross-referencing with a place of safety referral record sheet in the intensive psychiatric care unit (IPCU), which is where most place of safety referrals are assessed. The junior doctor's assessment book and mental health assessment team's diary were also consulted to ensure that as many place of safety referrals as possible were identified. In an attempt to determine completeness of these records the Mental Welfare Commission for Scotland was contacted. Information about the assessment team's wider activity was gained from their team diary, which is updated reliably after each assessment. The POS1 form completed by police is not statutory and therefore any referral identified in case notes as being under place of safety legislation was included.

The POS1 form has an open text box to give details of the 'circumstances giving rise to the removal of the aforementioned person to a place of safety.' In all cases where a POS1 form was available this information was qualitatively analysed to characterise the nature of police involvement, the reasons for concerns and the reasons for the decisions made. Diagnosis was determined from clinical records and kept to broad ICD-10 diagnostic categories; more than one diagnosis was permitted, for example comorbid substance misuse and personality disorder. Diagnoses were often already established from clinical records rather than being based on the single urgent assessment.

Population data for calculating rates of referral are from census data from National Records of Scotland, a non-ministerial government department charged with collecting information about Scotland's people and history.¹⁶

The project was part of service development and audit and therefore did not require ethical approval.

Statistical analysis

Statistical analyses were performed using Minitab 17.1.0 and SPSS 22.0 statistical software, both for Windows. The association between categorical and outcome variables was assessed using Pearson ²-tests; where the cell count was low the likelihood-ratio chi-squared test was used. For continuous variables, Student's *t*-tests were performed. Given repeated referrals of some individuals, multivariable binary logistic mixed-effects regression was performed to predict admission using individuals as the random effect in order to account for individual-specific effect and control for the fixed effects of age, gender, diagnosis and distance from place of safety on detention. Robust estimation procedure was used to obtain the estimate of covariance matrix in order to ensure that model assumptions were met. Estimates of effects are presented as odds ratios (OR) and 95% confidence intervals (CI). The level of significance was set at $P < 0.05$.

Results

We identified 237 place of safety referrals over the 1-year study period. Of these, 97% ($n = 231$) were recorded on the place of safety record form in the hospital IPCU and 99% ($n = 234$) had a completed POS1 form. The yearly referral rate under place of safety legislation for the health board was 74 per 100 000 population (NHS Highland serves about 320 000 people and is sparsely populated, covering an area of 32 500 km²: around a quarter of this population live in Inverness and surrounding areas). The referrals were for 185 different individuals, with 30 (16%) being brought on more than one occasion over the study period (the highest number was five referrals, which occurred for three individuals).

Time variation in place of safety referrals

The rate of referral was similar throughout the year and did not vary by month ($\chi^2 = 12.06$, $P = 0.359$) or day of the week ($\chi^2 = 4.63$, $P = 0.592$). Detention under place of safety legislation was most likely to occur between 12.00 h and 17.00 h and least likely between 06.00 h and 12.00 h ($\chi^2 = 48.81$, $P < 0.001$), however no particular time of detention was associated with admission to hospital ($\chi^2 = 6.99$, $P = 0.221$).

Characteristics and outcome of individuals referred

The characteristics and outcomes of place of safety referrals are detailed in *Table 1* (analysis of 230 referrals). The admission rate overall was 33% ($n = 75$), with only 15% ($n = 11$) of those admitted being involuntarily under the Mental Health (Care and Treatment) (Scotland) Act 2003. The admission rate for those brought on place of safety legislation is not significantly different from the admission rate for those seen by the assessment team referred from other sources, i.e. referred by health professionals not police ($\chi^2 = 0.41$, $P = 0.521$); 79% ($n = 182$) of those referred had at least one previous contact with local mental health services. *Table 1* Characteristics and outcomes of place of safety referral

Measure	All	Admitted	Not admitted	P

Where individuals were not admitted most were discharged to their own home or in care of friends/family ($n = 136/155$, 88%); in a small number of cases individuals were taken into police custody ($n = 6$, 4%) or transferred for medical care in the local general hospital ($n = 7$, 5%).

It is local policy for place of safety referral assessments, where possible, to be performed by two assessors. All place of safety referrals were seen by a doctor (of various grades but generally junior doctors in training up to CT3 grade; in only one case was assessment by a consultant) and most with a senior assessment nurse present ($n = 198$, 86%) – where senior assessment nurses were not available, doctors completed assessments with ward nursing or auxiliary staff or alone. There was a high degree of variability in admission rates, with a median of 29% (IQR = 39, range 0–100), but this was not influenced by the training grade of the doctor ($\chi^2 = 1.60$, $P = 0.809$). The presence of a senior assessment nurse was associated with patients not being admitted following assessment ($\chi^2 = 4.98$, $P = 0.026$).

Admission was less likely for individuals where it was thought difficulties were related to substance misuse ($\chi^2 = 9.88$, $P = 0.003$), social stress ($\chi^2 = 14.18$, $P < 0.001$) or if there was felt to be no evidence of mental illness ($\chi^2 = 6.43$, $P = 0.011$). A personality disorder diagnosis was proportionately more common in those admitted following assessment but not significantly so ($\chi^2 = 1.57$, $P = 0.209$). Diagnoses of non-affective psychotic disorders ($\chi^2 = 16.07$, $P < 0.001$) and affective disorders ($\chi^2 = 4.55$, $P = 0.033$) were more prevalent in individuals admitted following assessment.

Most of the place of safety referrals were from the local area, with 67% ($n = 154$) from within 5 miles of the hospital – this gives a yearly referral rate of 248 per 100 000 population for Inverness. The number of referrals reduces with increasing distance from the hospital but as distance from hospital increases admission is more likely ($\chi^2 = 11.87$,

² Excludes individuals who left the hospital during an in-patient stay and were returned by police under place of safety legislation.

³ Diagnosis obtained from assessment/discharge letters and kept in broad diagnostic categories, more than one diagnosis was permitted owing to frequent comorbidity, e.g. personality disorder and substance misuse.

⁴ Also known as learning disability in UK health services.

⁵ It was not possible to determine the location of detention in 12% ($n = 27$) of referrals from the Place of Safety (POS1) forms.

$P = 0.018$). The prevalence of substance misuse diagnoses reduces with increasing distance from the hospital ($\chi^2 = 12.18$, $P = 0.016$).

If individuals were admitted to hospital the median length of stay was 6 nights (IQR = 22, range 0–136). Significantly shorter admissions were seen for individuals who had a substance misuse diagnosis ($\chi^2 = 11.32$, $P = 0.023$). No other diagnoses were associated with the length of admission.

Nature of police involvement from POS1 forms

Police were alerted to individuals subsequently detained on place of safety legislation in a variety of ways (Fig. 1). Usually the alert came from concerned friends or family members (26%, $n = 62/234$), but it was also common for individuals to make themselves known to police (23%, $n = 53$), usually by telephone (15%, $n = 34$) but in some instances by walking into police stations (7%, $n = 16$). Fig. 1 How police were alerted to individuals subsequently detained under the Mental Health (Care and Treatment) (Scotland) Act 2003 (total $n = 234$). Self-contact included presentation to a police station, telephoning police or approaching police in the street. Professional report was concern raised by health professionals or mental health support agencies such as Breathing Space. In some cases it was not clear from the Place of Safety (POS1) form details how the police had been alerted.

The most common reason cited for police being involved was expression of suicidal ideation (73%, $n = 167/230$) (Table 2); 28% ($n = 65$) of individuals had made a gesture towards suicide (e.g. holding knife at their throat or being at a risky area on a bridge), and only 7% ($n = 17$) had made an attempt on their life (e.g. cut at their throat or removed from river after jumping in). Voicing suicidal ideation ($\chi^2 = 23.58$, $P < 0.001$), making a suicidal gesture ($\chi^2 = 5.45$, $P = 0.020$) and making an attempt on their life ($\chi^2 = 4.43$, $P = 0.035$) were all associated with not being admitted to hospital. Table 2 Qualitative analysis of Place of Safety (POS1) forms for place of safety referrals a Details recorded on POS1 forms All b ($n = 230$) Admitted ($n = 75$) Not admitted ($n = 155$) P Descriptors of harm to self, n (%) Voiced suicidal ideation 167 (73) 40 (53) 127 (82) <0.001 Had made suicidal gesture 65 (28) 14 (19) 51 (33) 0.020 Had made suicide attempt 17 (7) 2 (3) 15 (10) 0.035 Voiced intent to self-harm 24 (10) 4 (5) 20 (13) 0.057 Had performed self-harm 17 (7) 2 (3) 15 (10) 0.035 Police noted previous suicide attempt 20 (9) 5 (7) 15 (10) 0.413 Other descriptors, n (%) Precipitating events, e.g. break-up/debts 28 (12) 4 (5) 24 (15) 0.027 Anxiety 4 (2) 2 (3) 2 (1) 0.454 Depression/low mood 16 (7) 3 (4) 13 (8) 0.220 Odd beliefs, perceptual disturbance, paranoia 34 (15) 18 (24) 16 (10) 0.006 Agitation/emotional/strange behaviours 38 (17) 17 (23) 21 (13) 0.081 Expressed intent to harm others 3 (1) 1 (1) 2 (1) – Location of detention under place of safety legislation, n (%) Public minor road 56 (24) 18 (24) 38 (25) 0.932 High-risk area, e.g. bridge/major road 39 (17) 12 (16) 27 (17) 0.788 Inside public building 31 (13) 12 (16) 19 (12) 0.436 Directly outside own home 21 (9) 9 (12) 12 (8) 0.293 Inside own home 15 (7) 2 (3) 13 (8) 0.100 Within hospital grounds 5 (2) 2 (3) 3 (2) 0.721 Rural area, e.g. woodland 6 (3) 1 (1) 5 (3) 0.371 Unclear 57 (25) 19 (25) 38 (25) 0.893⁶⁷

In only a small proportion of referrals did police give information beyond that focusing on suicidality. Of note, there was infrequent recording of the events that led to the individual now experiencing difficulties. Where this was detailed it was usually brief and a social stressor (e.g. split from partner or financial concerns) – in cases where a stressor was identified (by police) individuals were usually not admitted ($\chi^2 = 4.87$, $P = 0.027$). Police did report details about odd beliefs, paranoia or perceptual disturbances (e.g. hearing voices or responding to unseen stimuli) in 34 referrals (15%) – this was associated with admission to hospital ($\chi^2 = 7.51$, $P = 0.006$) and with non-affective psychotic disorder diagnoses ($\chi^2 = 4.85$, $P = 0.028$). In the small number of referrals in which police described behaviours (outwith the suicidal acts/gestures), these descriptions were often very general and would not necessarily be related to mental ill

⁶ POS1 forms were available for 227 of the 230 referrals.

⁷

Excludes individuals who left the hospital during an in-patient stay and were returned by police under place of safety legislation.

health, for example ‘highly emotional’, ‘acting in a strange manner’, ‘agitated’, ‘shouting nonsense’, ‘unpredictable’ or ‘hysterical.’

Police were called to a range of areas in response to concerns for individuals subsequently detained under place of safety legislation (*Table 2*). The location from which individuals were removed was not associated with subsequent admission to hospital even when removal was from high-risk areas such as bridges or major roads ($\chi^2 = 0.07$, $P = 0.788$). In 7% of cases ($n = 15/230$) it appeared that individuals had been removed from their own home, which is not permitted under place of safety legislation in Scotland.¹

Multivariable binary logistic mixed-effects model

When controlled for age, gender and distance from the place of safety (i.e. the hospital) in a multivariable binary logistic mixed-effects regression with individuals as the random effect, the odds of admission were significantly higher for diagnosis of non-affective psychotic disorder (OR = 32.93, 95% CI 4.33–250.17, $P = 0.001$), affective disorder (OR = 15.13, 95% CI 2.15–106.61, $P = 0.007$), anxiety and stress disorder (OR = 7.01, 95% CI 1.21–40.93, $P = 0.037$), intellectual disability (OR = 17.58, 95% CI 2.32–130.02, $P = 0.007$) and personality disorder (OR = 5.49, 95% CI 1.21–24.86, $P = 0.027$) relative to those without a diagnosis of mental illness. Substance misuse was not significantly associated with admission (OR = 2.78, 95% CI 0.64–12.08, $P = 0.170$). Although not statistically significant, the individual’s age was positively associated with admission and the odds of admission were higher for women than men. Also, odds of admission increased with distance from the place of safety – the farther the distance the higher the odds of admission. The use of individuals as the random effect ensures that extra-individual variations resulting from repeat referrals are adjusted for and this is evidenced in the size of the confidence intervals of the estimates.

Discussion

Place of safety referrals constitute a significant proportion of urgent mental health assessments within the NHS Highland region – up to one-third of assessments within the study hospital. The recording of these referrals in the hospital appears to be reliable and numbers are in keeping with data from the Mental Welfare Commission for Scotland.¹⁰ NHS Highland accounts for perhaps up to 20% of all place of safety referrals in Scotland;⁸ this is proportionately lower than a local study 10 years ago, when up to 50% were in the NHS Highland health board.^{7,8} However, it is of note that in the current study almost 70% of place of safety referrals occurred within a few miles of the designated place of safety. This is unlikely to be simply due to population factors despite the place of safety being located in Inverness. The place of safety referral rate per year for Inverness is 248 per 100 000 – over 10 times the rate for Scotland as a whole and 3 times that for the health board with the highest referral rate in Scotland.¹⁰ Under-reporting in some Scottish health boards is likely to contribute to this variation but does not fully explain the vast differences. Looking more broadly, this referral rate is also significantly higher than in studies in England, where rates are reported between 59.8 per 100 000 in the North-East¹² and 169 per 100 000 in Ipswich, Suffolk.¹¹ There appears to be excessive use of this restrictive legislation in Inverness – factors driving this are likely to be poorer joint working, workload pressures and a lack of availability of alternative options of disposal/help for those in crisis. There are a striking number of referrals where individuals have sought help from police rather than from local mental health services. This supports the proposal in a recent Mental Welfare Commission for Scotland place of safety report that there is a gap between service provision and the needs of this distressed population.¹⁰

Police are responding to distressed individuals in a range of locations, from their own home to high-risk situations on major roads or high bridges. Where place of safety legislation is used, this is overwhelmingly in response to concerns about suicide risk. This study does show that police do well in identifying those in need of mental health support – the admission rate of police referrals is identical to that from other sources and they detail evidence of psychosis on their referrals. The language used by police in describing behaviours includes terms such as ‘highly emotional’ and ‘hysterical’ – these are commonly used terms but could be stigmatising for those with mental health difficulties. Targeted training and support for officers may well improve their interaction with distressed individuals and make involvement with police a less daunting experience for those with mental health problems.

The characteristics of those referred under place of safety legislation in the Scottish Highlands are similar to those reported elsewhere in terms of age, gender and outcome.^{11,13,14} However, in this study substance misuse problems

are possibly more prevalent and were felt to be contributing to presentation in almost 50% of referrals whereas the proportion of severe mental illness is probably slightly lower.^{6,14} The compulsory admission rate is significantly lower (15%, compared with up to 50%) than in other reports, likely reflective of the lower proportion of individuals with severe mental illness.^{11,13}

This study identified that presence of senior nurses influenced outcomes of assessments and recognised that there is significant variability in admission rates by doctors at all training grades. It is therefore important to ensure that experienced staff are conducting assessments and consideration should be given to a model that ensures multidisciplinary input such as that used in England and Wales,² where approved mental health professionals (AMHPs) support the assessment process, including follow-up care arrangements for those not admitted. Further, with evidence in Scotland that trainees are doing fewer emergency assessments,^{17,18} ensuring that trainees are well supported by senior medical staff in completing these assessments is crucial.

Predicting outcomes and length of hospital stay

Predicting outcome of assessments is challenging given the nature of any mental health crisis, as difficulties are very individualised. However, diagnosis appears to be a primary factor in the decision-making process. In general, where referrals are identified as being related to primarily social stressors or substance misuse problems admission to hospital is avoided or, where felt necessary, kept as short as possible. A diagnosis of severe mental illness was associated with admission but not any particular length of admission, and perhaps in some cases a short admission plays a containing role rather than being for treatment itself when individuals are presenting via police. Personality disorder diagnosis was associated with admission to hospital despite extensive local training, resource and a new integrated care pathway which states that admission for those with personality disorder is ‘at best neutral and at worst harmful’.¹⁹ It is likely that a combination of factors influence the decision to admit – those with personality disorder diagnoses may be in a high degree of crisis that cannot always be de-escalated over a single assessment and may be thought of as being at high acute risk of suicide, given their language, circumstances, social supports or expression of plans for suicide following assessment if they leave the place of safety. In addition, they may be displaying ‘pseudopsychotic’ phenomena that are felt to require admission for further assessment. In this context the seniority and experience of the assessing team is also likely to be important.

If individuals were detained further from the place of safety, admission was more likely – this is probably related to service provision in more rural areas, i.e. lack of crisis response teams as well as practicalities in supporting discharge to more rural areas in the evenings and overnight.

Expression of suicidality or self-harm in itself is not helpful in determining outcome, although it is an important factor in decision-making and risk assessment/management. Given that suicidal expression is actually associated with not being admitted, it may be that in such circumstances services could offer alternative interventions or supports (to police and individuals) to avoid use of legislation and the ‘frightening’ experience of being detained under place of safety legislation.²⁰ Future studies exploring outcomes and service use in those with suicidality not admitted would be helpful in guiding service development and delivery.

Strengths and limitations

This study has a lengthy period of data collection and a relatively large sample. This makes it similar to other studies in this field, which helps to allow any variation/patterns to be identified. Characteristics of the population are also similar to those reported elsewhere. This is the first study to analyse the nature of police involvement and link this with outcome of the mental health assessment. Efforts were made to ensure that all recognised place of safety referrals, especially those with completed POS1 forms, were identified over the study period – unfortunately, despite being contacted the Mental Welfare Commission for Scotland did not provide information to cross-reference those included in the project, which would strengthen the data-set. However, given the multiple sources and communications systems within the hospital and across the health board we are confident that the majority of place of safety referrals were identified. The study was carried out retrospectively, which limits the information available. Given the retrospective nature and use of a clinical cohort, diagnostic categories were kept broad and thus open to a degree of interpretation. However, the decisions and diagnoses made reflect day-to-day practice and thus findings are clinically informative.

Improving practice

When individuals are brought by police to a place of safety it is important to complete an individualised assessment. Diagnosis is an important factor in the decision-making process and practitioners should remember that individuals not expressing suicidal ideation also have a significant mental health burden and may require admission. Experienced practitioners should be involved in multidisciplinary assessment where possible and it is crucial that junior medical staff are well supported by senior colleagues in making decisions.

Police are frequently responding to mental health crises and seem to do well in identifying those in need of urgent service contact. Training would likely improve knowledge and interaction between service users and police²¹ but is unlikely to have a major impact on the use of legislation or characteristics of those referred.^{6,14,20} Street triage services where police work more closely with mental health services (via telephone or in mobile units) are becoming established across the UK and are positively received by police officers.²² Recent systematic reviews highlight that there is a suggestion of positive outcomes such as reduced referrals and use of police jurisdiction²³ but there remains limited robust evidence of efficacy and a lack of clarity on the best model for services.²²⁻²⁴

Ultimately this study identifies a breakdown between mental health services and those who require support, with police being recruited to fill the void. Joint working to improve awareness of and access to mental health services before crisis will be important in reducing use of restrictive legislation and improving outcomes.

We thank the nursing and medical staff of Affric Ward, New Craigs Hospital, Inverness, for their assessment of patients and record-keeping of police place of safety referrals, and the medical administration staff for their assistance in sourcing medical records and POS1 forms. We also thank Dr Amy MacAskill (consultant psychiatrist) and Barbara Brodie (clinical effectiveness coordinator) for their advice and guidance in putting together this study.

S.S. is the lead author; he designed the projected, carried out data collection, completed initial statistical analysis and wrote the majority of the paper. J.E. provided support to the basic statistical analysis and data presentation within the paper, carried out analysis for the multivariable binary logistic mixed-effects model, and wrote the sections describing statistical testing and the output of the multivariable binary logistic mixed-effects model. Both authors were involved in production of the final version after peer review and meet ICMJE criteria for authorship.

Abstract

Aims and method

To assess whether the combination of motivational interviewing and psychoeducation affects relapse rate and stimulates involvement of people with psychosis in their treatment. We conducted an interventional study including patients with schizophrenia or schizoaffective disorder treated with oral antipsychotics, without previous experience of long-acting injectable antipsychotics (LAIs). They were randomised to either psychoeducation with motivational interviewing or a control group. Hospital admissions 18 months before and after the intervention, and switches to LAIs 18 months after the intervention, were recorded.

Results

The two groups each comprised 101 participants. Fourteen from the intervention group and seven from the control group switched to LAIs. Five in the intervention group instigated the switch themselves, compared with zero controls ($P = 0.06$). Fourteen in the intervention group were readmitted to hospital during follow-up, compared with 23 in the control group ($P = 0.14$).

Clinical implications

Psychoeducation with motivational interviewing may increase patients' involvement in their treatment and reduce the relapse frequency.

Adherence to pharmacological treatment by people with psychotic disorders is one of the major challenges in psychiatry, and its lack is an important predictor of relapse, even with small gaps in treatment, regardless of formulation.^{1,2} However, in observational studies long-acting injectable antipsychotics (LAIs) reduce the risk of discontinuation when

compared with oral treatment.³ Patients are seldom encouraged to participate in the choice of antipsychotic medication and formulation,⁴ which is unfortunate, as it is known that their attitude to treatment becomes more positive with increased knowledge and experience of the treatment.⁵ Psychoeducation alone is not enough to improve adherence,⁶ but a combination of psychoeducation and motivational interviewing seems to be more promising.^{7,8}

We studied switches from oral antipsychotics to LAIs as a proxy for patients' involvement and adherence and hospital admissions as a proxy for relapse rate.

Method

We included 202 people with schizophrenia and schizoaffective disorder on oral antipsychotic treatment and no earlier experience of LAIs who were part of an earlier study conducted by our group.⁹ In the earlier study, apart from the individuals on oral treatment included in this study, we also included people currently on LAIs and questioned all participants on their perceptions and knowledge of antipsychotics in general, using semi-structured interviews.

The participants in the current study were block-randomised by diagnosis (schizophrenia/schizoaffective disorder), gender and age into two separate groups: either the intervention with psychoeducation and motivational interviewing group or a comparison group with no intervention. Participants in the intervention group were enrolled on giving written informed consent to participate in an intervention and to grant access to their own medical chart. If an individual refused to participate or was excluded for another reason, their matched comparator was excluded as well. The study was approved by the Regional Ethical Review Board in Stockholm (ref. 2015/47-31).

Psychoeducation

As part of our earlier study, participants in the intervention group underwent a single semi-structured interview by a study nurse specialised in mental health (L.C.), in which perceptions and knowledge of antipsychotic formulations were examined.⁹ In summary, the earlier study revealed that participants lacked knowledge regarding differences in plasma concentration, side-effects and risk of readmission to hospital between LAIs and oral treatment. At the end of the interview, the study nurse provided psychoeducation, discussing and correcting misconceptions of the differences between oral and LAI antipsychotics. The risk associated with gaps in medication was also discussed.

Motivational interviewing

The semi-structured interview, which included questions on beliefs and attitudes to treatment, was followed by an adapted form of motivational interviewing based on the original principles of the technique.¹⁰ L.C. had received training from a professional trainer on motivational interviewing in a 3-day course prior to the study. Participants were encouraged to discuss their personal ideas and ambivalences regarding their illness and treatment. Focus was on relapse-preventing factors, quality of life, exploring their own personal goals and treatment strategies, with no preference for either oral or LAI antipsychotics.

Follow-up

Data on admissions were extracted from the participants' medical records during the 18-months before and after the intervention. Participants were not called for extra visits during the follow-up, and clinical events were noted as they appeared in the medical charts. Hospital admission was considered a proxy for relapse. We observed the frequency of participants in each group with a hospital admission before and after intervention respectively. During the follow-up period, we also measured the number of participants who switched from oral to LAI antipsychotics. We noted whether the switch had been instigated by the participant, by clear indication of this in the medical chart, as opposed to it being described as a decision made by the treating psychiatrist or not described at all. The former was considered a proxy for increased patient involvement.

Statistical analysis

Anonymised data were analysed using Prism 5.03 for Windows. Sample comparisons were made using Fisher's exact test for categorical variables.

Results

In total, there were 101 participants in the intervention group and an equal number of comparators. Characteristics for both groups were proportionately matched regarding gender (46% females) and diagnosis (70% schizophrenia). The median age was 50 years for both groups, but the ranges differed slightly (21–84 years and 24–79 years for the intervention group and the comparator group respectively).

Switching

After 18 months, 14 participants (14%) from the intervention group had switched to LAIs, compared with 7 (7%) in the comparison group ($P = 0.17$, *Fig. 1*). Five out of 101 participants (5%) in the intervention group suggested a switch themselves, compared with zero in the comparison group ($P = 0.06$). Regarding switching by decision of the psychiatrist, there was no significant difference between the groups (9 v. 7, $P = 0.80$). *Fig. 1* Hospital admissions before and after intervention and switches to a long-acting injectable antipsychotic (LAI).

Hospital admission

In the intervention group, 20 participants (20%) were admitted to hospital at least once during the 18-month period before intervention, compared with 19 (19%) of the comparators ($P = 1.0$, *Fig. 1*). The numbers of participants admitted during the 18-month follow-up period after intervention were 14 (14%) and 23 (23%) respectively ($P = 0.14$).

Discussion

In this interventional study, we found that a single session of psychoeducation and motivational interviewing in combination may promote patients' involvement in treatment choices of oral and LAI antipsychotics and reduce relapse frequency.

The higher number of participants switching to an LAI in the intervention group could reflect less resistance to changing their medication after psychoeducation and motivational interviewing. However, as at least five participants in the intervention group actively initiated the discussion of switching, the higher switching rate could also be explained by increased involvement in their treatment. This supports results from an earlier study by Barkhof et al, in which a targeted use of motivational interviewing seemed to improve medication adherence at least for certain groups of people with psychosis.¹¹ Their adapted form of motivational interviewing had an active provision of psychoeducation, which makes it to some extent comparable to our interview, although their intervention included several sessions and included people with a recent relapse.

The number of participants admitted to hospital at least once in the 18-month period before intervention was comparable between groups, with only one more participant in the intervention group being admitted. In the follow-up period after intervention the corresponding analysis showed, however, nine fewer admissions in the intervention group. This could indicate an effect of psychoeducation and motivational interviewing on admission frequency, which in turn could be a result of increased adherence and involvement in antipsychotic treatment. This is in line with previous studies, which have reported positive effects of the combination of psychoeducation and motivational interviewing on adherence.^{7,8,11}

Exploring patients' fears is a less frequently used technique, as reported in our earlier study, and participants in the same study lacked knowledge.⁹ Moreover, other research groups have reported reluctance among medical professionals to initiate the discussion of treatment.^{4,12} The possible positive effect of psychoeducation and motivational interviewing may encourage a more exploring approach in treatment discussion with the patient.

Limitations

Our study has several limitations. Individuals with cognitive disorders and acute relapse at the time of inclusion were excluded from the study, and generalisations to these patient groups cannot be made. Not all targeted individuals were included in the intervention group, either because they could not be reached or they opted out, and their respective comparators were then not included.⁹ The participants were enrolled during regular visits, which are scheduled at least yearly, so the 18 months before intervention should be enough for most eligible participants. One could argue that patients who agreed to participate and had a least one visit in connection with the intervention represent a group with more commitment to their treatment and less prone to relapse at baseline than patients in general, creating selection bias. However, the number of admissions was comparable between the intervention group and the comparison group in the 18 months before intervention, suggesting similar illness characteristics. We lacked information on confounders such as socioeconomic status, illness duration and substance misuse. However, their potential impact on the results was limited by the randomisation process. All intervention visits were conducted by the same person, assuring consistency across visits. We used hospital admissions and switch to an LAI as proxies for relapse and for patient involvement respectively, which may be questioned. However, these outcomes were readily available hard outcomes in the medical charts,

Clinical and research implications

A combination of psychoeducation and motivational interviewing may be a valuable tool in the care of people with schizophrenia and schizoaffective disorder, stimulating their involvement in treatment and reducing the frequency of readmissions, but further study is needed to corroborate the findings of this study.

Abstract

Critical psychiatry takes the position that ‘mental illness’ should not be reduced to ‘brain disease’. Here I consider whether this particular stance is outdated in light of more recent exchanges on reductionism, which consider questions raised by new mental health sciences that seek truly integrative and specific biopsychosocial models of illness.

The anti-reductionist position of critical psychiatry

According to Duncan Double, the essential position of critical psychiatry is that ‘functional mental illness should not be reduced to brain disease’.¹ As it stands, this claim is ambiguous with regard to the basis of the normative (ethical) prescription contained within it: why does critical psychiatry maintain that we should not reduce ‘mental illness’ to ‘brain disease’? We are provided with a clue as to Double’s view when he writes that ‘most psychopathology is functional, in the sense that there are no structural abnormalities in the brain’.¹ Accordingly, we should not engage in such a reduction because we do not possess the evidence that it can be done. To insist on this reduction, and on the treatments and practices it entails, can therefore be construed as ethically problematic. Now this sort of justification for critical psychiatry’s essential position lands us in indeterminate territory: it relies on establishing the presence of ‘structural abnormalities’, which depends on how we define this term, on the state of the science and on the nature of evidence and its interpretation. There will always be claims and counterclaims as to the evidence for the biological basis of ‘mental illness’.

There is another more substantial argument that can be provided in support of critical psychiatry’s position: we should not engage in the offending reduction because even if there were ‘structural abnormalities in the brain’, the subject matter – ‘mental illness’ – requires an altogether different approach for its classification, understanding and management. Double seems to intend something like this when he argues, along with von Feuchtersleben, Meyer and Engels, for a holistic, non-reductionist and integrative conception of ‘psychopathology’. This is a valuable analysis, and it is hard to disagree with the general direction of Double’s argument in this regard: mental health conditions cannot be understood, treated or managed through radically reductionist concepts and approaches. And radical reductionism is the villain that critical psychiatry, on Double’s account, is engaged in a fight with. It is a reductionism that is so obtuse, it has no place for meaning, human relationships or social context. And it was certainly evident in the early days of psychiatry, through the wild goose chase prompted, in part, by the discovery of the celebrated causal connection between general paresis of the insane and the syphilis spirochaete. How far does this view exist today?

We can quarrel endlessly about critical psychiatry’s representation of the views of its opponents, and it is unlikely that we can ever resolve this to everyone’s satisfaction. Instead, I shall introduce a more recent exchange on reductionism, and from there we can discern where things are at and what critical psychiatry has to say to us today.

Towards a truly integrated understanding of health

In a paper published in the *BMJ* in 2012, White and colleagues argue for an end to the distinction between mental disorders and brain disorders in favour of a single overarching category: disorders of the nervous system.² One of the arguments they make in support of this proposal is that psychosocial factors ‘interact strongly’ with neurological disorders, whereas ‘disorders of the mind are rooted in dysfunction of the brain’.^{2,3} Psychological, social and biological causal and risk factors run across all medical conditions, whether mental or physical.² If so, there might not be much sense insisting on the distinction between mental disorders and brain disorders, especially, they argue, considering recent advances in the neurological and genetic bases of mental disorders. Standing in contrast to White and colleagues’ proposal is a position paper by Bracken and colleagues that rejects the suggested equivalence between psychiatry and neurology: ‘Psychiatry is not neurology; it is not a medicine of the brain. Although mental health problems undoubtedly have a biological dimension, in their very nature they reach beyond the brain to involve social, cultural and psychological dimensions’.⁴

These two papers, although they argue for opposite conclusions, are both non-reductionist in the sense that they do not propose a radical disavowal of non-biological causal and risk factors. Accordingly, neither falls foul of critical psychiatry’s essential position as articulated by Double. A key point on which they differ is a question of emphasis: White and colleagues emphasise genetic and neurological factors, whereas Bracken and colleagues emphasise psychosocial factors. Where should we stand on this point?

There is no doubt that mental health conditions and neurological conditions demonstrate ‘multifactorial pathways’, as White and Colleagues note. Nevertheless, psychosocial factors are more prominent in mental disorders across a wide range of dimensions.⁵ To the extent that this is the case, psychiatry differs from neurology in that it ‘has particular expertise in the management of psychosocial factors as well as internal biological factors’.⁵ We could take this observation to support the view that, in order to preserve the emphasis on psychosocial factors, we should not collapse the

distinction between mental disorders and brain disorders. Or we could decide that the terms of the debate and the forced choice between them are out of keeping with developments in the new mental health sciences. Here, gene–environment interactions, social determinants of health over the life-course, individual psychology and neuroscience are all relevant for an integrated understanding of health. As Derek Bolton puts it: ‘[These] new sciences do not work with ideological battles between the biological, the psychological, and the social, the old parallel universes with poor communication between them; rather they work with all of these factors and the diversity of interplay between them’.⁵

There is much work to be done, both empirical and conceptual, to understand how social, psychological and biological factors interact in specific conditions. However, that work applies across the board to all conditions of health-related interest.^{6,7} The aim is to move beyond a biopsychosocial model that is integrative only in name and towards one that can provide concrete risk and causal pathways across the range of factors of relevance to a particular health condition.

Critical psychiatry may have run its course, but the critique of psychiatry continues

Where does this leave critical psychiatry? Double’s editorial seeks to advance two aims. On one hand, it wants to affirm critical psychiatry’s continuing relevance as the defender of the position that ‘functional mental illness should not be reduced to brain disease’. On the other hand, it acknowledges that it might be beneficial ‘to look for the continuities, rather than discontinuities, with orthodox psychiatry’.¹ On the first aim, we have seen that it is possible to debate whether we should end the distinction between mental disorders and brain disorders without falling into the radical reductionism that critical psychiatry positions itself against. Moreover, as suggested above, the new mental health sciences have moved beyond the terms of this debate and seek genuinely integrative and specific biopsychosocial models of health conditions. Accordingly, in so far as critical psychiatry requires the continuing relevance of its essential position, then it might have run its course. This leaves us with the second aim of the editorial, from which, on Double’s own analysis, one gets the sense that there is very little that separates critical psychiatry from ‘orthodox psychiatry’. And that is not a bad thing, for it can be taken by critical psychiatry as a triumph, as evidence that its message has got through.

But critical psychiatry does not exhaust the constructive critique of psychiatry and society, which, as we enter the third decade of the 21st century, is going strong. For example, there are continuing debates on the boundaries of illness and on the definition of mental disorder (e.g.^{8,9}); there are attempts to resolve the classificatory complexity of mental health conditions and to critique the validity of existing classifications (e.g.^{10–12}); questions continue to be raised about the nature of mental disorders (e.g.^{13,14}); controversies remain surrounding the efficacy and risks of antidepressant and antipsychotic medications (e.g.¹⁵); debates continue on the ethical complexities raised by capacity assessments and coercive interventions (e.g.^{16,17}); and challenges to medical concepts and approaches – to medicalisation more generally – are experiencing a resurgence through mental health activism (e.g.^{18–22}).

In the midst of these exciting and still largely unresolved problems, the version of critical psychiatry presented by Double in his editorial is of historical value; it reminds us of a radically reductionist position that now – in light of developments in the science and philosophy of mental health – appears false and outdated.

1.3.41 Clinical course of 12 patients on a Covid-19 dementia isolation ward

- *Clinical course of 12 patients on a Covid-19 dementia isolation ward*

– Declaration of interest

Older adults have been particularly vulnerable to outbreaks of severe acute respiratory syndrome coronavirus 2 (Covid-19), and mortality rates increase with age.^{1,2} Physiological comorbidities and nutritional status are contributory factors, but there is limited understanding of the influence of mental illness, particularly for patients with dementia.³⁻⁵ Furthermore, cognitive impairment may also increase the risks of contracting Covid-19.⁶

We have summarised our experiences from a psychiatric in-patient unit to describe the clinical outcomes of 12 patients admitted to a dementia specialist ward, which later became closed to admissions after nine of the patients were isolated with confirmed or suspected Covid-19. The following patients, all over the age of 74, were selected to illustrate the typical clinical course that was observed in the most unwell patients. To ensure anonymity, patient initials, ages, and gender identifiers have been removed.

In Case 1, the patient had diagnoses of mixed Alzheimer's and vascular dementia, type 2 diabetes mellitus, hypertension and previous traumatic subdural haemorrhage. Isolation was commenced after a new cough, low oxygen saturations and vomiting were observed. The patient was then transferred to the acute hospital and treated with empirical antibiotics. Despite this, the patient refused all oral food and fluids, and a decrease of 24% of pre-Covid total body mass was recorded. The patient later developed hypernatraemia and an ischaemic left leg and was subsequently discharged to a palliative care hospice on an end-of-life care pathway.

In Case 2, the patient with a diagnosis of mixed Alzheimer's and vascular dementia and no relevant past medical history developed a cough and oxygen saturations of 88% on air. The patient was transferred to the acute hospital, diagnosed with lobar pneumonia, started on antibiotics and returned to the ward 5 days later. Throughout the period of isolation, food and fluid intake was observed as being minimal. Twelve days after isolation, a serum sodium level of 147 mmol/L was recorded, with a decrease of 12.7% of pre-Covid body mass. Features of pneumonia and dehydration persisted, with the serum sodium level climbing to 152 mmol/L. Following three further episodes of care at the acute hospital, the patient was treated on an end-of-life care pathway and died 30 days after isolation. Of note, 4 days before isolation was commenced, this patient was medically reviewed for a cough which was thought not to be due to Covid-19. Causes of death were certified as (1a) pneumonia, (1b) Covid-19 infection and (2) end-stage dementia.

In Case 3, the patient had a previous acquired brain injury and mixed Alzheimer's and vascular dementia, with past medical history including epilepsy and chronic obstructive pulmonary disease. Isolation nursing commenced after a new cough was noted, 5 days after a possible cough was interpreted as 'throat clearing'. Eleven days after isolation, the patient was initiated on antibiotics at the acute hospital after a significant drop in oxygen saturations was recorded. Serum sodium levels were sampled at 151 mmol/L, corresponding with a limited fluid intake. A decrease of 23% of pre-Covid body mass was recorded. Thirteen days after isolation, the patient developed hyperactive delirium with clinical signs of dehydration, serum sodium of 156 mmol/L and urea of 15.1 mmol/L. The patient was subsequently transferred to the acute hospital and placed on an end-of-life care pathway.

In Case 4, the patient had diagnoses of Alzheimer's dementia and treatment-resistant depression, having been admitted from the acute hospital. Isolation was commenced, followed by transfer back to the acute hospital, after oxygen saturations dropped to 90%. After correction of hypokalaemia and commencing antibiotics for pneumonia, the patient returned to the ward. Six days after the initial Covid-19 symptoms, the patient was readmitted to the acute hospital for management of reduced oxygen saturation and refeeding syndrome. A further 21 days later, the patient was placed on an end-of-life care pathway. The cause of death was recorded as (1a) end-stage dementia in Alzheimer's disease and Covid-19 infection and (2) urinary tract infection (treated).

All isolated patients with reduced mobility were prescribed venous thromboembolism prophylaxis. All isolated patients with a cough or fever were prescribed prophylactic antibiotics in case of a secondary bacterial pneumonia. All confirmed or suspected Covid patients were prescribed additional nutritional supplements. These plans were implemented with advice from acute hospital and dietician colleagues.

Of the remaining eight patients on the ward, one was asymptomatic throughout the 14 days of isolation despite testing positive for the virus, and four further patients tested positive, requiring various levels of medical input before being safely discharged. A further three patients did not record a fever, nor develop a cough, and did not test positive on throat or nasal swabs and were nursed separately.

In summary, of the nine patients who were confirmed or suspected of having contracted Covid-19, four subsequently received end-of-life care, eight required admission to an acute hospital for medical input, and all nine patients survived the period of isolation, which lasted at least 14 days.

All confirmed or suspected Covid patients were prescribed additional nutritional supplements under the guidance of a dietician. Adherence to these was variable but generally poor. Despite this, four patients experienced a weight loss of between 13% to 24% during their period of isolation. This weight loss was observed in the patients with the poorest outcomes.

Six patients also experienced clinical levels of dehydration, identified initially by raised serum sodium levels, despite best attempts to encourage oral fluids while being nursed in isolation. These patients also required the highest levels of medical input.

In our opinion, patients with dementia who contract Covid-19 are likely to require high levels of medical oversight to monitor their physical health, experienced nursing care to encourage adequate fluid and food intake, and input from a dietician to ensure nutrition is optimised.

The clinical outcomes of patients with dementia who contract Covid-19 are variable and difficult to predict. It can be expected that patients will require episodes of care in an acute hospital for physical consequences of Covid-19 that cannot be addressed on a psychiatric ward. Physical deterioration and death do not tend to occur during the 14 days of isolation and are usually due to secondary consequences of Covid-19, of which weight loss, dehydration and rising serum sodium are worrying clinical signs.

Self-reporting of Covid-19 symptoms by patients with dementia can be unreliable and can delay isolation nursing, putting other patients at risk.

Management of symptomatic patients who have refused confirmatory swabs must be carefully considered, balancing the risks and benefits of treatment in the Covid-19 cohort area or treatment among well patients.

Early discussions related to ceilings of care, Do Not Attempt Cardio Pulmonary Resuscitation orders and the application of end-of-life care pathways were recognised as essential to ensuring that the patient's prior wishes and best interests were considered.

We sincerely hope that the details we have included here will be of interest and use to readers. We will happily respond to any questions that may arise.

1.3.42 Disclosing mental illness: a doctor's dilemma

Rebecca Lawrence

Correspondence

Dr Rebecca Lawrence

(rebeccalawrence@nhs.net)

date

2020-12

Abstract

There is increasing evidence that doctors have high levels of mental illness, and there are concerns that, for some, this may be exacerbated by their working environment. It can be difficult for doctors to disclose mental illness, either to senior or junior colleagues, and perhaps even harder to know what, if anything, to say to patients. Many doctors may be unsure of their position as regards disclosing to governing bodies; others may disclose widely on social media. I am a psychiatrist who also has a significant mental illness, and refer both to my personal experience and the literature to explore some of these issues.

I became a consultant psychiatrist 14 years ago. When I started life as a psychiatric trainee, some 9 years prior, I had already been advised that this was not a good idea, as it would probably be too stressful for me. You might wonder why, given that I had previously completed general practitioner (GP) training; but I had also had the misfortune to have been a psychiatric patient. Briefly, I became ill in my GP trainee year, with what was almost certainly a perinatal mood disorder. I was in and out of hospital over the following 2 years, and had several courses of electroconvulsive therapy (ECT), before finally recovering sufficiently to return to work.

This was one of the hardest times of my life. I had minimal help with this return, and just had to apply for locums, at which I failed, and then 6-month junior hospital posts. There was no phased return, and I did full resident on-call from the start. I was determined and driven – I had to be. Just your average doctor, really, and with the usual tunnel vision. I regret this time, when I was a new mother, and recovering – it should have been gentler – but I felt that unless people saw me as tough, there was little hope of ever returning to work.

I was diagnosed with psychotic depression, and subsequently with bipolar disorder. After that first episode, I believed that I would never be ill again, until it became apparent, even to me, that this was a long-term condition, something that would probably never go away entirely. I have indeed had relapses, and my most recent encounter with ECT was this past year.

The high risk of anxiety, depression and suicide in doctors, particularly anaesthetists, general practitioners and psychiatrists, has been highlighted by Clare Gerada, and a link made between fear of exposure and suicide.¹ A recent survey by the British Medical Association (BMA) has emphasised the concerning levels of mental health problems in doctors and students, and how their working environment may have contributed to these.² Some of the reasons for these difficulties have been examined in Caroline Elton's book, *Also Human: The Inner Lives of Doctors*,³ which explores the stresses unique to medicine, the way doctors can be treated and what happens when they can no longer carry on.

Over the years I have chosen at times to disclose my illness, and at times to keep silent – probably more often somewhere in between, leaving out the nasty bits. My first really public disclosure was a *BMJ* article in 2012,⁴ but I had always been fairly open with colleagues. Interestingly, doctors do not always behave as they think they will, with younger doctors and doctors in training less likely to disclose mental illness.⁵

How one decides when to disclose, and how much should be said, often depends on the context. Initially I felt that I was the only doctor to whom this had happened, and only when a kind supervisor gave me an article by the late Belinda Brewer⁶ did it occur to me that this was unlikely. That brief article affected me profoundly, and I have found reading personal accounts hugely helpful, as both a patient and doctor. *Doctors as Patients*, edited by the late Petre Jones,⁷ contains many different accounts, as well as guidance and advice, and is a book I have come back to when unwell. It is sobering to reflect on the loss of both of these doctors, and I want to acknowledge their courage.

Rees et al have acquired a considerable amount of qualitative data from interviewing doctors, and have commented on the importance of the reaction to the first disclosure of mental illness, whoever this is made to.⁸ This has obvious implications for the training and support of those who actually support junior doctors and medical students.

Disclosing to patients

Disclosure of one's own illness to patients is a thorny area, and I do not think I have ever done it, although I have at times been tempted. But I have always thought this will make it more about me than them. It will close down the channels of communication, as my feelings become theirs. I work in a chronic pain clinic, and do not share my sciatica woes either. However sore I am, I cannot actually feel their pain.

De Vos et al discuss the use of disclosure by therapists in recovery, and make the important point that this must be done thoughtfully, without specific details of symptoms, and with support.⁹ There are growing numbers of blogs about the experience of mental illness, including those by doctors and psychiatrists. It is clear upon reading them that there is no one answer, implying that a great deal of consideration must be taken to ensure good patient care while treading sensitively. Howe specifically explores self-disclosure in psychiatrists, and concludes that a psychiatrist should only disclose what they are comfortable with, and what will benefit the patient.¹⁰

As a patient, I do not think that I would want my psychiatrist to disclose anything too personal to me. If they told me that they had been depressed, I think I would, in a peculiar way, feel out-manoeuvred, that there was no point in describing things further, as they already knew. Yet there can also be the odd sense that one's psychiatrist does not actually exist as a person themselves, leading to curiosity and sometimes alienation, which may be stronger when the patient is also a doctor.

As a doctor, my hope is that my experience will come through, that I will show rather than tell, and that this may influence my interactions with patients. I know that there is a school of thought that demonstrating one's own vulnerability may provide hope to a patient. Even then, I think the time to do so would be when the patient is better and less vulnerable themselves, as there is always a power imbalance in the patient–doctor relationship.

There is, of course, the reality that a patient may ask about your personal experience, particularly if you write or talk about it. I have always done this to some extent, but have expanded my efforts recently, both on Twitter and by blogging, and was interviewed on television earlier in 2019.¹¹ It is perhaps easier for me as an established consultant, with supportive colleagues and managers, but my main reason for speaking out is that my children are older now, and understand more about my illness and why I would speak about it. As regards to patients, I would always tell them if they asked a direct question. I might say that the focus should be on them, and I might say that I would rather not discuss it in any detail, but I would not deny it.

Disclosing to colleagues

Applying for training is both harder and easier now. I applied to several local training schemes, resulting in one outright rejection and two interviews. At both, I told them of my illness; one offered me a shorter contract in case I was not up to it, but the other just offered me the job. I was, and am, very glad that they knew of my illness from the beginning, and I experienced no stigma during my 2 years there, only support. But one would not now mention this at interview, which would, in any case, be done nationally. This lessens prejudice, but it also lessens your chance of discovering the right place to work, which I was fortunate to do. In other words, not being politically correct can, at times, be a bonus.

Throughout my training, I mostly worked with great consultants who knew my history, but I also tried to seek such people out whenever I could. There will always be those who, for whatever reason, are less able to support a trainee with difficulties, and my advice would be to avoid them whenever possible. The Royal College of Psychiatrists has resources for doctors and trainees returning to work,¹² as does the Psychiatric Trainees Committee,¹³ which can be helpful both for those returning and those supporting them.

Perhaps I share too much, but I would advise trainees to definitely tell their educational supervisors, and usually their clinical supervisors, of any significant mental illness (definitely if not entirely well). My own problems had been rather public, being an in-patient in the local hospital, so I felt I had little option. You do not have to tell everyone with whom you work, any more than you have to tell them about other conditions, but sharing with your supervisors can make life smoother. Sometimes it is hard to do this face to face; I would then consider emailing what you want them to know, explaining that it can be difficult, and this can give both some time to reflect before speaking.

Disclosing to governing bodies

The main body that governs doctors is the General Medical Council (GMC), and this can become very frightening when unwell. Unless a doctor is attempting to work against medical advice, the GMC should not become involved and the doctor should receive local support and treatment. This can include taking time off, but a reduction in hours or a phased return may also be recommended, and occupational health are well placed to help with this. There is no automatic need to inform the GMC unless there are legal issues, such as a drink driving charge, or other probity issues, when self-disclosure for health assessment should first be encouraged.¹⁴

Those doctors who are seen for health assessments face a number of possible outcomes, including not working for a period or working under supervision. I work as a health examiner and supervisor, and have seen how difficult this can be; there is undoubtedly much fear and stigma, but doctors often do very well, and many return to work. The GMC continues to work hard to dispel these fears as much as possible, and to provide more support, particularly following the concerns around increased suicide rates;¹⁵ but it is vital that doctors also receive support and validation from other sources, given that this can threaten the very meaning and identity of being a doctor.

When medical students apply to join the medical register, they too need to disclose any health conditions that may affect their fitness to practise.¹⁶ Medical schools have processes to manage students' fitness to practise, and should be able to provide help and advice for those with pre-existing conditions.¹⁷

There are services available, such as the Psychiatrists' Support Service,¹⁸ which provides anonymous telephone support to all grades of psychiatrist, and NHS Practitioner Health,¹⁹ which launched an immediate crisis text line this year, available to all doctors in England and Wales. Others include the BMA Doctor Support Service²⁰ and the Doctors' Support Network.²¹ DocHealth is a brief psychotherapy service available across the UK, staffed by medical consultant psychotherapists, and subsidised by the BMA and Royal Medical Benevolent Fund.²²

Disclosing being a doctor

It is extraordinary that saying one is a doctor can sometimes be harder than saying one has a mental illness. I was once part of a patient and carer group at the Royal College of Psychiatrists; it was a good experience, but I left because I did not really fit in, being a doctor as well as a patient. It is probably even harder being a doctor when an in-patient on a psychiatric ward, but this was not something that I ever broadcasted. I remember a patient shouting at me when, as a junior doctor, I visited a ward where I had previously been a patient: ‘You used to be one of us [patients], and now you’re one of them [doctors] and how did that happen?’ At times I felt like a combination of a fake patient and an incompetent doctor.

Disclosure to the wider community

More recently I have posted on Twitter, making it obvious I am both doctor and patient. The same things that garner support for a patient can enrage the online community when a doctor is involved. For me, one obvious example has been ECT, which I had this past year and have had previously. However, I recognise that although I am trained as a psychiatrist, my personal experiences are anecdotal and I try to present them as such, rather than generalising. I think this does take the heat out of things, although not always. I would, however, advise others not to post on Twitter when less well; there are many other gentler online forums that can provide helpful support. I have used the Doctors’ Support Network forum, which is completely anonymous, and a specific group for doctors with bipolar disorder.

I have started to speak and write more publicly about my illness,¹¹ although I find that it is actually quite easy to hide behind a pen or a lens. I have also spoken directly to both trainees and retired psychiatrists, which is more daunting, but also more rewarding; and I hope to continue to tell my story to others, both to help them know that they are not alone and to highlight what support is out there.

Receiving disclosures

Inevitably as a psychiatrist and trainer I have received disclosures from others regarding mental illness and other sensitive issues. I find this hard, and I think it is right to find it hard, not least because it has usually been very difficult for the trainee to raise. Acknowledge it, make no assumptions and ask how much the trainee wants to say. Ask them if they want to talk about it again, and think about what they have told you. Most importantly, remember that they are not you. Treat them normally, and do not make them feel that they have become ‘special’ or ‘different’. Help them, and guide them to find treatment if necessary, but do not be their doctor. Getting the balance can be very difficult, and it can sometimes be useful to discuss this confidentially, and with consent, with other senior colleagues involved in training.

When trainees are aware of my own illness, I sometimes worry that it makes it harder for them to talk of theirs. They may feel mine is ‘better’ or conversely ‘worse’, and that their illness is less important. So I try to open up generally about mental illness, in the hope that it will make it easier for them, particularly in the way that I talk about patients and other trainees.

‘Why?’ is a common question to ask, when doctors, nurses and others choose to work in psychiatry after an episode of mental illness, and there is no one answer. It is very hard to predict who will cope, who will shine, even, and who will find it hard. I can see, with hindsight, why I was advised against another long period of training and grinding exams, given the length and severity of my illness, and I now feel minimal resentment about this. I did feel angry with those who asked if I was trying to cure myself, but on the whole, they were not psychiatrists. And now, when I talk to others, I know it is important not to blind oneself with preconceptions, to know that there is not one route for all. Because I did, it does not mean all others should.

My illness has had a profound effect on my life and my work. I worked much harder and was far more organised during my psychiatric training than I had been previously. I had to be – there was always this thing at the back of my mind, this thing over which I had little control. I was determined to pass exams, even doing a Master’s degree during my maternity leave. I felt that if I did not do well, my abilities would be questioned and put down to mental illness. I still think this is a difficult area; we all have times when we may perform less well, and there is little doubt that supervisors may wonder about mental health in a trainee with a history of illness, when they otherwise would not.

This is reasonable, and hopefully not punitive in any way. But as a trainee you fear assumptions, even if they are based on some truth. So supervisors must be alert, yet resist jumping to conclusions, and the way to manage this is to get to know your trainees well. It can be difficult, I know this now as a trainer; sadly, there is often nowhere where trainers and trainees all meet for coffee or lunch, the kind of things that make this happen.

Living and surviving

It is unsurprising that I have always been interested in doctors' accounts of mental illness. They make me feel less alone, they inspire me, and above all they are all different. The accounts by Linda Gask²³ and Cathy Wield²⁴ are moving and human, and lifted me out of my self-obsessions. They, too, are real people, things happened to them, and they are doctors. The recognition that you can recover, succeed and then get ill again was also important – these are not always stories with a happy ever after. Kay Redfield Jamison's account of having bipolar disorder is a wonderful book, describing the experience of changing moods, as well as combining this with a remarkable career researching and treating the very illness that nearly destroyed her.²⁵ Mike Shooter, past president of the Royal College of Psychiatrists, describes becoming better able to recognise the warning signs of illness, and knowing when to stop.²⁶

For better or for worse

But the big question, for me, is whether my experiences make me a better doctor and psychiatrist, or even a better person. There is much written about the importance of lived experience, and it can all get a bit competitive. I trained in general adult psychiatry, but work in addiction psychiatry. I think I knew that working in general adult would potentially be harder, with reminders and triggers of what had happened to me, and that it would be very easy for me to become over-involved in a way that would be good for neither me nor patients. I am still drawn to occasional patients, where I think, 'that could be me', and I have to remind myself that no-one is exactly like another, no-one can experience the thoughts and suffering of someone else.

When I first started working in psychiatry, I think that I did feel that my lived experience made me better than others, and that I could more easily understand what patients were going through. I am much less sure now. There was a lightbulb moment for this, when I lost a baby late in pregnancy, early in my training. I was devastated. But it suddenly came to me that everyone's experiences are personal, that I had no idea what another mother would feel. It was a short step to realising that my experiences of altered mood, of side-effects and drugs, was only mine. I think what happened made me more alert to suffering, hopefully more empathetic and more prepared to listen. But I would never now say to someone, 'I know exactly how you feel'.

Whether I am a better psychiatrist because of my experiences is difficult to say, as I can never know what the alternative would have been. One thing I am fairly sure of is that I am a far worse patient. I question and doubt, and my knowledge, particularly of psychiatric medication, is very unhelpful. Obviously I want to think I am a better psychiatrist, but I do not think you need to have experienced psychiatric illness to be excellent. Most of us will experience difficulty and sorrow in our lives, and these will change us and make us what we are. There is no one prescription for empathy.

I would like to thank Dr Cate Bailey for inviting me to write this article, and for her very helpful comments regarding content and structure.

- *Kenneth Kendler: fully human*

“We shall not cease from explorationAnd the end of all our exploringWill be to arrive where we startedAnd know the place for the first time.” T. S. Eliot, ‘Little Gidding’ (from *Four Quartets*), 1942”

Born the son of two experimental psychologists (his father a ‘classic New York Jewish character’, his mother a ‘very intellectual, incisive’ woman who ‘overcame a lot of prejudice about being a woman in academia’), Professor Kenneth Kendler’s parents were initially sceptical about his choice of a career in psychiatry: ‘In my parents’ days (they would have trained in the late 1930s and early 1940s), the smart people went on to get a PhD and the physicians were sort of second class. They basically were either psychoanalysts or they went to state hospitals and gave lots of people ECT . . . My father, for example, worked in the mental health system during the Second World War. So he had a lot of contact with psychiatrists and was not, on average, very impressed’. He thinks he made them proud in the end though: ‘I think eventually I convinced them one could do rigorous research in this area’.

At the time of writing, Kendler is the second most highly cited psychiatric researcher in the world. Already a renowned expert in psychiatric genetics, he diverged later in his career to become an eminent scholar in the philosophy, and latterly the history, of psychiatry. He has gone to the lengths of employing a German speaking translator for the past few years, so he can read Emil Kraepelin’s writings in the original. These later interests were in part an attempt, it seems, to resolve his own *sturm und drang* about classification in psychiatry: ‘You cannot understand where we are in psychiatric nosology without understanding the historical context within which it exists’, he told me. In thinking about the arc of his career, I was reminded of the T. S. Eliot quotation in the epigraph to this piece.

¹

Claire McKenna talks to Kenneth Kendler, psychiatric polymath, about the consolations of philosophy, poetry and theology

His new book *Toward a Philosophical Approach to Psychiatry*¹ is a compendium of his most important philosophical papers, as well as some of his historical and genetics papers (necessary to understand his thesis about the nature of psychiatric illness). He is an exceptionally clear and engaging writer, which makes the book an accessible read for psychiatrists who are not academic philosophers.

When I talked to Kendler via Skype in March 2020 he seemed pretty serene in his quarantine. Holed up in his home in Virginia because of COVID-19, he remained hard at work. It seems a labour of love for him. ‘That’s what my kids say,’ he laughs, ‘This isn’t work for you, Dad!’ His eyes wrinkle quickly and frequently into mirth throughout the interview. His formidable intelligence combines with a warm and easy manner, which transmitted through the ether. In his scholarly search for what ails us, he seems more aware than many of the humanity that gives meaning to this suffering.

Kendler’s philosophical stance is poetically summarised (in a riff on Gerard Manley Hopkins) in the title of his 2015 paper, ‘The dappled nature of the causes of psychiatric illness: replacing the organic–functional/hardware–software dichotomy with empirically based pluralism’.² His philosophical approach to psychiatry is very much of the pragmatic kind. He examined my more speculative questions briefly during this interview (about mysterianism for example) and, in a manner I imagined might be born of his decades long habit of daily meditation, let them float away like flotsam of the mind, finding them unhelpful to advance his project.

‘It’s been a wonderful and fulfilling career,’ he says, but it is one that’s far from over yet. Now aged 69, he still directs a research institute at Virginia Commonwealth University, he teaches, edits the journal *Psychological Medicine*, serves on the DSM steering committee and is very active in several psychiatric genomic consortia groups. The fifth in the series of his books (edited with Joseph Parnas and Peter Zachar), based on presentations at the philosophy of psychiatry conferences in Copenhagen that they organise, is just coming out.³ He has also raced out a series of papers this year based on a close reading of Kraepelin’s original textbooks. ‘I can’t write it fast enough,’ he says, as he chips away at the great edifice of our ignorance, one flake at a time.

This conversation has been condensed and edited.

What are you most proud of in your prolific career?

That’s a really hard question. I think I’ve managed to show how careful methodological approaches can clarify how the familial influences on psychiatric illness act. I think they’re quite strong, if you had to rank all the other components, but they’re subtle and we tend to have very simplistic solutions, i.e. it’s all genetic or it’s all our environment. So, I think in the research I’ve done, I’ve laid some foundations for a kind of sound, rigorous empirical approach to these questions. And I think in the philosophy work, which has been later in my career, it’s been closely related to the empirical work, of trying to provide a contextual framework for thinking clearly about these conditions and human behaviour.

Because, of course, it’s our academic discipline, but we’re also studying ourselves and our own behaviour. It’s especially hard to think clearly and avoid previous biases. Its complexity is simply overwhelming. And although overly simplistic, one human reaction to great complexity is to develop tunnel vision. That’s one way to get closure. But that’s a bad way to do psychiatry. It’s a bad way to do it clinically and a bad way to do it research-wise. So, I’m trying to provide a framework to think clearly and rigorously. I guess that would be the most important. I think I contributed a bit.

I read two lovely papers^{2,4} of yours about a philosophical framework for psychiatry, which I thought were really good primers. I wanted to ask you a bit about the importance of philosophy for psychiatrists. It can sometimes seem to psychiatrists quite arcane and not necessarily applicable to their day-to-day practice.

Well, I have to say that this is not novel. We all make philosophical assumptions about the things we do and think. And you can either examine them or you can’t. But it’s not that they’re not there. And in psychiatry, they’re legion. Like, how does the mind relate to the brain? You cannot begin to practise psychiatry without thinking about those questions. How do you interpret evidence from different layers of science? So, we might study personality theory, we might study parent–child relationships, we might study molecular genetic variants, we might study signals in the amygdala or the nucleus accumbens. How do we put those all together? How do they relate to one another?

What you’ve just highlighted is that it’s very difficult to do psychiatry well, because of the different styles of thinking we need. And humans tend to think in heuristics, so we tend to default to that more categorical thinking. And it’s oftentimes really hard, actually, to hold in mind all of that pluralism whenever you’re with patients. For example, when I’m talking about a patient to colleagues and I’m thinking about a psychosis spectrum, at the

end of it the question is, well, ‘Is it psychosis or is it not?’ So, we default to a binary. I wonder whether it’s the nature of our brains that we think like this?

I think you’re probably right, that goes back to my concerns that, in the face of overwhelming complexity, it’s very understandable to simplify. I do believe rather deeply in pluralism, both in our research and in our clinical perspective. The best of psychiatrists, we have to wear a range of glasses: when we see someone acutely in an emergency room setting, versus in long-term therapy, those are not the same approach.

You know, ‘Beware the man with only a hammer, as he will see only a world full of nails’. And some people are like that. I grew up at a time when they were full of the hubris of biological psychiatry. And people would say things – they were not bad human beings – but they’d say things like, well, you wouldn’t talk with an individual with schizophrenia, any more than you want to work with a broken computer. Just give them their medicines. And I think that’s stunningly arrogant. People with schizophrenia have all the fears and wishes that we have. And providing good care is a very human process. That doesn’t mean I don’t try to think rigorously about dopamine pharmacology, but I think that’s a stunning misdeed to only think about that. And it’s not terrifically different from the psychoanalyst who used to say that thinking about the person as a working brain as well as a mind was somehow a defensive reaction. So, we’re full of these in this field of mental health of ours.

That analogy that you just used about seeing nails everywhere – similarly, I sometimes feel that as psychiatrists we’re using a sledgehammer to crack a nut. Psychotropic medication is so non-specific in it’s mode of action. Do you ever get that kind of cognitive dissonance?

The short answer would be yes. In my practice, I try to develop a nuanced and collaborative approach. I mean, I didn’t ever have to do very high-productivity kind of out-patient work. So, I think I was probably a bit spoiled. I hardly ever made any money at it, so I was not very good!

Yes, I agree. It’s truly a challenge. And especially, you know, there are certainly quite ill individuals, with schizophrenia for example, where medical models are needed. The traditional psychological therapies really have very limited effectiveness, but what helps is to provide support, often on quite practical matters, to your patients. But again, in those situations, the level of trust is a very important thing. In caring for people with psychosis, when their psychosis starts coming, do they feel that they can call you? So, I think those human things matter a whole lot in addition to getting the psychopharmacology right.

Did you coin the term ‘patchy reductionism’? I learned it from your writings.

No, that’s from Ken Schaffner.

I think it’s a helpful concept that we proceed in psychiatry by incrementalism.

Correct.

And in terms of your career progression, I’ve asked you about some of the high points, but do you have any wrong turns or regrets about how you’ve proceeded in your career at all?

I wish I had studied way more statistics. I did a fair amount. So, for a psychiatrist, I know a good bit. As a research physician, you make a bargain. So I spent my 20s, while most of my PhD colleagues were getting trained in research, going to medical school and getting psychiatric training. It means that there are limits. I will never be as good as they are in some particular areas. I try to compensate for that with a broader vision and understanding.

I did have this naive idea when I was travelling around the back roads of Roscommon County in particular, Tyrone, Fermanagh and other places [for the Roscommon family study of schizophrenia], that we were going to crack and definitively solve the genetics of schizophrenia. And that was certainly naive. I was naive along with many other people. But we’re making real progress now, real progress. But it’s not at all simple.

I was fascinated to read that you’d considered graduate school in religious studies at one point. Your positivist approach to psychiatry and then theology are quite different approaches.

I continued with my Biblical studies throughout my adult life. I meet with a nearby Rabbi on most weekends for an hour and a half of study.

I got very interested in religious studies but I think I made the right decision. But those broader issues about human existence have been an important interest to me. And I think it's not unrelated to the philosophical issues.

How do you square the metaphysics and theology with the empiricism?

Intellectually, I am a hard-nosed agnostic. But emotionally, there's no question that there are theistic elements within me, and that's been true my whole life, which my parents were very puzzled about. I don't really feel I need to apologise for that.

We've been working on the Book of Genesis now for about three and a half years and I find those very meaningful comments on human experience. I mean, I love Homer and I think one can learn tremendous amounts about humans in Tolstoy and others. There is a descriptive approach to the nature of human experience in high-quality poetry that I have always found to be useful. It's a different way of knowing, absolutely. But they are mutually enriching. So, I am quite intolerant of the Richard Dawkinses of the world. It's so full of hubris to feel that so much wisdom and human struggle, which has been articulated in a religious context – to sort of wipe that away with one sweep as if that's just, you know, silliness. I have very little patience for that.

That kind of tallies with what Noam Chomsky has written – that there are limits to what we can understand with science. I have a quote from him here: 'It is quite possible – overwhelmingly probable, one might guess – that we will always learn more about human life and human personality from novels than from scientific psychology'.

Well that's a question of epistemology. That is the ways of knowing. That's not very different from Karl Jaspers' 'of explanation and understanding' actually. It's actually very similar to that. And does clinical psychiatry rely on both of those? Absolutely. Good psychiatry is always going to involve first-person, empathic understanding and that is our *craft*.

I worry that for people like Richard Dawkins, scientism has become a bit of a religion. Do you think that?

Well, with the following exception. If you were to ask me what is the best way to get to know about the mechanistic features of any part of the universe, I would say science is. Now, when you're talking about the human mind and its emotions, that's a different business. So in the sense that one can have hubris that science can explain things that it's not very good at, like the meaning of life or the origin of the universe, then yes, I would agree, that's scientific hubris, perhaps.

And it's funny the way that we sometimes slip as psychiatrists. I'm certainly not comfortable with the role that society calls for us. You know, as religion has gone down for people, now it's the psychiatrist who goes on talk shows. And boy, that bothers me a lot. And then, of course, they want us to comment on political figures and all that stuff. That is a big mistake.

It's kind of like psychiatrists have become the priests of scientism.

That's really a misunderstanding and it's amazingly widespread.

There's this attribution to us of some special form of human wisdom. It's amazing how intelligent people tend to have these feelings. It's just so strange the things that we get projected upon us as psychiatrists.

Were your parents religious?

Not at all. They were very Jewish, but not at all religious. I mean, if you've seen Woody Allen movies, yes? That's my father. But they grew up at a time when being religious they thought was superstition.

And if we were going to be psychoanalysts about this, do you think that you might have had some unconscious urge to rebel?

Well, I don't actually think that my interest in religion was primarily rebellion. It was something much more deep. You know I read a lot of Walt Whitman and William James's *Varieties of Religious Experience* when I was a teenager. I was reading Alan Watts, reading a lot of Gary Snyder poetry and other 'Pacific Poets'. I was trying to make sense out of life in the way that I emotionally came toward it.

Is it mainly poetry that you read in terms of the arts?

I certainly would read poetry more than I would read fiction nowadays. I certainly started out with it. I mean, Gary Snyder is probably my paradigmatic poet of interest, and Kenneth Rexroth.

I always have several books of poetry on my table that I read.

What do you get out of those?

The best kind of poems are just like little prayers, little senses of pulling on the special, the contingent, even – if you want to use the word – ‘sacred’ out of our everyday life experience, which as we know kind of rushes by us. Poetry is kind of grabbing this potent observation and thinking through the emotional implications of often very small things in our lives.

1.3.44 Evaluation of the effectiveness and acceptability of intramuscular clozapine injection: illustrative case series

Abstract

Aims and method

A series of eleven patients prescribed intramuscular clozapine at five UK sites is presented. Using routinely collected clinical data, we describe the use, efficacy and safety of this treatment modality.

Results

We administered 188 doses of intramuscular clozapine to eight patients. The remaining three patients accepted oral medication. With the exception of minor injection site pain and nodules, side-effects were as expected with oral clozapine, and there were no serious untoward events. Nine patients were successfully established on oral clozapine with significant improvement in their clinical presentations.

Clinical implications

Although a novel formulation in the UK, we have shown that intramuscular clozapine can be used safely and effectively when the oral route is initially refused.

** How to use intramuscular clozapine**– Results*** Patient characteristics*** Use of intramuscular clozapine*** Prescribing and administering experiences**– Discussion*

Clozapine remains the gold-standard intervention for treatment-resistant schizophrenia (TRS), offering a wide range of benefits.¹⁻⁵ Case reports and series describing the use of intramuscular clozapine for patients unable or unwilling to take oral treatment have been published from authors based in Israel, the Netherlands and Australia.⁶⁻⁹ Although it is possible to successfully administer clozapine via a nasogastric tube as an alternative to the oral route, the more conventional option of an injection is usually preferable if a suitable preparation is available.¹⁰ Reports of the use of both intramuscular and nasogastric clozapine show that this ‘assertive’ approach can often result in improvements in mental state and a reduction in incidents and segregation, as well as facilitating progression to a less-restrictive environment. Also in practice, a stated intention to use ‘enforced’ nasogastric or intramuscular clozapine is often sufficient to persuade patients to accept the less intrusive oral route.^{11,12} Clozapine remains an underused treatment and ‘enforced’ clozapine in particular has been seen as controversial in the UK.¹³⁻¹⁵ The use of, and attitudes to, intramuscular clozapine in the UK have, to date, been described in poster presentations only.¹⁶⁻¹⁸ We now present the use of intramuscular clozapine in five UK settings with eleven in-patients.

Method

Data was collected between January 2017 and July 2018 at five UK sites: two medium-secure units, two high-secure hospitals and a locked rehabilitation unit. Clinical records were used to identify patients prescribed intramuscular clozapine, and their demographics, previous, response to clozapine use, use of oral and intramuscular therapy, subsequent response as assessed by clinical team impressions, adverse effects from intramuscular treatment and subsequent stabilisation on oral therapy were recorded. Pharmacy staff were consulted to report on the nurses’ practical experience of using the intramuscular formulation.

How to use intramuscular clozapine

Clozapine preparation and availability

Clozapine for injection is an unlicensed ‘special’ product made in the Netherlands by Brocacef and imported to the UK by Durbin PLC via Mawdsleys. The minimum order quantity is two packs of ten 125 mg/5 mL ampoules costing approximately £2000 in total. Hospital pharmacy departments have experienced delays with importation, supply shortages and stock being sent with a shelf life of only 2 months. When new, the ampoules have a 2-year shelf life in the dark at 25°C.

Legal authority

In England and Wales, incapacitous or non-consenting patients detained under the Mental Health Act (1983) may be administered drug treatments for mental disorders for longer than 3 months only if a second opinion appointed doctor approves the treatment, including the route of administration. A rationale needs to be given for the use of unlicensed preparations and so, even if the current authority includes oral and/or intramuscular antipsychotics, a separate request for this preparation will be required. The legal authority to allow enforced blood taking as part of clozapine treatment is provided by section 63 of the Mental Health Act (1983) as long as there is valid authority for the clozapine treatment itself.¹⁹

Administration and dosing

Administration is by deep intramuscular injection. Depending on the volume of injection, the gluteal, lateral thigh or deltoid injections sites were used in this series. The Brocacef preparation has no UK licence. The Netherlands licence specifies that volumes of 2–4 mL should be administered into the gluteal muscle and not the arm or thigh, and that volumes >4 mL should be given as separate injections. There is no evidence base to favour one site over another. Teams may choose to split doses exceeding 4 mL.²⁰ As the bioavailability is approximately twice that of oral preparations, oral doses are halved and injections are usually given once daily. Given the practical limits of administering large volumes of intramuscular medication initial plans for titrations up to volumes of 3.5 mL (87.5 mg intramuscular clozapine is equal to 175 mg oral clozapine) may require flexibility, depending on the response. This would enable the use of intramuscular clozapine beyond the initial 14-day titration.

Liaison with clozapine monitoring services

Although the intramuscular preparation is an unlicensed product, the aim is to establish the patient on oral clozapine as quickly as possible, with as little intramuscular use as possible (preferably none). The treating psychiatrist, pharmacy and patient will need to be registered with a clozapine monitoring service so as to allow oral clozapine to be dispensed. In practice, patients have been registered with a monitoring service. Oral clozapine has been prescribed and, if refused, then intramuscular injections of clozapine administered. Blood monitoring at the required intervals continues, so ensuring that the patient remains registered and that oral clozapine can be dispensed. The clozapine patient-monitoring service manufacturing the relevant oral brand of clozapine has no responsibility for the use of intramuscular clozapine. Our series involved patients registered with all current UK clozapine providers.

Available protocols and guidelines

Several trusts have produced guidelines and suggested dosing schedules for the use of intramuscular clozapine, which are available online.²¹

Results

Patient characteristics

All eleven patients identified were male: ten had a primary diagnosis of schizophrenia (ICD-10 code F20)²² and one had a primary diagnosis of bipolar disorder (ICD-10 code F31).²² The indication for clozapine was treatment resistance following previous failed treatments, including high dose and antipsychotic polypharmacy. Most had demonstrated a response to clozapine treatment previously, but had discontinued owing to various patient or clinician variables: complaints about blood monitoring, sedation, and a coincidental fall in platelet count owing to immune thrombocytopenia. At least two patients had experienced severe rebound psychosis when oral clozapine was stopped. All the units included have a smoke-free policy, which had been instigated before the data collection period, and so all patients were non-smokers. See *Table 1* for a summary of the patient demographics.

Table 1 Patient demographics

Patient	Age at first episode of psychosis (years)	Age at this admission (years)	Duration of psychosis at intramuscular clozapine prescription (years)	Previous clozapine response	Previous clozapine dose (mg/d)	Setting
1	17	24	Poor	1	100	MSU
2	28	34	Partial	3	50	MSU
3	22	39	17	Partial	3	HSS
4	23	37	14	N/A	N/A	HSS
5	21	47	26	N/A	N/A	AMSU
6	17	37	1	2	71	HSS

Use of intramuscular clozapine

In three patients the offer to choose between the oral and intramuscular route was sufficient to establish oral clozapine maintenance treatment at between 400 and 425 mg/day, with significant benefit. In the remaining eight patients intramuscular clozapine was required, and between 1 and 99 doses were administered per patient, predominantly into the gluteal muscle, with one being given into the lateral thigh after a patient developed nodules in the gluteal muscle, and one into the deltoid muscle when the patient refused to have the clozapine by any other route (it was the first dose at only 0.25 mL, and no additional effects were noted). Seven patients resisted intramuscular administration to the extent that restraint was used on between one and nine occasions during the initial 14-day dose titration. Restraint was required to take a blood sample in two individuals, one on five occasions and the other on four occasions, and there were no adverse effects during restraint. The remaining patients did not resist. By the end of 5 months, nine patients had been established on oral clozapine, the majority of these showing improvement at doses between 150 mg and 400 mg/day (mean 228 mg/day). No serious adverse effects occurred owing to either the injection itself or associated episodes of restraint. Minor injection site pain occurred in three patients; one experienced sedation, and the patient who had 99 doses of intramuscular clozapine experienced some injection site nodules. There were no injection site abscesses or infections. The maximum reported dose of intramuscular clozapine administered was 250 mg in 10 mL, which was given across three injection sites. *Tables 2 and 3* describe the use of intramuscular clozapine in this series.

Table 2 Use of intramuscular clozapine: titration over initial 14-day protocol (see section *How to use intramuscular clozapine*)

Patient	Route of first clozapine dose	Oral clozapine doses in titration	Intramuscular clozapine doses in titration	Restraint
1	Oral	9	5	2
2	Oral	0	14	4
3	Intramuscular	1	4	2
4	Oral	1	3	1
5	Oral	1	3	1
6	Oral	1	4	0
7	Oral	1	4	0
8	Oral	1	4	0
9	Intramuscular	0	1	1

Table 3 Use of intramuscular clozapine after 14-day initial titration

Patient	Intramuscular clozapine doses	Total
1	2	13
2	1	15
3	4	13
4	1	15
5	1	15
6	0	13
7	0	13
8	0	13
9	1	13

Serum levels were obtained from two patients who had intramuscular clozapine continuously for five or more days; see *Table 4*. The levels were consistent with the equivalent oral doses.²³ With regards to target plasma levels, all units aimed for the usual recommended plasma range, 0.35–0.6 mg/L, but then would be guided by individual patient symptoms and side-effects; higher than usual levels were used in certain cases. *Table 4* Clozapine serum levels

Intramuscular dose, mg	Equivalent oral dose, mg	Clozapine, mg/L	Norclozapine, mg/L
150	300	0.26	0.11
125	250	0.30	0.13

Prescribing and administering experiences

Nurses were familiar with the practice of intramuscular antipsychotics and in general terms the procedure was perceived as acceptable: the injection solution was reportedly easy to draw up and, despite the bright yellow colour of the solution, the syringe markings were clearly readable and administration was easy, with very little resistance against the plunger when administering.

Nurses needed reassurance and reminding about maximum volume for single intramuscular administration, so when, for example, 10 mL was administered, three injections (4 mL + 3 mL + 3 mL) were used. Overall, nurses reported that they were confident in their ability to administer intramuscular clozapine.

Doctors required advice on bioequivalence of oral and intramuscular clozapine and how to word the prescription so that it was clear the intramuscular was only to be used if oral was declined. They also occasionally needed to be reminded to document the rationale for intramuscular treatment in clinical notes and in the associated care plan. Assistance was sometimes needed, especially initially, to complete the required application and gain approval by trust approval bodies.

In the unit where nasogastric clozapine had also previously been used, the procedure for administering intramuscular was seen as much simpler, faster and less stressful for patients. However, the limitations on dosing with the intramuscular formulation owing to volume considerations were a perceived disadvantage in patients who had experienced benefit and were poorly compliant on higher doses after the initial titration.

Discussion

When presented with a patient with TRS who refuses clozapine and consequently faces distress, disability, risk and a potentially extended length of stay, clinicians can feel that they are dealing with an impossible problem.⁵ Alternatives to clozapine are unlikely to work and may well cause harm, although a cycle of depot changes, high dose or polypharmacy regimes may still be attempted.^{24,25} ‘Enforced’ clozapine (i.e. via nasogastric or intramuscular) is a rarity and, but for the handful of case series above, barely described in the literature; there is believed to be no previous published experience of its use in the UK. Although some NHS trusts have published guidelines for the use of intramuscular clozapine, these do not provide for all eventualities and will likely need adapting to local and individual patient circumstances, often while treatment is taking place; indeed, a flexible and pragmatic approach is more likely to succeed. Difficult decisions will include not only deciding whether to use the intramuscular route at the outset, but also when to stop treatment. Neither oral clozapine nor intramuscular clozapine will provide a solution to every patient with TRS; for example, the intramuscular route may result in patient benefit, but not within the time frame or ceiling dose allowed within a protocol agreed by the governance structure of the institution. In these cases the clinical team may need to consider higher doses and/or multiple intramuscular clozapine injections over the course of the day. A higher-strength solution for injection would be very useful and could enable intramuscular clozapine to be given as the doses increase during the titration, and to continue at higher maintenance doses if the oral dose is refused later in the treatment. Presently one unit in the study prescribes intramuscular clozapine doses lower than the equivalent oral dose if 48 h of non-adherence is approaching, essentially to prevent the need for retitration. An alternative would include the nasogastric route; however, nasogastric administration of clozapine is culturally less acceptable and less routine than intramuscular in mental health settings. With nasogastric administration, more time is needed in the restraint position, therefore reducing patient safety, and there is a risk the patient could vomit up the medication. The clinical team needs to consider whether the benefits of improvement, possibly in the long term, justify the short-term risks of daily restraint or the complications of using an unlicensed, relatively unused intramuscular drug treatment. Although in our series there were no adverse outcomes from the episodes of restraint, it does not necessarily follow that the procedure is devoid of risk. Our series is unusual compared to the experience elsewhere in that greater number of patients had a much higher number of injections. In the Israeli and Dutch series most patients were established on oral clozapine after one intramuscular dose only, almost all within 2 weeks of starting treatment with clozapine, and only one had treatment for 3 months. It is possible that our sites, which were all secure units, selected for a patient cohort that was more clinically complex and hence more difficult to treat.

In conclusion, given the lack of new treatments for TRS in recent years, it is essential that clinicians deliver the treatments that are likely to work, and clozapine in particular. The intramuscular route can be used to remove one of the impediments to its use, namely refusal of oral treatment. Although our experience was in secure settings, the use of

intramuscular antipsychotic medication is used throughout different mental health settings and there is no reason to suggest that 'enforced' clozapine, whether using the intramuscular or any other route, should be confined to secure services. As was found in the series from the Netherlands and with nasogastric clozapine in the UK, many patients accept oral clozapine when faced with the coercive alternative, which is ultimately the desired outcome. There has been concern that the procedure itself might be aversive and painful; however, reports of injection site pain and inflammation were very low. We have demonstrated that the use of intramuscular clozapine, although not without some drawbacks, is overall easy, safe and effective.

Abstract

Aims and method

To establish whether a dementia intensive support (DIS) service that is part of a crisis resolution and home treatment team for older people is preventing admissions to acute hospital and psychiatric wards. The number of referrals in 2017 to the DIS service was established and those admitted to hospital ascertained. Senior doctors examined 30 sets of notes in detail and reached a conclusion on whether DIS had contributed to admission prevention. This information was then re-examined in two meetings with at least eight senior psychiatrists present. A consensus opinion was then reached as to whether DIS had contributed to admission prevention in each case.

Results

Over 12 months, 30/171 patients (18%) referred were admitted to hospital. For the subset of 30 referrals examined in detail, DIS contributed to admission avoidance in 21 cases (70%).

Clinical implications

Our evaluation demonstrates that the DIS service is an effective way of preventing admission.

Dementia has become a major health concern in older people, with prevalence rates in those over 65 years of age estimated at 7.1%. The overall economic impact of dementia in the UK was costed at £26.3 billion, with an average annual cost of £32 250 per person, in 2013.¹

A quarter of hospital beds are occupied by people with dementia.² Admissions to hospital for patients with dementia are not always preventable but should be avoided where possible, as they are associated with increased length of stay, morbidity and mortality.³

The efficacy of crisis resolution and home treatment teams (CRHTTs) in general adult services is reasonably well established, with a Cochrane review confirming that crisis care was acceptable and less expensive. In addition, repeat admissions were avoided and users of crisis services showed greater improvements in their mental state and reported greater satisfaction than those who received standard care.⁴ However, the evidence base is much slimmer for older people and for people with dementia specifically.^{5,6}

Cambridge and Peterborough NHS Foundation Trust (CPFT) covers the county of Cambridgeshire (including Peterborough) and some small areas of adjacent counties in England. The total population served by CPFT is approximately 1 million people, of whom 165 000 were over the age of 65 at the last census in 2016. There were an estimated 8600 people with dementia in 2016, a number expected to increase to 16 110 by 2031.⁷ We have two regional CRHTT services for older people across the county (CRHTT-OP North and CRHTT-OP South), each covering approximately half of the county. To reduce or prevent hospital admissions, our dementia intensive support (DIS) service in CPFT was set up in its current format in 2016. The DIS service forms part of CRHTT-OP South. The role of the CRHTT-OP service is to support both people with dementia and people with functional health problems in crisis at home or in their community settings. The overall aim of CRHTT-OP South/DIS is to reduce or prevent hospital admissions of older people and to facilitate their discharge from hospital.

In this service evaluation, endorsed by management (authors B.R.U. and R.K.), we sought to examine the effectiveness of the DIS service in the South of CPFT, since additional funds were given to the service in 2016. In 2017, the period covered in this study, the team received referrals mainly from general practitioners who referred to a triage hub,

from the first response service (FRS) – a 24-hour trust-wide telephone triage service which accepts self-referral from individuals of all ages – and from liaison psychiatry services. The minimum guaranteed response time by CRHTT-OP South is 24 h and the maximum is 5 days. CRHTT-OP South usually provides contact with patients for between 2 and 6 weeks. Patients may then be referred onto community mental health teams for ongoing support or back to their general practitioner. Two old age consultants share the work of this team (0.9 whole-time equivalents to CRHTT-OP South) and also share the in-patient work of the functional ward. All clinicians in the team have several years' clinical experience. The team works from 08.00 to 20.00 h, 7 days a week, and operates with two shifts a day; each shift comprises 3–4 community psychiatric nurses, 1–2 community support workers, a team leader (working 09.00–17.00 h on weekdays) and full-time administrative support for the team from 08.30 to 17.00 h on weekdays. Non-medical clinicians usually undertake the initial assessment of all patients referred to the service, with medical support provided as needed. All patients seen receive a comprehensive psychiatric assessment and risk assessment recorded on our electronic notes. In addition, the interventions by the DIS team are noted in the patients' electronic progress records and letters to the general practitioner (GP). Pharmacological (antidementia drugs, antipsychotics, benzodiazepines and antidepressants) and non-pharmacological interventions for behavioural and psychological symptoms of dementia (BPSD) (typically, exploration of the reasons for the behaviour and suggestions of ways to address it, as well sensory and music stimulation and assistive technology, as described in NICE guidelines from 2018⁸ and Alzheimer's Society guidance from 2011⁹) are employed.

We evaluated, using qualitative and quantitative methodology, whether the involvement of the DIS team did lead to prevention of admission to hospital for older people with dementia.

Method

This service evaluation was approved by the CPFT governance committee and did not require ethics approval.

We first examined the total referrals to the DIS service over the year (2107) and recorded the number of admissions to medical and psychiatric wards. Exclusion criteria were referrals that the DIS team felt to be inappropriate (e.g. the patient needed a referral to social care or was not deemed to be in a crisis and was referred to the community psychiatric team) or where the patient was not seen because they were admitted to acute hospital before CRHTT-OP South engagement. All patients had a diagnosis of dementia.

We then invited eight senior psychiatrists (consultants and specialist trainees) to support this retrospective study and to examine the notes to see whether the DIS service had prevented admission to hospital. At the time the patients were seen by CRHTT-OP South, some of these doctors were working in CRHTT-OP South but others were working in the community teams or liaison service or had not joined CPFT yet. All patients referred to and contacted by the DIS team in June 2017 ($n = 12$) and November 2017 ($n = 18$) were included and the outcome of that contact with the CRHTT during that episode of care was noted, together with the number of days in contact with the DIS. The months were chosen at random. Basic demographic data were collected on the patients and the average length of time spent with the DIS team was calculated. In addition, notes were examined by J.S.R. and L.C. to identify the main reasons for referral and the main interventions offered by the team for each of the 30 patients. The frequencies of these reasons for referral and main interventions recorded were noted. The eight senior psychiatrists were asked to evaluate each patient's notes following referral to CRHTT-OP South in these 2 months to assess whether the DIS team had helped to avoid hospital admission (medical or psychiatric). The notes themselves were not anonymised, but J.S.R. ensured that the clinicians were not given patients from areas that they usually covered clinically, to try to avoid bias in their interpretation, and when these patients were discussed by the group this was done in an anonymous fashion to avoid bias as far as possible. Clinicians had to summarise on a pro forma the issues pertinent to the DIS contact and then reach a conclusion as to whether the DIS service had contributed to 'admission prevention'. In cases where patients had been admitted to hospital, it was straightforward to conclude that admission had not been prevented. In cases where the patient had not been admitted, a qualitative judgement had to be made as to whether, from the type of interventions provided by the DIS team (psychosocial or medical), hospital admission had been avoided. The pro formas regarding the DIS team's involvement were then re-examined collectively in two group governance meetings to provide an 'expert consensus opinion' on whether CRHTT-OP South had contributed to admission prevention, with eight senior psychiatrists present at each meeting.

Results

Figure 1 shows the total number of patients referred to the DIS service from January to December 2017 and the number of admissions to medical and psychiatric wards from those referrals. There were 171 referrals during that period, 30 of whom (18%) were admitted, i.e. approximately 1 in every 5 patients referred to the DIS was admitted. Fig. 1 Total referrals accepted by the dementia intensive support (DIS) team over 2017 and numbers admitted to psychiatric and acute (medical) hospitals.

The demographics of the patients whose records were examined in detail by the expert panel are shown in Table 1. The average length of stay with the DIS team was 19 days (range 4–43 days). The ICD-10 diagnoses were: Alzheimer's disease (14 patients), vascular dementia (5), Alzheimer's of mixed type/atypical (4), dementia not otherwise specified (3), dementia with Lewy bodies (2), alcoholic dementia (1) and frontotemporal dementia (1). Four of the patients with Alzheimer's disease were noted to also have delirium and one patient with Alzheimer's of mixed type was noted to have delirium and alcohol dependence. Table 1 Demographics of patients with dementia seen by the dementia intensive support team over 2 months in 2017

Month	Sample size, n	Male	Mean age, years	Age range, years
June	126	83	70	–96
November	189	166	–98	–98
Combined	301	582	66–98	–98

The main reasons for referral to the DIS team and their frequency are noted in Table 2. Aggression (verbal and physical) was the most common reason for referral but often several reasons were noted. The key interventions that were recorded in the electronic notes and the frequencies of these are also summarised in Table 2. Combinations of interventions were often offered. Table 2 Reasons for referral to the dementia intensive support (DIS) team and key interventions offered

Frequencies reported	Main reasons for referral to DIS (usually a combination of reasons)	Key interventions offered by DIS team (usually a combination of interventions)
18	Aggression (physical and verbal)	Advice and support for carers
11	Agitation	20 Pharmacological interventions for BPSD
10	Shouting out/disruptive behaviour/entering other residents' rooms	17 Non-pharmacological interventions for BPSD
10	Worsening hallucinations or delusions	16 Referral for increased social support/different care home/respite
4	Sexual disinhibition	9 Supportive counselling/advice to the patient
3	Depression	4 Recommendation of a change to physical health medication
2	Supporting discharge from ward (acute or psychiatric)	4 Admission to psychiatric ward
2	Safeguarding issues	4 Admission to acute hospital
2	Delirium management	4 Recommendation of a move to a higher level of care in the same care home
1	Suicidal in the context of a new diagnosis of dementia	1 Fall prevention
1	Carer burnout/stress	1 Delirium assessment management
1	Key interventions offered by DIS team (usually a combination of interventions)	1 Educational programme for care home
1		1 Benefits advice to carers

Table 3 shows the number of patients for whom admission was considered to have been avoided by DIS engagement, as well as the average across both months. There were some discrepancies (three in total) between the initial assessor's views and those of the group in deciding whether an admission had in fact been prevented by DIS engagement with the patient. The group view prevailed and is quoted in Table 3. In our qualitative judgement, the DIS service contributed to admission avoidance for 21/30 patients referred (70%), averaged over the 2 months. Table 3 Admission avoidance over 2 months in 2017

Month	Admission avoided (group decision)	Admission avoided (initial assessor's view)
June	11/12 (92%)	10/18 (56%)
November	10/18 (56%)	21/30 (70%)
Combined (June and November)	21/30 (70%)	21/30 (70%)

Discussion

Our service evaluation shows that over a 1-year period only few referrals received by the DIS service were admitted to medical or psychiatric wards (18%). We conducted a qualitative review of patients referred in 2 months of the year using a panel of senior doctors. These doctors examined 30 referrals to DIS in detail to judge whether DIS had contributed to admission prevention. The panel felt that the DIS service contributed to admission avoidance for 70% of patients referred to the service in these 2 months.

Strengths and limitations

Previous criticism of crisis and home treatment studies centres on the definition of a 'crisis' and whether all referrals would in fact meet 'thresholds' for admission. This study sought to circumvent this issue to some extent by examining whether patients in crisis who were seen by CRHTT-OP South had received an intervention from the team which contributed to admission prevention. However, we acknowledge that the discussions that took place among the panel of senior clinicians were of a qualitative nature and subjective. However, the strength of this methodology was that the decisions were not left to a single clinician but were examined by a group of senior clinicians and decision makers in the service.

Although we tried to minimise bias by giving the assessing clinicians patients not from their own teams and by anonymising data when discussed as a group, sometimes clinicians may have recognised the patient under discussion from the particulars of the clinical history, which could have introduced some bias. A further limitation is that this is a naturalistic study and it is possible that not all of the interventions offered were recorded. Only the major interventions identified by the authors examining the notes (J.S.R. and L.C.) have been noted.

The wider evidence base

We acknowledge that case-control studies are needed to be sure of the efficacy of DIS services. Such studies are very difficult to set up as most services now have some form of crisis or intermediate care service to prevent admission of people with dementia to hospital, and services frequently change structure or function over time.

The most recent systematic review of the literature on crisis team management of dementia in older people, from 2017, describes the results of six cohort studies and one case-control study.⁵ However, several studies include both patients with functional and psychiatric disorders, making direct comparisons with our study more difficult. A positive effect on factors such as reducing the number of hospital admissions, readmissions, length of stay and mortality rates was reported in these studies. However, caution needs to be exercised in interpreting the review's findings as the studies were small, of variable design and sometimes lacking in statistical rigour.⁵ There was only one case-control study (from the USA) in which a non-randomised concurrent control treatment outcome trial was conducted.¹⁰ This study reported a lower mortality rate, a significant decrease in hospital readmissions (with people remaining in their homes for longer), significant improvements in caregiver outcomes ($P < 0.001$) and fewer neuropsychiatric symptoms for those in the intervention group. It is difficult to be sure how reproducible this service would be in the UK. In addition, the control group did not seem to be similar to the intervention group as they were more likely to die in the first year, suggesting that they may have been a more physically ill group from the outset. Further case-control studies in the UK are needed to establish whether DIS teams are effective in reducing admissions. Our own previous cohort study is one of the few to examine this question before and after the introduction of an ageless CRHTT in the UK,¹¹ but it did not examine crisis services for patients with dementia specifically (all crises for older people were included) and other service changes may have affected the result.

Service implications

Commissioners of our service have enthusiastically endorsed the approach of crisis and home treatment: indeed, ‘at home is best’ is the top priority for the Cambridgeshire and Peterborough Sustainability and Transformation Partnership (STP).¹² This has been reflected in additional investment in DIS teams as one of the key areas for the STP investment fund. This study shows that very few patients referred to our service over the year required hospital admission. Admission cannot always be prevented and of course the reasons for in-patient admission to psychiatric or acute hospital are notoriously complex to analyse (and beyond the scope of this study), involving specifics of particular patients, carers and clinicians. Supportive measures (such as care packages, medication and explanation about the management of delirium) may help to support carers and prevent acute hospital admissions. However, these patients were all referred in crisis and, although some were excluded by our expert panel as not reaching the threshold for the DIS team having contributed to admission prevention, many were helped by interventions from the team. The DIS team has therefore proved to be a worthwhile asset to our service.

We thank Dr Ian Rowbotham, CRHTT consultant in the North of CPFT, for advice and discussion in the early phase of the project, and Christie Walker for administrative support. We thank the librarians at Fulbourn Hospital Library for help with the literature search and sourcing paper.

1.3.46 Supporting people in mental health crisis in 21st-century Britain

Andrew Molodynski Stephen Puntis Em Mcallister Hannah Wheeler Keith Cooper¹

Correspondence

Andrew Molodynski

(andrew.molodynski@oxfordhealth.nhs.uk)

date

2020-12

Abstract

Recent years have seen a surge in interest in mental healthcare and some reduction in stigma. Partly as a result of this, alongside a growing population and higher levels of societal distress, many more people are presenting with mental health needs, often in crisis. Systems that date back to the beginning of the National Health Service still form the basis for much care, and the current system is complex, hard to navigate and often fails people. Law enforcement services are increasingly being drawn into providing mental healthcare in the community, which most believe is inappropriate. We propose that it is now time for a fundamental root and branch review of mental health emergency care, taking into account the views of patients and the international evidence base, to ‘reset’ the balance and commission services that are humane and responsive – services that are fit for the 21st century.

Contents

- *Supporting people in mental health crisis in 21st-century Britain*

Recent years have seen a surge of interest in mental healthcare. Media columns, royal endorsements, prominence in policy and legislative agenda all point to the gradual erosion of stigma surrounding mental illness. However, the most recent Care Quality Commission report on mental health services showed that services still struggle to provide people with the help they need, with 40% of National Health Service (NHS) providers being rated as poor or requiring improvement in the most fundamental domain of all, safety.¹ Although this is widely acknowledged, it has not as yet been remedied and is particularly problematic in the management of so-called mental health crises.

Emergency medical services still operate on the historically established principles developed during the birth of the NHS, with a single means of emergency transport to large accident and emergency (A&E) departments staffed and equipped to largely deal with physical problems. This was entirely understandable in an era when few treatments were available for mental health crises and few people presented to services, but it has become increasingly outdated over time. A significant and rising proportion of A&E attenders come with a mental health crisis of some sort.^{2,3} Many community mental health services (for all age groups) are increasingly stretched owing to a period of significantly rising demand, and the relatively flat workforce is leading to more people presenting in crisis as we are less able to intervene early and avoid such presentations. It is important to bear this wider picture in mind while thinking about emergency mental healthcare.

There have been welcome developments in emergency mental healthcare, including crisis teams,^{4,5} but these are generally restricted to those already under secondary mental healthcare, with only one service in England to our knowledge

being genuinely ‘open access’, with people able to just turn up and be seen. Otherwise, people must go through a general practitioner, the police, or A&E. Indeed, many crisis services have shrunk in recent years, with providers being ‘freed’ from adhering to the evidence-based care of the national service framework and operating under reduced funding.⁶ Many struggle to offer a fast and flexible service to those in need in the face of increasing demand, and many people are discharged early from hospital or not admitted owing to chronic NHS mental health bed shortages.

Other developments have included police street triage services,⁷ which despite their name often support people in mental health crises in their own homes as well as in public places. Their introduction has come alongside a welcome drop in the use of police custody for up to 24 h under section 136 of the Mental Health Act, although overall section 136 use has not seen such reductions.⁸ However, these welcome reductions in police custody use are not universal and cannot solely be attributed to triage services, as both legislation and policy have also substantially changed.⁹ Street triage services vary markedly; while being part of a crucial safety net, they operate alongside police officers, which consumes significant police time and means that for many the response to their health crisis comes in a police car – a marked contrast to physical care, and distressing and stigmatising for many.

Other welcome initiatives include places where people in crisis can drop in and receive support, generally from staff employed in the charity/third sector. Terminology varies (crisis café, safe haven, etc.), as do mode and hours of operation. Again, provision is variable and few such places, if any, are open 24/7. We could find no empirical evidence for their effectiveness or specific service models or components of models.

The result of all the above is a patchwork of provision developed during isolated attempts to patch up the problem of mental health crisis response rather than developing system-wide solutions. They make crisis care hard to negotiate for anyone, let alone people in distress and their families. It is widely agreed that the current evidence base is poor.^{2,10–12} We need to ask ourselves some fundamental and difficult questions. Are busy A&E departments the right place for those in crisis, such as those at risk of suicide or self-harm, or those with symptoms of psychosis? Are uniformed police officers the correct response to people in distress who have not acted unlawfully? Why are there so many cracks in provision that people can, and do, fall through during crisis?

We believe a root and branch review of crisis services based upon evidence from this country and overseas is needed. This should be guided by those who receive services and their families, alongside those who provide them. Such a process could move our mental health crisis services (belatedly) into the 21st century. We need to be bold. Initial evaluations of dedicated mental health ambulances in Sweden that work on a similar basis to their physical counterparts are encouraging, with much demand and favourable reports of patient experience.¹³ In Australia, projects of peer-to-peer support with care packages to avoid hospital admission have shown encouraging results.¹⁴ We need to evaluate the current movement of crisis cafes and safe havens rigorously, both in terms of effectiveness and of models that work (or don’t).

The NHS long-term plan (www.longtermplan.nhs.uk) has an ambitious vision for emergency mental health services in particular, with improved access and greater patient focus. It also promises a bolstering of services for people with severe and enduring mental illnesses, and that out of area placements (OAPs) will end. Unfortunately, a very recent NHS report¹⁵ has shown that OAPs are actually rising again. However, detailed analysis of spending commitments and the current worsening workforce problems in all disciplines makes it clear that these worthy ambitions cannot be realised without a step change in our thinking about and our valuing of mental healthcare. This, alongside the review of mental health legislation and the universal acknowledgment that services are inadequate, means that now is the time to invest in the future by taking a considered and evidence-based approach to decide what should be available to provide the best experiences of care and the best outcomes. To continue with our ongoing *ad hoc*, piecemeal approach does our patients a disservice.

1.3.47 The emotional and mental health needs of young carers: what psychiatry can do

Roswitha Dharampal Cornelius Ani¹

Correspondence

R. Dharampal

(r.dharampal@doctors.net.uk)

date

2020-06

Abstract

Aims and method

To review the literature on the emotional and mental health needs of young carers of parents with mental illness and the extent to which such needs are recognised and supported by professionals. Three databases were systematically searched from 2008 to 2018, and five studies met the inclusion criteria.

Results

The key findings were that young caregivers had a significantly higher dose-response mortality risk than their peers; were at increased risk of mental health difficulties, especially where the ill family member was a parent and had mental illness or misused substances; were overlooked by professionals owing to a lack of awareness; but could derive benefits from their caring role when appropriately supported.

Clinical implications

Young carers are at increased risk regarding emotional and mental health needs; this risk could be mitigated by professionals recognising the young carer's role and including them in their parent's treatment plan.

Background

Societal awareness of young carers and the potential effects of caring on their health and development has increased in the past 20 years.¹ A ‘young carer’ is ‘a child or young person under 18 who provides regular or ongoing care and emotional support to a family member who is physically or mentally ill, disabled or misuses substances’.^{2,3} The 2011 Census in England and Wales showed that 166 363 children in England cared for their parents, siblings or family members, an increase of 20% on the number recorded in the 2001 Census.^{4,5} However, this was thought to be an underestimate.² The prevalence of informal caring in the underage population was estimated as a minimum of 2–4% in Western countries.⁶

Dearden and Becker reported that most young carers cared for parents, particularly mothers, although some provided support for grandparents, siblings or other relatives. Tasks undertaken by young carers included housework, general healthcare – for example, assisting with mobility or giving medication – intimate personal care such as bathing or toileting, and emotional support.⁷ Emotional support by young carers was more likely to be offered to parents with a mental health problem.^{7–10} Caring responsibilities ranged from a few hours a week to over 100 in extreme cases.¹¹

Half of all conditions supported by young carers involved physical health, but almost a third (29%) were for mental health problems, while 17% related to learning difficulties and 3% were for sensory impairments.^{7,12} Extrapolating from these figures suggested that 55 000–60 000 children in the UK cared for a parent with mental illness.¹³ According to 2018 estimates for England, 3.7 million children aged 0–17 (31.7%) were in a household where a randomly selected adult had at least moderate mental health symptoms, including 1.6 million (13.5%) where the adult had severe mental health symptoms.¹⁴

For psychiatrists, the young carers most likely encountered in work are those of their adult patients with mental illness. Estimates in Australia and the USA of the proportion of people accessing mental health services who were parents ranged from 20 to 60%.^{15–18} In the UK, the majority had common mental disorders such as depression or anxiety, but some (0.5%) had a psychotic condition.¹⁹ According to recent UK estimates, parents comprise at least 25% of adult mental health patients with significant interpersonal/personality difficulties, including 63% of women with psychosis and 25% of adults in acute psychiatric hospital settings.²⁰

The 2011 Census in England and Wales showed that one in eight young carers was under the age of ten, and some were as young as five.⁵ According to Canadian research among youth aged 15–24 years, females accounted for the majority of carers, and there was an increasing feminisation of care as youth aged, the differences being most acute at the highest care levels.²¹ It was suggested that this pattern was similar to that in the UK and Australia.^{7,10,21} A further UK survey suggested that young carers were 1.5 times more likely than their peers to be from Black, Asian or minority ethnic communities, and twice as likely to not speak English as their first language. They were 1.5 times more likely than their peers to have a special educational need or a disability.¹¹

How the young carer and parent were viewed often depended on the disability or diagnosis, such that having parents with mental health problems was presumed to pose more adverse challenges.¹ Young carers were often considered as a homogenous group; however, it has been argued that those caring for a mentally ill parent could experience particular risks and needs. Studies from several countries have found that children of parents with a mental illness were at a greater risk of poorer outcomes than their peers,^{22,23} with higher rates of mental illness²⁴ and poorer development in behavioural,^{25,26} social,²⁷ and academic²⁸ domains.²² According to Pakenham and Cox, the presence of any family member with an illness was associated with a greater risk of mental health difficulties for young people, relative to their peers from ‘healthy’ families. This risk was further elevated if the ill family member was a parent and had mental

illness or abused substances.²⁹ In the UK, parental mental ill health was a significant factor for children entering the care system.³⁰

Aggregated data suggested that a child had a 30–50% chance of developing a serious mental illness if they had two parents with mental illness.³¹ A child of a parent with an affective illness had a 40% chance of developing an affective disorder by age 20, compared with a 20–25% risk in the general population.^{32–35} However, the increased risk noted in these studies may have a multifactorial aetiology.

It has also been argued that younger carers can sometimes overcome the effects of extreme adversity³⁶ with information, recognition of their role, and inclusion in their parent's treatment plan. Studies suggest that some young carers may even derive some benefit from their caring role.

Aim

The main aim of this literature review was to explore the emotional and mental health needs of young carers and their circumstances, particular those related to their parents' mental health. The review also explored the extent to which the needs of young carers were recognised and supported by the psychiatrists and other professionals working with their parents.

Method

The PRISMA guideline³⁷ was followed to search three databases (EMBASE, Medline and PsychInfo), which are accessible from the Royal College of Psychiatrists library. The search covered 2008–2018 using the terms 'emotional health or emotional stability or psychological health or social psychology or mental health' and 'young carers' or 'young and carers' or 'young caregivers' or 'young and caregivers'. Boolean operations and truncations were employed to allow for alternative endings in the keyword searches. The search was limited to the past 10 years in order to focus on more recent developments in the field, which are more likely to be relevant to current practice. Additional literature was accessed through contact with the authors of some of the papers, a charity that supports young carers, and references from retrieved papers.

Studies were included if they were published in English and involved a primary study published in the past 10 years that identified the emotional and mental health needs of young carers and had a minimum of 14 participants. The latter criterion was based on the fact that very small sample sizes would limit the generalisability of results to the wider young carer population.³⁸ Four hundred and eighty-eight abstracts were identified; initial screening identified 43 relevant studies, whose full texts were assessed. Finally, five studies were selected (*Fig. 1*). *Fig. 1* Study selection

Results

The literature review focused on five recent papers published between 2013 and 2018 which investigated the emotional and mental health needs of young carers, the circumstances which gave rise to them, current psychiatric practice and possible improvements. One study³⁹ was census-based, retrospective and longitudinal. The others, reflective of the majority of studies in the search, were qualitative and recorded the experiences of young carers. The papers showed the increased and particular needs and risks of young carers of a parent with mental illness, with one study identifying what it referred to as a 'young carer penalty'.³⁸ The census-based study further found a higher mortality risk among young carers.³⁹ The shortcomings of mental health services in their consideration of young carers were also raised. The studies are summarised in *Table 1*. *Table 1* Summary of studies reviewed

Census-based mortality linkage study

Northern Ireland Caregivers aged 5–24 yearsYoung caregivers more likely than non-caregiving peers to report chronic poor mental health. They also differed from older caregivers and were at significantly higher mortality risk than peers. Dose-response relationship between hours devoted to caregiving and mortality risk evidentYoung caregivers at significantly increased risk of poor health outcomes

A study by Pakenham and Cox examined differences in adjustment between children of a parent with an illness and peers from ‘healthy’ families, controlling for whether a parent or non-parent family member was ill, the illness type, demographics and caregiving.²⁹ The study was questionnaire-based and had a total sample of 2474 youths, comprising those from ‘healthy’ families = 1768 and those from families with parental illness = 336, other family member illness = 254, and both parental and other family illness = 116. The youths, aged 9–20 years, were recruited in Queensland, Australia, mostly from schools. However, recruitment also took place through church groups (*n* = 35), scouts (*n* = 23), university vacation care (*n* = 13), and a young carer association (*n* = 42) in order to achieve more diversity in the sample.

The youths completed questionnaires to obtain information on their age, gender, home postcode, employment, dual-versus single-parent family, number of siblings and ethnic background. An eight-item family responsibilities subscale of the Young Carer of Parents Inventory⁴⁰ was used to assess youth caregiving. A range of positive and negative youth adjustment outcomes were assessed by behavioural-emotional-social difficulties, somatisation and health. Positive adjustment outcomes were assessed by family satisfaction, life satisfaction, positive affect and pro-social behaviour.

The results showed that the presence of any family member with an illness was associated with greater risk of mental health difficulties for youths compared with their peers from ‘healthy’ families. Using Cohen’s effect size conventions, the effect sizes for the significant outcomes for parental illness group ranged from small (0.22) to very large (1.0), but they were uniformly small for the ‘other family members’ illness group (range 0.08–0.18). This risk of poorer adjustment was elevated if the ill family member was a parent and had mental illness or misused substances. The latter risk held even when caregiving and demographic factors were considered. Incidentally, caregiving itself was associated with poorer adjustment in six of the seven outcomes considered, even after controlling for illness type and a range of sociodemographic factors.

Parental illness and illness in other family members were both significantly associated with more negative outcomes compared with ‘healthy’ families for all but two outcomes. The effect of ‘parental illness’ was significantly larger than for ‘other family member’ illness for all but one outcome, although the effect sizes were small. However, as these data were cross-sectional, the associations may not be causal, as it is also possible that the additional risk attributed to caregiving may be confounded by other unmeasured factors such as genetic influences.

A recent study³⁹ investigated the association between caregiving and health/mortality risk in young caregivers when

compared with non-caregiving peers and older caregivers. They used a census-based record to link all residents enumerated in the 2011 Northern Ireland Census with subsequently registered deaths data, until the end of 2015. Among those aged 5 to 24 years in the 2011 Census, approximately 4.5% were reported to be caregivers. The presence of a chronic physical and/or mental health condition was measured through the Census, and all-cause mortality was assessed by official mortality records.

This study found that young caregivers had a significantly higher mortality risk than their peers (adjusted hazard ratio = 1.54, 95% CI: 1.10, 2.14). A dose-response relationship between the hours devoted to caregiving duties and mortality risk was evident. Young caregivers were also more likely to report chronic mental health problems than their non-caregiving peers (adjusted odds ratio (OR) = 1.44, 95% CI: 1.31, 1.58).

Further, young carers differed from older caregivers, with the odds of reporting poor mental health inversely related to age. Tseliou *et al* maintained that although the majority of studies found that caregiving may be associated with poor mental and emotional health,^{41–44} this had been moderated by growing recognition that older caregivers had a reduced mortality risk compared with non-caregiving peers.^{45–52} At older ages, less intense caregiving was associated with a reduced risk of chronic poor mental health. However, by 25–44 years old, this was reversed such that a positive dose-response association was observed between caregiving status and mental ill-health. This adverse effect was most evident among 5–17-year-olds. In this younger cohort, those providing more intensive caregiving were more than twice as likely as non-caregiving peers to have poor mental health (adjusted OR = 2.46, 95% CI: 1.70, 3.56).

Light caregiving may be associated with a positive effect on physical health, such as fewer chronic mobility problems compared with non-caregivers.³⁹ However, this apparent benefit of caregiving was not observed among younger carers providing higher levels of care. The authors hypothesised that the protective effect of light caregiving, especially for older carers, could be due either to the physical requirements of the caregiving role or an instance of ‘selection into the role’ by healthier individuals.³⁹ To further illustrate the differential effect of care givers’ age, the authors stratified the data by age group (young adults versus children and adolescents) and found that although less-intensive caregiving in the older cohort was associated with 35–40% reduced odds of reporting chronic mobility problems, those aged 5–17 were more likely to report mobility problems (OR = 1.61, 95% CI: 1.16, 2.23).³⁹

Although the census-based study by Tseliou *et al* had unsurpassed population coverage and encompassed many hard-to-reach groups, it was nonetheless limited by the fact that it may have missed a disproportionate number of young adults and caregivers in deprived inner-city areas. Also, the proxy nature of census returns makes it likely that the parent or guardian completed the ‘self-assessed’ health question, which might have led to confounding, although not for mortality risk.

The literature search identified a study which explored the experiences and needs of children living with a parent with young-onset dementia.⁵³ The study recruited 215 patients and their families through memory clinics, regional hospitals, mental health services and specialised day care in The Netherlands. For ethical reasons, inclusion was restricted to children older than 14 years. There were a total of 35 eligible participants living in 29 families, of which 15 agreed to participate. The method involved semi-structured interviews with 14 of the young people, six males and eight females, aged between 15 and 27, with an average age of 21 years. In three families, the mother had dementia. The mean age of the parent was 53.6 years. Five of the parents had Alzheimer’s disease, four had frontotemporal dementia, one had vascular dementia and one had dementia not otherwise specified. Most of the parents had mild to moderate dementia. The type of care the young people provided included housekeeping tasks (cooking, cleaning, and grocery shopping), supervision and social contact.

Semi-structured interviews were analysed using a qualitative inductive content analysis, which revealed three major themes. The first theme indicated the effects of dementia on daily life, including changing relationships within the family, children’s difficulties managing responsibilities while maintaining a life of their own, and children’s concerns about their future. The second theme reflected the different ways the children coped, including acceptance, avoidance, searching for relief and actively dealing with changes. The third theme revealed the need for care and support. Many children wanted to know more about dementia but received little information after the diagnosis from either their parents or healthcare professionals. In addition, they wanted practical guidance in dealing with their parent.

However, the study by Millenaar *et al* was limited by the less-than-optimal representativeness of the sample due to the restricted availability of children in the target population and high refusal rates. The authors acknowledged that these sampling difficulties may have led to an underestimation of needs, because those who were not included may have

found it too demanding to participate in the study or too difficult to talk about their needs.

A qualitative study with young carers and young adult carers in Switzerland further explored the role of communication with professionals about the caring situation.⁵⁴ Interviews were conducted with 16 carers aged 10–17 years and 14 aged 18–25 years. The interviews were recorded, transcribed and analysed following a grounded theory approach.

The study reported that the participants found talking to professionals was often seen as difficult. The young people described situations in which they were simply overlooked by experts from healthcare or social services. It was recognised this generally did not happen because of malicious intent by professionals, but rather owing to a lack of awareness about young carers and their roles and responsibilities.⁵⁵ In particular, getting into contact with healthcare professionals in hospitals seemed to be challenging when young people were the main carer. Information was often withheld by healthcare personnel owing to a perceived need for confidentiality. Some young adult carers had to resort to alternative ways, for example, the internet, to access necessary information when neither professionals nor the care-receiving family member provided it.

In the final study selected for this literature review, a qualitative focus group design was chosen to explore the ‘lived realities’ of young people providing unpaid familial caregiving in Canada.³⁸ Two focus groups and one in-depth interview were held with 15 young people aged 15–19 years, who were current or past members of a formal young carers programme. Participants also completed a short survey after the discussion, representing a form of ‘concurrent triangulation’. Purposive sampling was used to recruit young carers.

Over half the youth provided care primarily to a sibling, with the next largest group caring for a parent, and several caring for multiple family members. The main conditions ranged from substance (alcohol) abuse to terminal cancer to autism, and a high likelihood of comorbidity existed. A diverse range of ethno-racial profiles were captured, with just under half the participants self-identifying as Caucasian and the remaining as Arab, Black, South Asian and Chinese. However, gender imbalance was evident, with only three male young carers in the sample. The author maintained that this partly reflected the conflict boys experienced when discussing or recognising their care contributions. ‘This gendered reticence by young men due to the presumed violation of expected gender roles makes it more difficult for them to get recognition and receive dedicated support as carers’.³⁸

The young carers derived a range of positive benefits, including added maturity, empathy and the strengthening of familial bonds. However, they also incurred a range of difficulties that caused short- and long-term harm to their personal and professional development. Together, these difficulties presented what the author referred to as a ‘powerful young carer penalty’, a term used to highlight the personal (emotional, familial and social) and professional (education and employment-based) disadvantages incurred by the young person’s substantial and ongoing caregiving.³⁸

Discussion

The main aim of this literature review was to investigate the emotional and mental health needs of young carers and their circumstances, particular those relating to their parents’ mental health. It also explored the extent to which the needs of young carers are recognised and supported by psychiatrists and other professionals working with their parents, with shortcomings raised. The review concentrated on five papers that showed the increased and particular needs and risks of young carers of a parent with mental illness. One even found a higher mortality risk among young carers. The findings are further explored here.

According to Pakenham and Cox the type of illness present in the home was associated with differential adjustment outcomes, with mental illness and substance problems associated with more negative adjustments across a range of outcomes.²⁹ They suggested a potential explanation for these findings: that in general, compared with physical illness, mental illness and substance misuse were less understood in the community and more likely to be associated with greater social disadvantage, unpredictability of symptoms, family and social disruption, stigma, discrimination and parent-child attachment difficulties.

These results are similar to findings from previous studies. Cooklin and Hindley suggested that parental mental illness could be responsible for serious interruptions in a child’s cognitive and emotional development.⁵⁶ They cited a list of adversities faced by children affected by parental mental illness, which could affect their emotional life, attachment and development. These included the ill parent’s disordered thinking and behaviour, the loss of emotional closeness and the witnessing of distressing side-effects of treatments.⁵⁶ According to Mechling, many children witnessed or had to

assist their parent in a mental health crisis, such as a suicide attempt, psychotic episode or aggressive state,⁵⁷ leading other authors to highlight that this was a responsibility beyond young people's years.^{8,58,59}

Millenaar and colleagues discussed the influence on the daily lives of children of parents with young-onset dementia. Children felt that the child-parent bond was inverted as their parent became increasingly dependent.⁵³ There was more tension at home due to the stress of the caring process and changes in the parent with dementia. They witnessed strain on a healthy parent, had difficulties adjusting to the behavioural, cognitive and personality changes in the parent with dementia, and had to contribute more to the household. Millenaar *et al* also suggested that parents of young carers were not always aware of their child's needs.

Similarly, according to Stamatopoulos, substantial caregiving by young people affected their joint familial, social and emotional well-being. Numerous young carers revealed strained familial bonds, often linked to a real or perceived inequality in the provision of care, in addition to limited opportunities for socialisation outside the household. A heightened sense of missing out created strain on existing friendships and was tied to an inability to partake in social outings outside school.³⁸ Unbalanced friendships, resulting from parental-role spillover, further strained young carers' existing peer network.

Pakenham and Cox hypothesised that the elevated mental health problems in children of a parent with illness relative to those from healthy families were due to their extra caregiving demands.²⁹ However, they found that the effects on youth adjustment of a family member with serious illness were not attributable in the main to factors such as differential access to community services, being in a sole parent family, the age or gender of the youth, or increased caregiving responsibilities, although all these factors were implicated in adjustment outcomes. They acknowledged that the absence of significant interactions in their results was not consistent with a previous study,⁶⁰ where a complex set of potential moderators including age of children, socioeconomic status and single parenthood were identified. Stamatopoulos also found that the severity of the 'young carer penalty' was associated with two key factors: family size and type of condition requiring care. Specifically, participants from single-parent and single-child families generally incurred a greater 'penalty', as did those providing care in the context of more stigmatised illnesses such as mental illness and substance abuse, and/or more debilitating physical illness or disability.³⁸

In their study on the variation of caregiver health and mortality risk by age, Tseliou *et al* proposed a number of reasons that caregiving may be deleterious to the health and well-being of young carers.³⁹ Providing care could have interfered with schooling and the formation of healthy social networks, thereby creating issues with other aspects of social and emotional development and leading to a problematic transition to adulthood. The authors suggested that many of the positives associated with caregiving at older ages may not hold true for younger ages. At older ages, where activities such as paid employment no longer applied, caregiving may provide a purposeful role that tightens interpersonal bonds appropriate to expectations of both age and existing relationships, and may be seen as a natural progression, with positive caregiving attributes being associated with lower mortality risk. At younger ages, the expectations of role relationships and function are different, and significant caregiving responsibilities are likely to be at variance with perceived social norms. In contrast to older ages, young caregivers may feel constrained in undertaking a role they had little choice in accepting and that they considered inappropriate for their age. The authors highlighted that the feeling of duty to provide care has been linked to high caregiver burden and worse outcomes among child caregivers.

Leu *et al* raised the failure among professionals to identify young carers and some potential causes of their health and emotional difficulties.⁵⁴ Although many parents may have had an earlier diagnosis of, for example, depression, bipolar disorder, schizophrenia or personality disorder, they may later have gone unnoticed by services.⁵⁷ A secure attachment between child and parent could have been undermined if the parent was inadequately treated or supported.⁶¹ When treatment did occur, clinicians may not have asked whether the adult client had children, and, if parental status was discussed, the focus of treatment was on the adult and the child's needs may have been overlooked.⁵⁷ Millenaar *et al* found that professionals in contact with families often failed to identify children as providers of informal care because they did not ask about their caring role.⁵³ A Royal College of Psychiatry report recognised that professionals may have agreed that offering support to the children of their patients was important but often felt this was not their role, and their natural sympathy and alliance with their patient may have led to 'blindness' about the needs of the child.³³ Staff in mental health teams or in-patient services may have seen themselves as solely the 'patient's person'.⁶² Some may have seen it as above or outside their expertise or responsibility, and therefore the province of someone else's responsibility.⁶² Wolpert *et al* maintained that the needs of young carers had been traditionally overlooked, falling between adult and child mental health services. However, Child and Adolescent Mental Health Services only see a small proportion of

children affected by parental mental illness.⁶²

Cooklin suggested that for some young carers, the involvement of services can sometimes worsen aspects of their experiences. Even though a young carer had often been managing the situation for months, no one asked their advice, what they knew about their parent's illness, or what made it better or worse.¹³ Ali *et al* found that young carers received several kinds of information about mental illness and advice about what to do as long as the person with the mental illness was within the healthcare system, but as soon as they were discharged, support for the young carer ended too.⁶³ Despite the statutory requirement in the UK that mental health services elicited the views of children and young people about the care plans for their parents' treatment, relatively few were talked with directly about the nature of the illness.⁶² McAndrew *et al* cited young carers' experience of their relative being discharged from hospital but no one explaining about changes in their medication, the administration of which had previously been the young carer's responsibility.³⁰ Similar to other young carers, some children of parents with young-onset dementia were not included in conversations with healthcare professionals after diagnosis.⁵³

Not all children of parents with a mental illness reported poor outcomes.^{22,38} Dearden and Aldridge maintained that there were positive aspects of caring for children and parents, as long as support services were in place which adequately addressed the needs of all family members. These positive aspects included enhanced maturity, responsibility and independence, life skills, increased understanding about disability issues and stronger family ties.⁶⁴ According to Fraser and Pakenham, this led to the development of a resilience model whereby the potential harmful effects of risk factors were mitigated by the influence of protective factors. Interventions should therefore focus on targeted modification of risk factors such as isolation, while promoting protective factors including independence and psychosocial skills.²²

Bilsborough reported ten demands of mental health professionals by young carers, of which the top three were (a) introduce yourself, (b) tell us who you are and what your job is, and (c) give us as much information as you can.⁶⁵ Cooklin identified what children said they needed: a two-way explanation of the parent's illness' access to a neutral adult with whom the child could discuss the illness and contact in times of crisis, and who could act as the child's advocate; an opportunity for the child to address their fears that they would 'catch' or that they 'caused' the illness or that the parent may die from it and/or they might not see them again; interventions to diminish the child's social isolation, to learn they are not the only one with the problem, and to allow them to meet other young people with similar experiences; and rebalancing the child's inverted role as carer, including opportunities to do childish or youthful activities with other young people and sharing the load of responsibility with one or more adults.⁶² However, Cooklin warned of the dangers of offering counselling unless the child explicitly accepted the idea of therapeutic help, as this might increase their unwelcome sense of identification with the ill parent and define them as on a similar pathway.⁶²

It was noted that family work or therapy has become more available within adult mental health services.⁶² Thus, a 'whole family approach' model, developed in the UK has begun to be the dominant paradigm internationally. In an NHS England presentation, Cooklin recommended that all psychiatric adult care plan assessments should establish: knowledge of all children face to face; who if anyone has assessed the needs of the child or the effects of the parent's illness on them, and what if any referral needs to be made; and who has explained the patient's illness to the child.⁵⁶

In the UK, the Care Act 2014 and Children and Families Act 2014 provided statutory recognition for young carers' entitlement to regular assessments of their ability and suitability to provide care, and, importantly, of the effects of the role on them.⁶⁶ Of note, the UK alone was classified as 'advanced' in an international comparison of awareness and policy responses to young carers.⁶⁷ The UK was advanced in terms of awareness, research, law, social policy, government guidance and service delivery. No country was identified as having developed extensive awareness or sustained or sustainable policies. The analysis noted that the reality in most countries is that young carers still fall through gaps in policy and legal safety nets.

Limitations

The main limitation of studies in this review was the absence of intervention studies relating to young carers. Most of the studies were qualitative and recorded the experiences of young carers and professionals in contact with them. Although the qualitative studies were limited by small sample sizes, resulting in poorer generalisability of their findings, they had the strength of seeking out more detailed and in-depth accounts.²¹ The review was limited by searching only three main databases. Also, the search was limited to recent papers published in the past 10 years. Finally, only the first author applied the selection criteria.

Conclusion

This literature review found that children and adolescents who cared for a parent with illness may be at higher risk of a range of emotional and mental health needs. Those who specifically care for a parent with mental illness could be at an increased risk, possibly owing to the potential for a more disordered relationship with the parent as a result of their mental illness. However, it is argued that such adversities could be mitigated with the help of information, recognition of the young carer's role, and their inclusion in the parent's treatment plan. Internationally, the UK appears to afford the most recognition to young carers. However, many young carers in the country are still falling through the net because mental health professionals who treat their parents fail to recognise the significance of young carers. Changes in practice to address this are crucial.

We thank Dr Ananta Dave, Medical Director, Consultant Child & Adolescent Psychiatrist, Lincolnshire Partnership NHS Foundation Trust, for continual support as Fellowship Supervisor; Dr Peter Byrne, MD MRCPsych, Consultant Liaison Psychiatrist, Royal London Hospital and Associate Registrar RCPsych for Public Mental Health; and Dr Alan Cooklin, FRCPsych, Consultant in Family Psychiatry and founder of Our Time, a charity for the children of parents with mental illness, for advice; Our Time for use of its resources; and Shaun Kennedy, Librarian, Royal College of Psychiatrists, for undertaking the literature search.

Abstract

¹ Declaration of interest: None.

Aims and method

Northern Ireland presents itself as an anomaly – a region in which only 31.8% of doctors enter into any training programme after completion of the Foundation Programme, but where Core Psychiatry has been consistently oversubscribed. Here, we aim to find what other regions can learn from this success. All doctors of any grade, working in psychiatry, who had been through the Foundation Programme were questioned on their motivations for becoming a psychiatry trainee.

Results

Sixty-two doctors currently working in psychiatry responded, including over 60% of current trainees, and 45% stated they had not considered a career in psychiatry before their foundation attachment. Over 80% preferred foundation placements in FY2 only, rather than in either foundation year 1 or FY2.

Clinical implications

This survey identifies that for the majority of people who ultimately chose to train in psychiatry, in a region that has consistently attracted candidates to core and higher level training, completion of a foundation psychiatry post was an influencing factor in this decision. A strong majority of doctors prefer the foundation psychiatry placement to be offered in FY2.

 - *Discussion*

Recruitment into core psychiatry training in the UK has been a longstanding area of concern.¹ Despite the success of the Royal College of Psychiatrist's 'Choose Psychiatry' scheme and the subsequent increase in the fill rate in 2018,² there still remains 18% of posts that are not filled nationally. There are, however, variations based on geographical area, with Northern Ireland consistently achieving a 90–100% fill rate at core recruitment.

Following the Collins Review³ in 2010 highlighting the need for more community foundation placements and the Royal College of Psychiatrists recruitment strategy⁴ of 2011, one option put forward was to increase exposure to psychiatry during the Foundation Programme. A target was set to have 22.5% of all foundation year 1 (FY1) and 22.5% of all foundation year 2 (FY2) doctors offered placements in psychiatry. Northern Ireland is the only region of the UK that does not offer any placements in FY1, but it does offer a 4-month psychiatry placement to approximately 33% of FY2 doctors.

In this survey we aimed to explore why psychiatry doctors working in Northern Ireland chose their specialty and whether having a psychiatry foundation post in FY2 influenced their career choice. We also examined the opinions of

the doctors who chose psychiatry following an FY2 placement on when psychiatry should be offered in the Foundation Programme.

Method

Participants

The participants for this survey were doctors working in psychiatry in Northern Ireland who had completed Foundation Programme training since its establishment in 2006. This consisted of a group of psychiatry core trainees, speciality trainees (in all areas of psychiatry) and consultants.

Survey design

The survey was designed using the SurveyMonkey online questionnaire system, following collaboration between the Northern Ireland Foundation School and the Northern Ireland School of Psychiatry.

The survey questionnaire (*Fig. 1*) consisted of 12 questions establishing baseline demographic data with regards to gender, medical school, year of graduation, current grade, year entering into core psychiatry training and, if applicable, year entering specialist training in psychiatry. There were questions that established the trajectory of foundation training and if this was planned, coordinated by the UK Foundation Programme and the duration of their foundation programme. Respondents were asked if they had considered a career in psychiatry before selecting their foundation programme and what may have influenced their decision in this (i.e. undergraduate experience, training reputation). The respondents were then asked if they had a psychiatry placement in foundation training and if they agreed with the statement, 'After completion of a psychiatry post within foundation training I was influenced to pursue a career in psychiatry'. The final question was examining the preferences of respondents in the option of having psychiatry available as a preference in FY1 (which is not currently offered in Northern Ireland but is offered in other parts of the UK). The nature of the survey resulted in retrospective data being collected. Fig. 1 Survey questionnaire. FY1, foundation year 1; FY2, foundation year 2.

Distribution

It was an open and voluntary survey. The survey was populated via an email from the current Head of School of Psychiatry to all doctors who had been enlisted in psychiatry training from 2006 (i.e. after the first full 2-year cycle of the Foundation Programme). The survey was open for 3 weeks. This email list was obtained from records within the School of Psychiatry at the local deanery (Northern Ireland Medical and Dental Training Agency; NIMDTA). Reminders were sent via email and social media to encourage completion. The survey was sent to 92 psychiatry trainees and 25 specialty doctors/consultants; as updated lists of consultant emails are not held by the deanery, emails may not have reached all the doctors who were no longer in training, so the figure of 25 is approximate.

Analysis

Following the closure of the online survey, the results were collated in their entirety for evaluation by the authors. Quantitative data was exported to Microsoft Excel 2016 (v.16.0) for analysis. As a portion of the data was from 'white space' or free-text questions and thus qualitative in nature, these were assessed for common themes.

Results

A total of 67 participants responded to the survey, and demographic data is represented in *Table 1*. Of the 12 questions, 7 were answered by all respondents (questions 2, 3, 4, 6, 7, 8 and 10). Of the remaining questions, there were 66 responses, with the exception of one in which there were 65 responses (question 11). The majority of the respondents were female ($n = 42$, 63.6%). *Table 1* Demographic data Total ($n = 67$) Gender Female 42 (63.6%) Male 24 (34.3%) Current grade Specialty trainee 32 (47.8%) Core trainee 26 (38.8%) Non-trainee doctors (i.e. consultant, specialty doctor) 9 (13.4%) Foundation scheme 2-year planned programme 60 (89.5%) Recruited to a 1-year standalone FY2 programme 5 (7.5%) Other 2 (3%) Psychiatry placement in Foundation Programme In FY13 (4.5%) In FY2 (first placement) 33 (49.3%) In FY2 (second placement) 13 (19.4%) In FY2 (third placement) 11 (16.4%) No psychiatry placement 10 (10.4%) Considering psychiatry before Foundation Programme Yes 37 (55.2%) No 30 (44.8%)²

A high proportion of respondents had completed their undergraduate training at Queen's University Belfast ($n = 62$, 92.5%) and year of graduation ranged from 2006 to 2016. The vast majority of respondents had completed their foundation training within the deanery in Northern Ireland, NIMDTA ($n = 63$, 94.0%).

The majority of respondents were in training; almost half of respondents were currently in specialty training ($n = 32$, 47.8%), with a slightly smaller percentage in core training ($n = 26$, 38.8%). Consultants made up a small proportion ($n = 7$, 10.4%), with a smaller number of specialty doctors and associate specialists ($n = 2$, 3%). *Figure 2* shows the distribution across training levels. *Fig. 2* Grade breakdown of participants, $n = 62$. LAS, Locum Approved Service; LAT, Locum Approved Training; SAS, Specialty and Associate Specialist; ST, Senior Trainee; CT, Core Trainee.

The year of entering core psychiatry training ranged from 2007 to 2017, and year of entering into specialty training ranged from 2011 to 2018 for those that this was applicable to.

The vast majority of respondents were recruited through the Foundation Programme UK system on a planned 2-year Foundation Training Scheme ($n = 60$, 89.6%). A small number ($n = 5$, 7.5%) were recruited through the Foundation Programme UK system on a single 1-year FY2 programme.

The majority of participants had a foundation placement in psychiatry ($n = 60$, 89.5%). The breakdown of when participants had their placements is shown in *Table 1*. Those who had a psychiatry placement in FY1 had completed their foundation training outside of Northern Ireland.

When asked if they had considered a career in psychiatry before selecting their foundation programme, 55.2% of respondents ($n = 37$) reported they had and 44.8% ($n = 30$) reported they had not. When asked what influenced their decision to choose (or not choose) to pursue a career in psychiatry before commencing foundation training, the most commonly cited theme was undergraduate experience of psychiatry ($n = 47$, 70.1%). Generally, the majority of respondents who cited this as a factor reported a positive contributor ($n = 34$, 72.3%) toward their choice to pursue psychiatry as a career. The second most commonly cited factor was the positive reputation of psychiatry training in Northern Ireland ($n = 20$, 29.9%). This factor encompassed the positive reputation of training and also of having positive interactions with trainees and consultants in their undergraduate training. The third most commonly cited factor positive influencing people's decision to enter psychiatry was of having an interest in the subject ($n = 11$, 16.4%).

Other less commonly cited positive factors were of having a qualification in a related field (such as psychology), enjoyment of a psychiatry locum post, the expectation of a positive work–life balance over the course of their career, media and mental health group influences and future job prospects.

The most commonly cited reasons that led people originally to not consider psychiatry as a career was a negative or

ambivalent undergraduate experience ($n = 13$, 19.4%) Those that were negative or ambivalent reported not enjoying their experience, feeling daunted by how different psychiatry was from other medical specialties and also by their experiences in in-patient settings in undergraduate training.

Exposure to negative opinions of psychiatry in placements in other specialties was also cited as a reason people did not consider psychiatry. In response to the statement 'After the completion of a psychiatry post within foundation training I was influenced to pursue a career in psychiatry', the majority of respondents agreed with it ($n = 60$, 92.%).

The final questions gathered the views of respondents as to whether psychiatry should be offered to FY1 doctors. The majority of respondents ($n = 54$, 81.8%) felt that psychiatry should only be offered as an FY2 rotation in the Foundation Programme. By far the most commonly cited reason for this was to allow for the development of general skills and improve general medical and surgical knowledge in FY1 ($n = 42$, 77.8%). Many felt this to be important as often psychiatry units were isolated from acute hospitals and out-of-hours work in psychiatry is often non-resident with senior assistance also being non-resident. One respondent felt that a job in psychiatry for an FY1 may not be representative of a psychiatry experience as the doctor would likely complete more administrative and medical tasks. Another respondent felt that FY2 was when doctors are more likely to be considering their career options.

For those who reported wishing to have a psychiatry placement in FY1 ($n = 12$, 18.2%) the most common reason for this was that it would give doctors earlier exposure, which may encourage them to apply for psychiatry ($n = 8$, 80.0%). Some reported they had missed an application process owing to having psychiatry as their last rotation in their FY2 year. Two respondents reported that psychiatry would be useful in FY1 to give doctors early exposure to a more holistic care approach.

Discussion

This survey adds to previous findings⁵⁻⁷ that exposure to psychiatry in foundation training is a powerful tool in recruiting doctors to work in the field. Remarkably, of doctors working in psychiatry in Northern Ireland, 45% had not considered a career in psychiatry before their foundation placement, and 92.31% went on to agree with the statement 'After the completion of a psychiatry post within foundation training I was influenced to pursue a career in psychiatry'.

Doctors working in psychiatry spoke positively of the undergraduate experience and the close local ties between the medical school and the deanery in establishing a programme that encouraged them to apply. Northern Ireland has one medical school, Queen's University Belfast, of which around 70–80% of foundation doctors working in Northern Ireland graduate from.

In considering recruitment strategies, the proportion of those who are attracted after undergraduate level should not be underestimated: in a survey including 51 core trainees, Denman *et al*⁸ found that most chose psychiatry during their foundation placement as opposed to as an undergraduate, a finding that resonates with our conclusion of the importance and influence of foundation training experience to the specialty's recruitment. There has been extensive research into the factors that affect recruitment into psychiatry and our findings are similar to those identified in previous studies.⁹

The importance of a positive experience of psychiatry in medical school has been highlighted in numerous studies. Mukherjee *et al*¹⁰ identified the significance of a genuine interest in the subject as being important to recruitment and proposed that the way some undergraduate placements are structured (mainly in acute in-patient settings) expose students to complex patients who are potentially the most unwell, perhaps resulting in a skewed perception of those with mental illness. They highlight the need for more doctors to complete foundation placements in psychiatry and that the process of choosing a specialty within a year of qualifying disadvantaged psychiatry in terms of recruitment, it being a career choice for 'late bloomers'. This was specifically highlighted in our study with one participant missing the application window owing to not having a psychiatry placement until the end of their foundation programme, forcing them to wait a further year before applying. They also identified a perception that psychiatry was less scientific and of lower status than other areas of medicine as an important factor with regards to negatively affecting recruitment.

Given the unique cohort of doctors in Northern Ireland, we looked to establish what attitudes were toward the current approach of having 100% of psychiatry placements in FY2. An overwhelming 81.82% felt that this was what they would personally choose. They speculated that a FY1 doctor may be seen as the 'medical doctor' and may not get the same breadth of experience of acute psychiatric care as an FY2 doctor.

This survey identifies that a strong majority of doctors prefer the foundation psychiatry placement to be offered in FY2, from a region that has consistently attracted candidates to core and higher level training. As a region without an FY1 placement, the generalisability of the results must be considered as a weakness of the survey. It could be argued that those who stated that they would prefer psychiatry in FY2 have limited frame of reference for such an argument.

We believe there are a number of reasons that could help explain why recruitment in Northern Ireland is higher than in other regions in the UK. As we have already alluded to, there is a sense of collegiality in Northern Ireland with regards to the speciality. Northern Ireland has one medical school, one medical training body and one Royal College of Psychiatrists headquarters, allowing for the promotion of psychiatry to be streamlined and coordinated between these entities.

There has been a concerted effort to promote psychiatry in undergraduate training and to ensure that this is of good quality. Medical students have a 6-week placement in psychiatry in their 4th year and also opportunities earlier in their studies to partake in psychiatry-themed, student-selected modules. Enthusiastic psychiatry trainees are also visible within the undergraduate teaching, delivering teaching sessions to a variety of undergraduate years, promoting the speciality from the start of the curriculum. Queen's University produces proportionally more psychiatry doctors than any other university in the UK, which is indicative of the successes of these efforts.

Following a positive undergraduate experience, more doctors then experience a FY2 placement in psychiatry than in other regions in the UK, which this survey has shown to be an important influencing factor for those not previously considering the specialty. The structuring and delivery of psychiatry training is potentially another important reason why Northern Ireland has higher recruitment figures: psychiatry training has a good reputation in Northern Ireland because of its weekly protected teaching time, with subsequent examination pass rates that are above the national average.

Nationally there is evidence of green shoots in psychiatry recruitment⁹ and there is a momentum being built by the Choose Psychiatry movement. However, there is still cause for concern with recruitment of doctors into psychiatry and continued efforts are needed to build upon the progress already made. Here we show that a strong foundation programme in Northern Ireland, focused on FY2, showcases the specialty as a beacon for recruitment in the UK. This is reinforced by strong links at local university and college level, supported by trainers who buy into personal and professional development and trainees who provide role modelling at an early stage for trainee doctors.

Michael Doris is a higher trainee in learning disability psychiatry with Belfast Health and Social Care Trust, and an ADEPT Leadership Fellow at Northern Ireland Medical and Dental Training Agency, Northern Ireland. **Amy Grimson** is a higher trainee in forensic psychiatry with Belfast Health and Social Care Trust, Northern Ireland. **Damien Hughes** is a consultant psychiatrist working in learning disability psychiatry with Belfast Health and Social Care Trust, and Head of the School for Psychiatry at Northern Ireland Medical and Dental Training Agency, Northern Ireland. **Edel O'Neill** is a consultant psychiatrist working in learning disability psychiatry with Southern Health and Social Care Trust, Northern Ireland. **Lorraine Parks** is a consultant anaesthetist with Southern Health and Social Care Trust, and Associate Postgraduate Dean for the Northern Ireland Foundation School at Northern Ireland Medical and Dental Training Agency, Northern Ireland. **Angela Carragher** is a consultant surgeon and former Associate Postgraduate Dean for the Northern Ireland Foundation School at Northern Ireland Medical and Dental Training Agency, Northern Ireland.

This research received no specific grant from any funding agency, commercial or not-for-profit sectors.

Abstract

Aims and method

We aimed to explore access by Black, Asian and minority ethnic (BAME) elders to the memory services in Leicester and Leicestershire, examining any trends over time. We then compared the odds of referral by ethnicity, using observed versus expected referrals for the city of Leicester. We gathered data on a comprehensive county-wide memory clinic used by people with suspected dementia and memory problems from the Trust electronic record system during the period 2011–2017. For Leicester city, we compared referral rates for 2011–2017 and compared observed and expected referral rates with demographics from the UK Census 2011.

Results

In Leicester, there was a significant underrepresentation of referrals from the BAME population as compared with the White population in 2011, 2012 and 2013, when compared with population estimates of those aged 60 years from the 2011 UK Census Leicester city data. Data for the Black population were too small for comparisons. The odds of being referred to a memory clinic for the White group was double that of the Asian group in 2011 (odds ratio 2.15, 95% CI 1.52–3.02) and nearly 1.5 times in 2012 (odds ratio 1.40, 95% CI 1.01–1.93). This difference did not persist after 2014. However, this differential odds of referral changes when the age difference between the groups is accounted for. After adjusting for age, there were no differences between the two groups in their odds of referral to the memory clinic from 2011 to 2013, but from 2014 to 2017, members of the Asian group had higher odds of being referred.

Clinical implications

The relationship between BAME and access to memory services is complex. The relative lower prevalence of Asian people among referrals to memory services in Leicester from 2011 to 2013 may partly be explained by the lower ages of the Asian population at referral. The higher prevalence of Asian people in 2014–2017 may be owing to use of denominators from the 2011 UK Census, which are likely to be disproportionately low for this group. Further studies are needed to explore any potential barriers to the access of services by BAME communities.

There are an estimated 25 000 people currently living with dementia from Black, Asian and minority ethnic (BAME) backgrounds in the UK.¹ It is estimated that this figure will rise to 50 000 by 2026 and 172 000 by 2051, given the growing and ageing UK BAME population.² This increase parallels the projected increase in the numbers of older BAME people. In 2001, approximately 532 000 people from BAME groups were aged 65 years, and this is expected to rise eightfold to approximately 3.8 million by 2051.³

BAME people are generally underrepresented in dementia services and often present later in the course of the illness⁴; development of appropriate health and social care services to meet their needs has been a longstanding priority. A national study⁵ found that the incidence rates of dementia diagnosis are higher among Black ethnic groups compared with White and Asian groups in the UK. This study reported that the incidence of dementia diagnosis was 25% higher among Black women than White women, and 28% higher among Black men than White men. Asian women and men were 18% and 12% less likely than White women and men, respectively, to have a dementia diagnosis. Vascular dementia is thought to be more common among Asian and Black Caribbean people because they are more prone to important risk factors for vascular dementia, such as cardiovascular disease, hypertension and diabetes,⁶ and some evidence suggests that people from BAME groups present later in their illness.⁷

In the UK there are primary care-based studies estimating the prevalence of dementia diagnosis rates⁸ in BAME groups, but there are not many county-wide studies on mental health services use within secondary care services by people with dementia. UK-based secondary care studies tend to have small population sizes; a recent study⁹ examined data on referrals to an inner London memory service to explore any differences in referral rates, cognitive assessments and stages of dementia at presentation. Although Black and Black British patients comprised a quarter of all referrals, Asian patients comprised only about 2.6% of the referrals. Another secondary care study¹⁰ paradoxically found BAME overrepresentation, but this is the only UK study to find this. Such studies that are small and with seemingly opposite findings suggests that referral patterns may not necessarily reflect the BAME distributions in the local population and could well be representative of other factors. Further, it emphasises the need for studies with larger BAME population samples.

Several qualitative studies have explored why BAME groups may be reluctant to seek professional help for symptoms owing to dementia.^{4,11–13} There are several barriers to seeking help identified for South Asian people. They include patient, carer and community factors, health professional factors and the type of services concerned.¹⁴ Health professional factors include culture and communication, lack of knowledge of dementia, lack of knowledge of available services (including any for BAME groups) and high workload/lack of time. There are several other reported barriers, such as

lack of support, time and financial constraints, stigma, diagnostic uncertainty and disclosure of the diagnosis.¹⁵ Furthermore, interventions raising awareness¹⁶ have not shown much improvement in diagnosis or management,¹⁷ which might suggest an associated reluctance to seek help.

Demographic characteristics of Leicester and Leicestershire

Leicester is unique in the UK in probably now being the only city to have a sufficiently large BAME population (with only 51% reporting themselves as White British) in the UK Census 2011 data; population changes have been affected over time by immigration patterns. Further, Leicester is also unique in having a South Asian population as the majority within the BAME population. Additionally, Leicester has the highest proportion of BAME adults of any city in the UK, with the BAME population being the majority population in some areas. The Leicester data from the 2011 UK Census gave the three main ethnicity estimates in the city to be 51% White, 37% Asian and 6% Black.¹⁸ The Leicester Action Plan 2016/7 estimates that 3000 people aged >65 years in Leicester live with dementia, and this is forecast to increase to about 4500 people by 2030.¹⁹ Estimates suggest that each year about 850 people diagnosed with dementia are from Black and minority ethnic backgrounds.²⁰ Leicester has a high-performing diagnosis rate for dementia of 88.4% of the predicted population value.²⁰

The demographics of Leicester show that the increase in the proportion of those aged >65 years is much greater in the South Asian population than other groups, and that overall, the proportion of this age group from BAME communities will have risen from 31% in 2016 to 40% in 2026.¹⁹ This raises the question of whether local referral patterns reflect the real prevalence of the Asian population among BAME referrals. It provides us with a good opportunity to explore secondary care service use by BAME groups in a setting where the BAME population is high, in a city with only about 51% reporting themselves as White British in the UK Census 2011 data.¹⁸

Aims

First, we wished to examine the access by BAME elders to memory services in Leicester and Leicestershire and examine any trends over time. Second, we aimed to compare the odds of referral by ethnicity, using observed versus expected referrals for the city of Leicester.

Method

Data collection

We gathered data on comprehensive county-wide memory clinic use within mental health services by people with suspected dementia and memory problems. For this we used the Leicestershire Partnership National Health Service Trust (LPT) electronic record system, RiO.

The LPT moved to an electronic system of patient records in 2010 and this included electronic records of all referrals to the memory clinics, out-patient referrals and referrals to the community mental health teams. As a part of a National Institute of Health Research (NIHR) study, the findings of which will be reported elsewhere, we identified all referrals to the LPT memory clinics where patients suspected of cognitive disorders and dementias would be referred and diagnosed. Memory clinics provide assessment for cognitive problems across the city and county to adults referred with suspected memory problems. Patients are offered comprehensive assessments, including standardised tests, brain imaging and neuropsychological tests as needed. Diagnoses are considered by a multidisciplinary team and appropriate treatments and follow-up are arranged as required.

For this study, we report only the findings of ethnicity data and findings related to patients referred to mental health services for the elderly who were referred by general practitioners for memory assessment. Ethnicity was coded as per the National Health Service (NHS) criteria for recording ethnicity data at the time of referrals. We were able to stratify the data according to the ethnicities as recorded on NHS patient-recording systems. The data collected included data for older people referred for a memory assessment, but not those suspected of having a young-onset dementia or cognitive syndromes in younger adults, this information being reported separately. We collected date of referral,

ethnicity recorded at the point of receiving the referral, gender, general practitioner details and whether the case was active or discharged. Age was not routinely recorded at the time of receiving the referrals.

We collected data for 8 years, from 1 January 2010 to 31 December 2017. Analysis used anonymised data from a yearly referral database with LPT maintained for the purpose of service monitoring and includes all the referrals received by the Trust. NHS ethnic data categories include White British, White Irish, Asian or Asian British, Black or Black British, any other White, mixed, Chinese, other ethnic, not known and not stated. We studied patterns yearly to look for any emerging trends.

Ethics approval for this study was granted by University of Leicester as a part of the NIHR study application (reference PB-PG-0416-20019). The study also had approval from the LPT Research and Development Department (ELMH0818; Integrated Research Application System reference 232861).

Age imputation

The age distribution of the entire Leicester city population at risk was already known for 2011 in 5-year age bands. As age was not routinely recorded at the time of receiving referrals, we collected these data only for a sample of randomised individuals. Because we lacked age information for the non-randomised referrals, we decided that it was reasonable to assume that the age distribution for the randomised referrals (in 5-year bands) would be the same as for the non-randomised referrals, and imputed the age data on that basis. So, if a third of randomised White referrals in 2011 had ages in the 80–84 years age band, the same proportion was imputed for non-randomised White referrals in 2011. This resulted in the creation of seven data-sets, one for each year (2011–2017). Age distributions were calculated and created separately for the non-randomised referrals in the two ethnic groups in each year. In each year, the total number at risk was the same, so no account was taken of population growth in those aged 60 years, for which we had no information. The total number at risk in each year consisted of 49 115, with the number at risk being constrained to be constant from 2011 to 2017. The number of referrals in each year was subtracted from the number at risk to give the number of non-referrals. The numbers of non-referrals in the years subsequent to 2011 were not removed from the at-risk group to take into account the fact that the referrals in previous years may no longer have been at risk of being a referral. Having estimated the numbers of referrals and non-referrals in each age band in each year for each ethnic group, we generated these data in Stata version 14 for Windows, using the ‘gen’ command.

Statistical analysis

A separate analysis was performed for each year, and *P*-values were correspondingly adjusted for multiple comparisons with the Bonferroni method (significance level $0.05/n$, two-tailed). Logistic regression was used to compare proportions of referrals between ethnic groups, using 5-year age bands to calculate age-adjusted odds ratios and 95% confidence intervals. Population-at-risk estimates were derived from the published UK Census (2011) data for Leicester. Age was only available in the form of six (mainly 5-year) age bands, ranging from 60–64 to 85 years and was treated in the logistic models as a continuous predictor, ranging from 1 (60–64 years) to 6 (85 years). We used 60 years as the cut-off for population-at-risk estimates, as it is reflective of the age generally used as a cut-off age for population-at-risk estimates in defining older adult services and has face validity in clinical practice. However, beyond 2013 it is highly likely that the denominators for the two ethnic groups will have both increased and also diverged non-trivially, leading to potential biases in the estimated proportions and differences in proportions, so estimates of individual proportions and differences in proportions beyond this time should be treated with caution.

Randomisation

Simple randomisation by a computerised program (SAS version 9.4 for Windows) had previously been carried out from the memory clinic referrals in the White and Asian groups separately, to obtain a representative sample of 260 cases from each group; the ages of referral were then individually collected from those case notes for comparison. The number of Black referrals was too small for meaningful comparisons, and hence this study did not include data for the Black population. All analyses were exploratory.

Results

Over the analysed period, LPT memory services received a total of 15 634 referrals, of which 191 (1.2%) had been entered in error. These included referrals that were deemed inappropriate or had other medical problems present and hence were not suitable for memory clinic assessments. A total of 1493 (9.6%) people had blank values in the ethnicity data rows, whereas 'not known' ethnicity was recorded in 994 (6.4%) people. These missing data were missing at random with no consistent pattern, and were all excluded from the analyses. Formal statistical analyses were conducted on just the two main groups of interest here, namely White British and Asian groups; other ethnic groups and mixed groups were excluded because of the low numbers in each group. Comparisons of the main groups are shown in *Table 1*. *Table 1* Referral data for Leicestershire memory clinics, 2011–2017 Referrals by ethnicity N Gender % Female Percentage of the sample, N = 15 443 Male Female White British 11 1664631653558.572.3 White Irish 152658757.21.0 Asian or Asian British 112847665257.87.3 Black or Black British 141677452.40.9 Any other White 2889319567.71.9 Mixed 35171851.40.2 Chinese 93666.60.06 Other ethnic 37162156.70.2 Not known 99445354054.36.4 Not stated 149365184256.39.7

Despite the overall higher proportion of BAME in Leicestershire compared with many other counties, during the period 2011–2017, of all the referrals across the county, only 1128 were Asian (7.3%) and 142 were Black (0.9%).

The proportion of Asian ethnicity referrals was higher in the city of Leicester (*Table 2*), but it was still only 22.6% compared with the expected Asian proportion of 37% based on the 2011 UK Census data population size estimates. *Table 2* All memory services referrals for Leicester city and county, 2011–2017 Total referrals Referrals White White, % Asian Asian, % Black Black, % City 4182252960.5% 94622.6% 1202.9% County 11 452863775.4% 1821.6% 220.1% Total 15 63411 16671.4% 11287.2% 1420.9%

Yearly comparison of referrals in Leicester city and Leicestershire county

We have presented the referral rates among the three largest ethnic groups over the period 2011–2017 (see *Table 3*). Referral numbers increased consistently in all the groups for part of this period. There were 529 referrals combined in all the three groups in 2011, peaking at 3313 in 2016, but then decreasing to 2033 in 2017. This drop may be explained by the increase recorded in the 'not known' and 'not stated' ethnic categories. White British referrals increased from 461 in 2011, peaking at 2350 in 2015 and dropping to 1337 in 2017. Asian ethnicity referrals also rose from 43 in 2011, peaking at 295 in 2015. Black ethnicity referrals were relatively low throughout, ranging from 5 in 2011 to 25 in 2017. *Table 3* Annual referrals for Leicester and Leicestershire (n, % referrals) White British Asian Black Other White Not known Not stated Total n, % n, % n, % n, % n, % n, % 2011 461, 87.143, 8.15, 0.09, 1.72, 0.32, 0.35292012870, 87.543, 4.34, 0.020,

The proportion of White British referrals fell over this period from 86.9% in 2011, to 65.6% in 2016 and 65.7% in 2017 (*Table 3*). In contrast, referrals from the Asian population remained relatively similar over this period, from 8.1% in 2011, peaking at 9.8% in 2015 and then slightly falling again to 7.2% in 2017. The Black population proportion remained low, rising from 0.09% in 2011 to 1.2% in 2017.

Comparison with Leicester city population estimates

As the raw referral rate data suggested a lower referral rate among BAME groups compared with the White British population, for Leicester city we compared annual referral rates between 2011 and 2017, based on an estimate of the population at risk, derived from the 2011 UK Census. We obtained this population-at-risk estimate by an age-defined cut-off of 60 years, obtained by stratification of the known population estimates taken from the 2011 UK Census data. A cut-off age of 60 years holds greater relevance and reflects the age cut-offs normally associated with the way services reflect clinical practice. We restricted this analysis to Leicester city as the city has a sufficiently large BAME population to make statistical comparisons meaningful. It is interesting to note that the referral patterns from the city rose from 2011, peaking in 2016, but fell again in 2017 (*Table 4*). *Table 4* Comparison between Asian and White groups in Leicester city (unadjusted) 2011 UK Census White Asian Comparison 166 636 122 470 Population at risk ($n > 60$) 34 750 14 365 n Rate per 1000 n Rate per 1000 White (reference) versus Asian, odds ratio (95% CI) 2011 2075.96 402.78 2.15 (1.52–3.02) 2012 1624.66 483.34 1.40 (1.01–1.93) 2013 35710.27 1006.96 1.48 (1.18–1.85) 2014 48513.96 19113.30 1.05 (0.88–1.25) 2015 52615.14 25317.61 0.86 (0.73–0.99) 2016 45213.01 18813.09 0.99 (0.83–1.18) 2017 2657.63 1238.56 0.89 (0.71–1.11) Total 24547.06 9436.56 1.08 (1.00–1.17)

To control for the effects of age at presentation, we compared the White ethnicity and Asian ethnicity groups, using age-adjusted logistic regression over the period 2011–2017 (*Table 5*), with data from each year being analysed separately. There is a clear trend between 2011 and 2015 showing the odds ratio changing increasingly in favour of Asian patients being referred. *Table 5* Comparison of Asian and White groups in Leicester city in 2011–2015, adjusted for age (results 2011–2017) Year Odds ratio (95% CI) for ethnicity

At any given time only a proportion of patients referred for a memory clinic were actively being managed within the service. Some would be waiting for an assessment and some would have been assessed, treated and discharged. To get a fair representation, we compared the numbers of referrals that were considered actively open to see if they matched estimates of patients with suspected dementia in Leicester. As of 2017, there were 932 open cases in the city, with White British cases being 54% of the total. We compared the active cases from the three groups with their at-risk estimates in Leicester city (based on the Leicester 2011 UK Census). Statistical comparison of active memory clinic use data shows significantly lower use by BAME groups. The odds of being actively open to the memory clinic were 1.67 (95% CI 1.42–1.96; $P < 0.0001$) times lower in the Asian population (24% of active cases compared with the 40%

²

Reference category for ethnicity is Asian (coded as 0). Age is modelled as a linear and continuous variable, so for 2011, for every rise in age category (5-year bands), the odds of being referred increase by a factor of nearly 3. After Bonferroni correction for multiple comparisons (0.05/14), the adjusted significance level becomes 0.003, so all results for 2014–2017 are significant.

of total at-risk Asian population estimates), whereas the odds of being actively open to the memory clinic were 2.72 (95% CI 1.79–4.15; $P < 0.0001$) times lower for the Black population (among the 2.4% of active cases compared with the 7% of total at-risk Black population estimates).

Discussion

Referrals of patients to memory services in Leicester and Leicestershire have increased fourfold over the period 2011–2017, although the drop of 39% between 2016 and 2017 is not easy to explain. We found that Asian people represented 22.6% of all the memory service referrals in Leicester city and 1.5% within the county of Leicestershire. The Black population appears to be severely underrepresented among referrals to the service.

Referrals from White British groups rose sharply from 2011 to 2014, but then stabilised. Interestingly, the referrals from the BAME groups have correspondingly not increased, suggesting the role of other factors (i.e. access difficulties, immigration changes) that need to be accounted for. However, this could be partly explained by the higher proportion of ‘not known’ or ‘not stated’ ethnicity groups. The role and the nature of the assessments in memory clinics have also perhaps changed over these times, with increasing awareness of the newer concept of minimal cognitive impairment and changes to the assessments of cognitive issues associated with functional illness and/or physical illnesses. There could also be influences arising out of the National Dementia Strategies²¹ and the changes within primary care (such as Quality Outcomes Framework targets)²² or the changes in costs associated with anti-dementia drug prescribing. This may mean that the population presenting to memory clinics for assessment may have altered in its composition over the years, with a greater emphasis on early assessment for cognitive problems. Administrative reasons may affect data collection, explaining the higher ‘not stated’ scores, and perhaps political influences affect the ethnicity documentation or the ‘not known’ scores. We suspect these uncoded data may also affect the ongoing activity and open case contacts, and may need to be taken into account when interpreting the results.

In this study we demonstrate underrepresentation of Asian ethnicity groups in Leicester city memory clinic referrals in 2011, 2012 and 2013 when we compare them with unadjusted population-at-risk estimates derived from the Leicester BAME demographic data from the 2011 UK Census. However, this difference can be explained by the finding that the Asian population is younger than the White population at the time of the referral. After adjusting for age, there were no ethnic differences between the two groups in their odds of being referred to memory clinic before 2014, from which time the denominators become increasingly unreliable. Age is thus the more important predictor of being referred to memory services. For every rise in age category (5-year bands), the odds of being referred increased by a factor of around 1.5 to 3. There is a clear trend between 2011 and 2015 showing the odds ratio changing in favour of Asian people being referred. There may be two main reasons for this. First, this is likely to be because of the denominator for the Asian population increasing more than the denominator for the White population, leading to increasingly high numbers at risk for Asian people relative to White people. However, we could not take this into account in the analyses as the data which could confirm this are not available. Second, it is also possible that the clinical presentations in this group may be such that general practitioners feel more inclined to refer to memory clinic for a specialist assessment. We cannot identify any other factors that might change the likelihood of Asian people being referred compared with White people, regardless of the number at risk, and there are no changes that we can identify in referral methods or local clinical practices.

As far as we know, this is the first comprehensive study of BAME referral rates at a county-wide level within secondary care services. Although there have been other studies looking at secondary care memory clinic use, they have been confined to district or borough levels, often covering a few memory clinics and community mental health teams. This study’s strength is that it covers the whole of Leicester/Leicestershire, which has multiple memory clinics and covers all the community mental health teams in the county. By that nature, our study is comprehensive and cover practices across an entire healthcare system.

Reinforcing the findings from other UK studies, our findings also suggest underuse of services by BAME groups within secondary care memory services; however, the lower odds in the BAME group of being referred to services may be explained by their lower ages at the time of referral. The odds of getting referred to memory services are changing, with the odds ratio favouring Asian people being referred in the latter years of the sequence. However, this finding is likely to be owing to underestimation of the population at risk for this group. This is an important finding as Leicester has a very high BAME (chiefly Asian) population in inner city areas and so arguably has sufficient BAME populations

to study trends in service use by BAME (chiefly Asian) groups. A study such as ours helps in adding substantively to findings in this area, where there have previously been contradictory reports.

Our findings reinforce the need for more in-depth research to identify reasons for varying presentation of BAME patients in memory clinics and mental health services across different regions and also across different generations.

Limitations

Despite the comprehensiveness of the study, the numbers in the BAME population in Leicester are relatively small. It is possible that with greater numbers and larger studies across regions, the outcome may be different. Moreover, Leicester's geographical and historical immigration patterns are unique and a similar study elsewhere may have different findings. Consideration should also be given to the role of the primary care physicians and the diversity of the ethnic backgrounds they may come from, which could affect referral practices. A major limitation is using the age data from the 2011 UK Census to adjust rates beyond the year of the census. The population profile would have changed since the 2011 UK Census data estimates, and comparing the referral rates in the latter years with this data would limit its applicability, but the 2011 UK Census data remains the last officially published national estimates of UK population data. Also, an at-risk population with an alternate cut-off age other than 60 years may result in different findings.

There may be other reasons apart from age and ethnicity that could also explain the underrepresentation of BAME patients in our sample. Additional missing variables relate to physical morbidity and health service use elsewhere (e.g. acute physical health services), traditional cultural practices and reluctance in seeking help from Western services, the role of the extended family system, and the perception of the inevitability of dementia and it being seen as a part of normal aging decay. The barriers these pose should be explored in further studies.

This study is limited by the way ethnicity is coded by NHS staff at the point a referral is received. Further, the categories have been broadly classified; not analysing further subtypes of ethnicity and its clinical implications may be a limitation, but it was beyond the scope of this study. Similarly, there are changing migration patterns and intergenerational differences, which again are beyond the scope of this study.

In light of these limitations, caution is needed in interpreting the findings. BAME groups by their nature are heterogeneous and subject to constant change, owing to cultural, immigration or political influences. BAME groups may vary in different geographical regions and may be affected by other factors, such as economic indicators and deprivation. It is possible that the BAME groups in Leicester may be economically not as deprived as in other areas such as the north of England, and the pattern of referrals to memory services in such areas may be different. Furthermore, there are intergenerational effects and as such a repetition of this study in the coming decades may reveal different findings.

Future work

Future work is needed to carry out additional investigations into any perceived barriers to help-seeking in BAME populations. We are currently in the process of undertaking an NIHR-funded study to look at diagnostic challenges and the severity of presentation of dementia in BAME populations, and this will be reported in due course.

Leicestershire Partnership NHS Trust provided support with access to data and information. The University of Leicester supported with intellectual and research support.

Abstract

Medical recruitment and retention are national problems. Psychiatry has been more affected than many specialties, as a result of stigma from the public and other healthcare professionals. The Royal College of Psychiatrists has undertaken several initiatives to redress this, notably the ‘Choose Psychiatry’ campaign. In this editorial we argue that student-led university psychiatry societies are a wonderful but frequently untapped resource to help attract the brightest and best medical students to our profession. We describe the activities of three ‘Psych Socs’ across the UK and propose next steps to continue this work.

2019 saw the best psychiatry core trainee recruitment for some years, with 92% of places filled.¹ However, the figures for higher training remain a concern, with a cumulative fill rate of 52% and considerable regional variation in both core and higher training.¹ Staff recruitment and retention remain key challenges across the National Health Service,² with overall vacancies predicted to double by 2030.³ Psychiatry has historically faced unique difficulties, not least stigmatising attitudes from the public, other doctors and medical students,⁴ and we need to remain active and focused on attracting the brightest and best to our profession. The time at medical school is a key period when attitudes and beliefs about psychiatry are most susceptible to change,⁵ and students' personal experience of psychiatry has been described as the 'critical variable' in recruitment rates.⁶

A survey by Curtis-Barton and Eagles⁷ reported 'push' factors that discouraged students from choosing psychiatry as a career, including a perceived lack of scientific evidence underpinning diagnoses, the perception that patients generally have a poor prognosis, the amount of 'paperwork' in the specialty and general stigma about mental illness. A qualitative study conducted at the University of Bristol echoed these findings, adding that the emotional burden of seeing patients at the lowest point of their lives and the focus on 'non-medical' social issues were also reasons reported by students choosing not to pursue psychiatry.⁸

Psychiatry and general practice have been shown to attract most negative comments or 'bashing' from academic staff, doctors and students.⁹ Halder *et al*¹⁰ found that across 18 medical schools, 16% of medical students considered psychiatry as a future career upon entering medical school; by the final year 17% reported still seriously considering it, but only 3% had decided to actually pursue the specialty. A total of 27% of students reported that they had changed their future specialty choice as a result of 'direct bashing'.⁹ By the latter years of undergraduate study, the point at which many students begin direct psychiatry teaching, many more medical students held negative beliefs about the specialty less adaptable to change.^{11,12}

Conversely, a positive experience of a psychiatry rotation and extracurricular enrichment 'pull factor' opportunities, such as engaging electives and special study modules, can ignite an interest and have been found to be one of the strongest predictors of career choice.^{5,10}

Royal College strategies

The Royal College of Psychiatrists (RCPsych) has attempted to tackle both push and pull factors. In 2016, it ran the 'Anti-BASH' campaign,¹² utilising the Twitter hashtag '#banthebash' to identify and address badmouthing, attitudes and stigmatising in healthcare, in particular from clinicians in other specialties.

More recently, the College has emphasised positive pull factors, offering free Student Associate membership¹³ to the College and providing free access to network events and College journals.¹⁴ The 'Choose Psychiatry' campaign¹⁵ has adopted a strategy of demonstrating the many positive aspects of a career in psychiatry, with the use of short video-clips encompassing real-life patient stories and the impact that psychiatry has made on their lives, as well as pieces by psychiatrists explaining why they chose and enjoy their careers. This encourages viewers to join the conversation on social media, using the hashtag #choosepsychiatry.

The 1-year 'Psych Star' scheme supports medical students through mentoring and financial support.¹⁶ A 2-year 'Foundation Fellowship' offers a parallel route for foundation year doctors, with both schemes supporting candidates to act as local ambassadors for promotion of the specialty. Although it is not possible to causally link these efforts and the recent improved recruitment, we should still acknowledge the College's work to achieve this result.

Psychiatry societies

A less-explored area is the momentum generated by university psychiatry societies (Psych Socs), which are led by students with support from clinicians and the RCPsych. These bottom-up initiatives host diverse local events with the aims of raising the profile of mental health issues, challenging stigmatising attitudes by increasing understanding of the central role that psychiatry has in medicine and inspiring students to choose psychiatric careers. They also come together annually for a national Psych Soc conference, hosted by one of the organisations. Here we describe the types of activities undertaken across three UK societies, in London, Birmingham and Belfast.

Augmenting the syllabus: guest lectures and exam practice

The societies host diverse free guest lectures across the range of psychiatric subspecialties complementing and extending the undergraduate curriculum. Mukherjee *et al*⁵ argued that placing a particular focus on liaison psychiatry during undergraduate teaching allows students to appreciate that psychiatry has a central role in the aetiology and outcome of many medical disorders. In our Psych Socs, we have had particularly positive experiences when collaborating with other university societies to promote this understanding (see *Box 1* for more detail): for example, gastroenterology societies to discuss eating disorders; paediatrics and obstetrics and gynaecology societies to discuss perinatal psychiatry, autism and neurodevelopmental disorders; emergency medicine societies to learn about patients presenting in crisis; and oncology societies to discuss psycho-oncology. Some Psych Socs also organise additional examination practice, for example via mock OSCEs and history-taking workshops, as well as providing more links and discussion around psychiatry electives and research opportunities. *Box 1* Examples of well-received Psych Soc events ‘Evolution and the brain’, discussing how brain functioning and psychopathology can be understood using evolutionary perspectives. ‘Real people sharing real stories’, five students shared their personal experiences of living with mental illness. ‘Time to put the psychedelics back into psychiatry?’, a discussion on psychedelics in modern psychiatry. ‘Trauma and violence’ with trauma surgeons, a psychiatrist and young victims of knife crime discussing post-traumatic stress disorder. ‘Through the lens’ mental health photography workshop with the Health and Humanities society, discussing the portrayal of borderline personality disorder in the arts. Psychiatric themes in Don Quixote and Othello syndrome in ‘A Winter’s Tale’ ‘Homelessness and healthcare’ with individuals who had been street homeless, describing how this impacted their ability to access care, and their experiences of living in the streets. ‘Disfigurement and quality of life’, with maxillo-facial surgeons and psychiatrists discussing the impact of facial surgery on perceived quality of life. ‘Mental health in developing countries’ hosted by psychiatry trainees and ‘Students for Global Health’, discussing different practices in other countries, and career opportunities in international assistance. ‘Not guilty by reason of insanity’, exploring the roles of forensic psychiatrists. ‘Mental disorder and autonomy: classical and romantic perspectives’, a seminar co-hosted with a Philosophy Society discussing varying philosophical views of mental illness across time. ‘Sex and psychiatry’ seminar with the university ‘Sexpression’ group, discussing psychiatric bases for dyspareunia, tocophobia and so forth.

Talks on novel fields not typically covered in lectures are usually very popular, such as evolutionary psychiatry, psychosexual medicine and cutting-edge research (for example, therapeutic use of psychedelics). These have the additional value of attracting a wider range of medical students who might not attend more ‘standard’ psychiatry talks, and indeed are often enriched by pulling in students from different disciplines, such as philosophy and the arts, and members of the local community. This reinforces a message of mental health at the centre of medicine and society, and challenges stigmatising attitudes.

Crucially, as membership is open to all students, these events are great opportunities to attract pre-clinical medical students several years before their psychiatry teaching and placements, and potentially before more significant exposure to any ‘psychiatry bashing’.

Tackling stigma and discussing student mental health

Brown and Ryland¹⁷ emphasised the importance of involving people with mental health disorders in student education, particularly those who have recovered, as placements are often too short for students to experience this. Psych Soc speakers are encouraged to explore relevant case studies, and we endeavour to invite speakers with lived experience. One Psych Soc has published a single-arm pre–post comparison study, which demonstrated statistically significant reductions in student stigma in the domains of knowledge, attitude and behaviour following exposure to a perinatal event when a mother spoke of her personal journey.¹⁸

Students can feel less able to disclose their own mental health problems because of perceptions of peers' negative views,¹² and successful Psych Soc events have also discussed and promoted resources for student well-being especially during examination periods. Psychiatrists have helped with this, with events on 'Mental Health in Healthcare' and 'Bipolar Disorder: Don't Believe Everything You Hear' hosted by health care professionals who themselves have recovered from psychological problems.¹⁹ This also addressed psychological challenges and pressures students might face once qualified.

Work in the arts

Broader Psych Soc initiatives involving the arts have proved very popular. These have included a student film and book club (one in conjunction with the local psychiatry trainees' book group) and exploring the perception of mental illness in popular literature and media. Popular talks have discussed the portrayal of psychopathology in historic literature, such as Othello syndrome in 'A Winter's Tale' and wider psychiatric themes in 'Don Quixote'. The 'MedFest' film festival is a popular international event for Psych Socs and mental health more broadly, displaying and discussing short films that touch on pertinent issues in mental health.

Dissemination through new tools: social media

Psych Socs successfully use a range of social media, from Facebook to Twitter and Instagram, and more 'old-fashioned' email to reach students. These regularly share information regarding wider opportunities, such as summer schools (unlike many parallel schemes in other specialties, most of these are free), RCPsych events, prizes and bursaries, student-selected components in psychiatry, research and elective opportunities and so forth. They also provide guidance and encouragement to students on becoming College Associate Members of the College, and advertise College resources, articles and podcasts. Anecdotally, many students have informed us that Psych Soc posts on social media have alerted them to opportunities of which they had previously been unaware.

In October 2019, Queen's University Belfast 'Mind Matters' Psych Soc hosted a highly successful 1-hour 'Twitter Takeover'. Numerous psychiatrists and other Psych Socs across the country participated, answering questions on how medical students can get involved with psychiatry early, personal reasons for choosing psychiatry, upcoming events and interesting books and articles relevant to students. Twitter in particular affords an opportunity to engage and connect with the many psychiatrists and medical students online, unhindered by distance.

Starting a Psych Soc

Medical students and psychiatrists interested in starting a Psych Soc at their own local university should firstly endeavour to recruit a core committee of students for the academic year. The committee should attempt to make contact with the Undergraduate Lead for Psychiatry at their university, the RCPsych regional division and other local psychiatrists. Such contacts may be called upon to act as speakers at evening lecture events, mock OSCE examiners and mentors.

Psych Socs should also contact the RCPsych to receive funding for events, as each university society receives a grant of £500 per annum. The College also offer free promotional material such as pens, key rings and leaflets, which can be handed out as 'freebies' during events. The RCPsych website includes detailed advice for setting up a local Psych Soc, event ideas and contact details for useful stakeholders.²⁰

Psychiatrists' perspectives and next steps

As senior clinicians, we recall the difference that enthusiastic and passionate trainers, teams and rotations made to our career choices at all stages, from medical school through to our own training.²¹ Sadly, we have also all experienced the negative effect of 'bashing' of psychiatry and our patients by other medical students and doctors. All psychiatrists need to remain proud advocates for our profession and remember that every contact counts. The recent College initiatives for recruitment appear to be paying dividends with the positive message of 'Choose Psychiatry' particularly pleasing.

The Psych Socs, however, speak to students in a way we cannot, and it is heartening to see the positive energy they generate. Enthusiastic medical students deliver the compelling message that psychiatry is a mainstream part of medicine and offers a diverse and rewarding career and a flexible work–life balance. Their bottom-up initiatives relevant to their local teaching and training, identification of gaps and novel areas they wish to explore, and the fun, interesting and culturally broader events in turn have refreshed us. The Psych Socs typically offer compensation to speakers through covering their expenses, but in our experience the real payment is the pleasure of sharing and contributing to their enthusiasm.

Several next steps can be recommended both locally and nationally. Students require enthusiastic engagement from local psychiatrists: as guest speakers, mock OSCE examiners and mentoring via 'buddy schemes'. The relationship should be reciprocal: assisting students with areas they request as needing redressing, but also using our contacts and experience to suggest and link-up additional input. Students often need discrete guidance in organising events and making sure that these are well balanced in the views that are expressed.

Nationally, the RCPsych has created a supportive linking webpage to share ideas and learning; this and the annual National Student Psychiatry Conference need to be nurtured and grown. In a time of austerity, there are inevitable challenges about 'who funds' travel and attendance, but medical schools and the College need to continue to encourage and maximise subsidised student engagement, including through poster presentations, oral presentations, student sections and prizes. This is not just a 'central' issue, it falls to all divisions and faculties to review their engagement. We propose that Psych Socs are an excellent opportunity for outreach to catch the best future colleagues. As a College we need to be better at recognising, celebrating and sharing what is working with our medical students. A recently published RCPsych report²² makes explicit recommendations for a range of initiatives on enhancing interest in psychiatry, including developing medical student psychotherapy schemes and Balint groups, and better working with Psych Socs. The College's Choose Psychiatry Committee has an initiative to make sure that each Psych Soc for the next academic year has a link senior member of the Committee to help support local initiatives.

We believe that university Psych Socs are a secret, but as yet not fully exploited, tool to improve recruitment into psychiatry, as well as promoting respect for the profession and mental health amongst those who do not become psychiatrists. They offer a valuable opportunity for students and psychiatrists to work together, and for us to continue to encourage the brightest and best to join what we know to be the most rewarding of medical specialties.

1.3.51 What neuroscience has already done for us

: Commentary on... Why hasn't neuroscience delivered for psychiatry?

Lindsey Isla Sinclair¹

Abstract

Each of the components of the biopsychosocial model of mental illness is important for understanding mental illness. Biological and genetic abnormalities have been demonstrated in major mental illnesses. These are leading to changes in our understanding of these conditions, as well as our understanding of the link between life events and mental illness.

As readers will be well aware, the biopsychosocial model has underpinned psychiatry for several decades.¹ Each component of this model is important for our understanding of mental illness. Professor Kingdon is therefore correct to say in his interesting editorial that neuroscience is unlikely to hold all of the answers to why people develop mental disorders and when they occur in their lifetime.² I challenge, however, his assertion that 'biological changes have yet to be shown to be relevant to the major mental disorders'.

Brain imaging and schizophrenia

Taking schizophrenia as an example, there are clearly demonstrable differences in the brains of individuals with schizophrenia compared with those of controls. It was first shown in the 1970s that people with schizophrenia had enlarged cerebral ventricles.³ Since then abnormalities in both grey and white matter have been convincingly demonstrated in the disorder.⁴ More sophisticated brain-imaging techniques have allowed the discovery in recent years that differences in brain volume are present even in medication-naïve individuals with first-episode psychosis.⁵ It seems increasingly likely that there are differences in volume even before the at-risk mental state, although this remains difficult to prove definitively.⁶⁻⁸

Recently developed scientific techniques such as the use of induced pluripotent stem cells to create a ‘cortex in a dish’ (*aka* brain organoids) have allowed tantalising insights into why these imaging abnormalities may emerge. Using cells from individuals with schizophrenia (some with a range of predisposing genetic abnormalities) multiple studies have shown abnormalities such as impaired cellular differentiation and synapse formation.⁹⁻¹¹

These studies add to the emerging hypothesis that the brain of someone at risk of schizophrenia differs from controls at an early stage and that these differences increase as psychosis emerges. These neuroscientific findings are a good fit with the long-standing findings from more psychosocially focused research that differences can be seen in childhood behaviour in those who later develop schizophrenia.¹²⁻¹⁵ They also suggest that, to develop better treatments for schizophrenia, we need to look beyond compounds targeting dopamine receptors.

Genetics in intellectual disability and depression

I would also challenge Professor Kingdon’s assertion that no genetic findings of use to the practising psychiatrist have been found for the major mental illnesses. Genetic testing for copy number variants is starting to form part of practice in intellectual disability services.^{16,17} Using his example of depression he is correct to say that the much vaunted candidate genes studied in the 1990s and 2000s have not been replicated in later, large studies.¹⁸ However, more recent, vastly better powered studies have produced findings of greater potential use. The most recent genome-wide association study on depression found 87 independent loci that were associated with depression, with a startling lack of genes involved in the 5-HT system.¹⁹ This may suggest that, although drugs acting on the 5-HT system are effective in treating depression for many people, disturbances in 5-HT are not the cause of depression. Findings such as these are likely to be of great benefit in developing new treatments.

Epigenetics and treatment targeting

Neuroscience can also help us to explain the link between life events, which are frequently assessed in psychosocial research, and mental health outcomes. For example, epigenetic studies have shown that maternal behaviour influences the expression of genes, including those involved in the glucocorticoid stress response.^{20,21} Because this work was done in rats it was possible to demonstrate that this effect was not genetic as it was abolished by cross-fostering with more affectionate mothers.²¹ Childhood maltreatment such as physical abuse has long been recognised as a risk factor for mental illness. Recent genetic and epigenetic studies are helping us to understand why some people are more resilient to the effects of this abuse than others.^{22,23} It has been suggested by some authors that this information could be used to better target childhood interventions, such as providing more intensive interventions to those likely to be least resilient to the effects of childhood maltreatment.

Conclusions

Our understanding of mental health problems has started to change radically in the past few decades. It is only 50 years since it was widely believed that parents could be responsible for their offspring developing schizophrenia.²⁴ Within the past 50 years patients with intractable epilepsy were cared for in psychiatric hospitals, something that would now be unthinkable, and the parent–child relationship was seriously considered as a cause of epilepsy.^{25,26}

This improvement in understanding has the potential to reduce stigma, to ultimately lead to new treatments and to provide patients with a better understanding of what is happening to them and why. It is critical that mental health researchers work together, rather than in methods-based silos, to further improve our understanding of why and how patients develop mental health problems.

1.3.52 Highlighting some of the challenges COVID-19 has posed to the European Convention on Human Rights

Oluwatoyin A. Sorinmade

date

2020-08

Contents

- *Highlighting some of the challenges COVID-19 has posed to the European Convention on Human Rights*

The European Convention on Human Rights (ECHR) came into force in 1953 to guarantee specific rights and freedoms for people in countries that belong to the Council of Europe and to protect their human rights and prohibit unfair and harmful practices.¹

COVID-19 took the world by storm and invaded all aspects of humanity. The ‘normal approach’ we had to life and issues relating to everyday living changed. New norms/ways of thinking as well as laws² emerged to tackle the sweeping public health crisis with consequent implications for accepted rights and freedoms under the ECHR.

Governments’ world over (including Europe) variously imposed lockdown measures to limit the spread of the disease and subsequently introduced schemes to alleviate the financial difficulties imposed on their populace and pioneered schemes such as volunteer services to help the less able with shopping, collecting medication from pharmacies etc, to lessen the hardship(s) imposed by lockdown measures.

The powers available to public authorities under Article 5(1)(e) of the ECHR to lawfully detain people for the prevention of the spreading of infectious diseases were imposed by governments across Europe with the consequence that health and law enforcement agencies acquired powers to confine otherwise healthy individuals to their homes and to isolate and screen individuals suspected to have contracted COVID-19 using powers under Article 5(1)(b) of the ECHR.³

The promotion of powers under Article 5(1)(e) of the ECHR did not seem to have been extended to the promotion of provisions of Article 5(4) of the same convention, which allows for everyone deprived of their liberty by arrest or detention to be entitled to take proceedings by which the lawfulness of their detention shall be decided speedily by a court and their release ordered if the detention is not lawful.

The exigencies of COVID-19 especially in the early stages meant that health resources were diverted to combat/contain the pandemic with the consequent effect that the care of some individuals were delayed and, in some instances, can-

celled, for example clinics and operations, possibly leading to death as an indirect consequence of COVID-19 and interference with Article 2 rights of these individuals.

There were concerns about issues relating to the blanket approach taken to writing ‘DNAR’ (do not resuscitate) on the notes of older adults and people with intellectual disabilities without proper consultation⁴ in disregard of their Article 8 rights.⁵

There were also problems with the supply and availability of personal protective equipment⁶ to health and care professionals, with consequence on the human rights of workers⁷ to be protected from toxic exposures at work.⁸

There were concerns that the exigencies of the pandemic had the potential to cause doctors to consider factors such as the availability and capacity of current resources⁹ when making decisions about whether to continue life-saving treatment on an individual with a potential scenario where an individual could be deprived of continued treatment, consequently interfering with their Article 2 rights.¹⁰

A Court of Protection judgment¹¹ considered the interface between the right to private and family life (Article 8), right to liberty and security (Article 5) and right to life (Article 2) among others, and drew out the primacy of absolute rights under ECHR such as Article 2 rights over qualified and limited rights (Article 8 and Article 5 rights, respectively).

Patient consultation via telephone and video calls has grown in popularity and acceptance¹² with possible implications for Article 8 rights of patients. The effect of the lockdown on the physical and mental health of the populace as well as mortality rates, including suicides will become apparent as time goes on.

Time will tell with regard to whether the exigencies of COVID-19 had an impact on the speed of hospital discharge as well as the care of people in care homes and the care and survival of the less able and whether this interfered with their Article 2, Article 3 and Article 8 rights.¹³

Although there is the possibility under Article 15 of the ECHR for governments, in time of war or other public emergency threatening the life of the nation, to temporarily derogate from their obligation to secure certain rights and freedoms under the Convention,¹⁴ some of the measures put in place to tackle the exigencies of COVID-19 will endure long after the pandemic has abated in the UK – otherwise we would have learnt nothing from the pandemic and forgotten nothing. There is therefore the need, going forward, to carefully calibrate the fine balance between public health needs and safety with human rights.

The understanding is that the European Charter of Fundamental Rights that brings together the fundamental rights of everyone living in the European Union, including the rights protected by the ECHR (as brought into UK law by the Human Rights Act) will stop having effect in the UK after the UK leaves the European Union. The government has however guaranteed UK’s continued commitment to ‘respect the framework’ of the ECHR.¹⁵

1.3.53 The value of assessing suicidal ideation

Gethin Morgan

date

2020-02

Contents

- *The value of assessing suicidal ideation*

The paper by Gibbons *et al*¹ concerning the distress experienced by psychiatrists who lose a patient through suicide is very welcome. We all know that such an event is difficult to bear, and this paper will encourage us to get support from others if things get really difficult, rather than soldiering on alone.

In describing how hard it is in clinical practice to detect suicide risk, let alone prevent it, the authors assert that recent research based on meta-analyses provides no evidence that suicide risk assessment in clinical practice can usefully guide clinical decision-making.

I believe that such a bald overall dismissal is regrettable because it discourages acquisition and critical evaluation of relevant clinical skills. Furthermore, I submit that it is not justified in the case of psychiatric in-patient care when addressing the problem of suicide prevention in the immediate or short-term future.

Surely all would agree that in managing severe short-term risk we ignore evaluation of suicidal ideation at our peril. When less immediate short-term risk is considered, there is also much to affirm the important role of assessing suicidal ideation in guiding clinical decision-making.

We described two series of psychiatric in-patients (1982–1984, N = 27; 1991–1993, N = 18) who died by suicide either during hospital admission or within 2 months of discharge from hospital.² In each of these, a high proportion of patients, 20/27 (74%) and 15/18 (83%), had discussed their suicidal ideas with members of staff in the ward during their in-patient stay. Suicidal ideation, as recorded contemporaneously in the case notes and not retrospectively, was a key clinical feature in delineating these patients, because they could not be distinguished from others in the ward across a range of behaviours. 12/27 (44%) and 9/18 (50%) showed significant clinical improvement during their in-patient stay, even though stress in the community had remained unresolved. In the 10 years that had elapsed between our two series, the proportion of patients that killed themselves after discharge from hospital increased from 7/27 (26%) to 11/18 (61%).

These findings, based as they are on two small series of suicides, must be regarded as provisional. Yet they do suggest that knowledge of suicidal ideation can be useful in guiding clinical management decisions. Clinicians should be vigilant that clinical improvement in these particular patients may be temporary and misleading, possibly related to removal from stress in the community. They should be particularly careful to ensure that such stress has been resolved, or at least contained, by planned provision of adequate ongoing support in the community if discharge from hospital is envisaged. With the increased emphasis on community care, the proportion of these patients who kill themselves after discharge from hospital is likely to have increased further since our studies took place. Our findings suggest that clinicians should be mindful of the increased hazard which is likely to be associated with premature discharge of these patients from hospital.

Our in-patient psychiatric wards should be fertile ground for the necessary further research that is needed to clarify the many other possible aetiological factors in these suicidal deaths, and so help in the development of good clinical practice. The identification and evaluation of suicidal ideation must surely have a central role in this.

1.3.54 The recruitment legacy of COVID-19

Rajaei K. Sharma Bhupinder Sharma Harriet L. Ogle

date

2020-08

Contents

- *The recruitment legacy of COVID-19*

With increasing thought being put into COVID-19 and the implications for psychiatric care in the months and years to come, it would be remiss to not consider the potential impact this could have on recruitment to the specialty.

Recruitment in psychiatry is a national, if not global problem, and has been for some time. Although frequently highlighted, there has been limited work clarifying the reasons behind the problem, which in turn has led to muted and potentially ineffective responses. This could all now be amplified by the COVID-19 crisis.

We know that foundation doctors already have very low exposure to psychiatry placements and teaching; the proportion of psychiatry teaching time has been found to be as low as 2.3% relative to surgical and medical specialties seeing 44.1%. We also know that there is a significant correlation between trainees having a foundation placement in psychiatry and going on to apply for specialty training.¹ This has been replicated in targeted studies with a surprisingly high 45% of psychiatric specialists found to not have even considered the specialty before their foundation years.²

So, it is not an understatement that the current foundation year trainees are to be drastically affected. Not only have rotations been paused, but huge numbers have been redeployed. Already, the invaluable experiences of an entire cohort have been curtailed, with more likely to follow. Additionally, national exams have been cancelled; the impact of this and the choices made thereafter may even lead to very immediate-term shortages and unknown ramifications.

This is before we even consider those that will shortly follow them through, the medical students. The proportionally enormous amount of time lost directly affects many of the clearly identified factors attracting students to the field such as placement and elective exposure.³ There have recently been some targeted strategies implemented by the Royal College of Psychiatry to try and improve recruitment – especially the ‘Choose Psychiatry’ campaign – these outreach programmes might serve to be a much-needed lifeline more than ever before. Psychiatric societies within universities might be the great untapped resource that prevail the shutdown and educational restrictions.⁴ Could they, in turn, be a vital commodity?

There is a growing recognition that although it may appear to be minutiae relative to the scale of a global pandemic, COVID-19 could have a profound effect on the career progressions of a generation of doctors.⁵ Only by addressing this early and actively can we mitigate potential disaster for years to come.

Abstract

The transition from child and adolescent to adult mental health services for young people with mental health problems is of international concern. Despite the high prevalence of mental disorders during adolescence and their tendency to continue during adulthood, the majority of young people do not experience continuity of care. The aim of this review paper is to unravel the complexity of transitional mental healthcare to clinicians, policy makers and mental health service managers, and to address challenges to a smooth transition process at all levels.

 - *Conclusion*

Young people's transition from child and adolescent mental health services (CAMHS) to adult mental health services (AMHS) has gained increasing international interest in recent years. At around the age of 16–18 years, young people with chronic mental health problems are confronted with two simultaneous transitions: a situational transition (from CAMHS to AMHS) and a developmental transition (to adulthood).¹

Transition is defined as an efficient, planned, patient-oriented process that meets the medical, psychosocial and educational/occupational needs of young people with chronic conditions.² Additionally, the developmental perspective

is important in conceptualising transition as young people, those aged 16–24 years, are confronted with changes in various life domains.^{3,4}

The transition age refers to the age at which the care of the young person in CAMHS is continued in AMHS, and in most cases, concerns young people in the 16–18 year age range. The following findings linked with psychopathology are relevant for transitional care at this time point: first, psychopathology has a high persistence from an early age into adulthood⁵; second, the onset of many psychopathologies has been shown to coincide with the transition age.^{6,7} Critical changes in the brain occur during late adolescence, which make this age group more vulnerable for developing psychopathology.⁷

Moreover, 75% of all psychiatric disorders in adults start before 24 years of age, and 50% before 14 years of age.⁸ However, there is a discord in the pattern of increased risk of psychopathology in young people and mental health service use.^{1,9} Older adolescents access care far less (28.9%) than 13- to 16-year-olds (50.9%) or adults over 26 years (41.1%).^{10,11} Furthermore, the gap between CAMHS and AMHS, the so-called ‘transition gap’, results in a clear discontinuity of care. A sizeable number of youth and young adults who ‘fall’ in this transition gap access adult services at a later point in time, when more serious and chronic problems have developed.^{12,13}

The care gap affects not only the young people, but also their families, communities and society as a whole. Mental health problems are associated with poorer physical health and poorer functioning in the social, educational and economic life domains.¹⁴ At the societal level, the presence of a mental disorder during childhood leads to a 10-fold higher health cost during adulthood compared with children without mental health problems.¹⁵ To date, it is unclear what the real societal impact of the care gap in late adolescence is and to what extent adequate transitional care reduces this impact.

The aim of this paper is to summarise the new insights and developments investigated since the review of Singh in 2009.¹² Furthermore, this paper includes research on youth mental health services and shared management components, which is one of the limitations of the review of Paul *et al.*¹⁶

Continuation of care is a complex process, with important players at the policy and organisational level, service level and at the level of individuals: patients, their families and healthcare providers. However, care discontinuity cannot be explained by only one level.^{4,17} This paper attempts to unravel the complexity of transitional mental healthcare to clinicians, policy makers and mental health service managers, and to address challenges to a smooth transition process at all levels. The advantage of splitting the findings according to the three levels makes the extensive research regarding transition more manageable. Furthermore, it emphasises the complexity of the topic, but also makes clear that solutions are possible at every level.

Challenges regarding transitional mental healthcare

Policy and organisational level

Improving transitional care has been on the policy agenda in different European countries for some time now; however, it has been one of a number of competing priorities. Furthermore, there has been a gap between policy and implementation in practice, insufficient research regarding transition, and a lack of transition protocols guiding transitional care of service providers.¹⁶

Historically, the way in which mental health services have been structured, with separate facilities for children/adolescents and adults is a significant bottleneck to transitional care.¹³ Eligibility thresholds for referral to CAMHS and AMHS often differ; thereby causing young people to fall through the care gap.^{4,18} Furthermore, the CAMHS-AMHS interface is characterised by different cultural approaches, a lack of communication and doubts about AMHS staff being proficient in managing young peoples’ care.¹⁹

Waiting lists form another major barrier in the provision of mental healthcare to youth and young adults.^{20,21} As a result, young people presenting with a mental health problem at 17 years of age are often referred directly to AMHS because the waiting time for CAMHS coincides or exceeds their 18th birthday, i.e. the transition boundary. Adult services, in turn, hesitate to treat these young people before 18 years of age, because the expertise or the adjusted setting for this patient group is lacking, or because internal or external regulations prevent care providers from forming a treatment

plan. Young people who have attended CAMHS but find themselves on a long waiting list for AMHS – usually with no interim support in place – describe this as highly anxiety-provoking.²²

Another challenge is the lack of training requirements for care providers and variations in the content of training programmes.^{23,24} The knowledge clinicians in either child/adolescent or adult speciality acquire about young people largely depends on whether they are provided with adequate training on psychopathology of adolescents. A lack of confidence amongst mental health practitioners to work with young people in transition is an area of concern frequently identified by young people.²²

Healthcare financing is another policy challenge affecting the care trajectories of young people. Gaining financial responsibility at the age of majority can have a real effect on the provision of care in some countries. Differences in financial benefits for minors versus adults may relate to the cost of a consultation, the possibility to organise family therapy or the reimbursement of medication. Some health insurance policies provide partial reimbursement for therapy sessions for young people up to 18 years of age, but not for (young) adults. Hence, although they have reached the age of majority and the ability to organise their mental healthcare independently, young people often still remain financially dependent on their parents to pay for their care. If there is a serious disruption in the parent–child relationship, the continuation of care at a new mental health service may be in jeopardy.

Service level

Different treatment approaches at CAMHS and AMHS pose a significant challenge. In CAMHS, treatment is reported to be more family-oriented and holistic, inherent to the legal position of the parents, whereas in adult psychiatry, individual patients and their symptoms are the main focus. These differences are described by young people and their families as an important reason for discontinuing care in AMHS.²⁵ This perception may also lead to hesitance among CAMHS clinicians to refer young people.¹⁶ In addition, the lack of common registration and information systems hampers the exchange of information between services.¹⁷

Level of the individual

Youth and young adults

Characteristics specific to young people can influence the transition process. Having a severe and enduring mental illness, e.g. schizophrenia, enhances the chance of being referred to AMHS, whereas having a neurodevelopmental disorder decreases the chance of being referred. Moreover, receiving medication, having a history of hospital admissions and living with both parents or independently are all variables that can determine whether a young person is more likely to be referred.^{4,26–28}

Even if a transition to adult services has been carefully planned, a young person's urge for autonomy and self-determination may influence their care trajectory. For example, the young person can decide to abandon psychological care or to not make the transition to AMHS, even when a referral has been made.^{4,26,28,29} The reasons for this are diverse: young people want to solve their problems themselves, or they may not want to repeat their story to a new clinician. The lack of information about mental healthcare, the stigma associated with mental health problems,^{30,31} anxiety about how confidentiality is handled and the physical accessibility of mental health services can all act as barriers to seeking help or accessing care.³² Young people have also suggested that further investments should be made to improve the accessibility of mental healthcare and have pointed out to the importance of e-health.¹⁷

Furthermore, service (dis)engagement is influenced by an identity change that accompanies the transition from CAMHS to AMHS. Besides adopting an adult identity, transitioning to AMHS implies adopting a new illness identity.³¹ Although CAMHS is associated with temporary psychopathology, AMHS is associated with having a severe and enduring mental illness, as this is often the prerequisite for being referred to or accepted by AMHS.⁴ Disengagement can be attributed to failure in adopting a new illness identity, an illness identity that is incompatible with AMHS service remit or fractious professional relationships between CAMHS and AMHS during the transition, which causes anxiety and uncertainty to the young person.³¹

Although young people want to make autonomous decisions and are concerned about the confidentiality of information, the loss of parental or other psychosocial support is an important negative factor for care continuation or adequate help-seeking behaviour.³²

The relationship of trust with the CAMHS clinician must not be forgotten, as at the transition to adult services this relationship comes to an end. Entering into a new social and trust relationship at an AMHS can be daunting for young people. On the other hand, a positive relationship with the new clinician can enable the development of other positive relationships.³³

The parents and important others

The parents' position changes the moment a young person becomes an adult, as their legal right to be involved in the care for their child is no longer there. Furthermore, because of the distinct service cultures, CAMHS and AMHS clinicians' training regarding family involvement differs considerably; in adult psychiatry, the focus is more on the individual, not the family.^{25,34}

The need to give a young person autonomy to make their own decisions regarding treatment can be a difficult process for the parents, who may also require additional support.³⁵ Many parents and carers would like to remain involved in the treatment, although they respect their child's wishes and their right to privacy.^{36,37} They also want psychoeducation about how to deal with their child and to attend parent support groups where they can benefit from increased knowledge, shared recognition and exchange of experiences.³⁸

The clinician

Mental healthcare transition should be a planned and efficient process. This implies starting on time to prepare individuals and their families for the transition. Some authors state that this process should start at 14 years of age,³⁹ whereas others stress that it should start at least 1 year before the transition boundary.⁴⁰ For the process to be efficient, by the time the young person reaches the transition boundary it should be clear whether they need further care or not, and whether this care will be continued in CAMHS or whether a referral to AMHS, or another type of service (e.g. private practice), is appropriate. In any case, the clinician should consider all these options to make the best possible decision.

To date, there is no consensus about this decision-making process, and the follow-up trajectory of the young person thus depends on the practitioner's clinical judgement. Because of the lack of transition protocols, this clinical judgement is not usually based on a structured assessment of transition-relevant factors, such as severity of symptoms, the patient's motivation regarding further mental healthcare and the risk and protective factors in several psychosocial domains.¹³ CAMHS and AMHS should, therefore, be supported in the initiation, advancement and supervision of the transition process. The National Institute for Health and Care Excellence and Cleverley *et al* have produced guidelines on transition.^{41,42} The Managing the Link and Strengthening Transition from Child to Adult Mental Healthcare (MILESTONE) project developed an instrument for assessing transition, the Transition Readiness and Appropriateness Measure, a process called managed transition, which uses the Transition Readiness and Appropriateness Measure to guide clinicians' actions, and training regarding transition.^{43,44}

The transition process is also influenced by professional relationships between CAMHS and AMHS. Clinicians' decisions regarding referrals may depend on the (not always comprehensive) knowledge they have of the other care provider and their prior experience with the service and clinician.⁴⁵ Furthermore, incompatible beliefs about who is responsible for the different steps during the transition process, lack of confidence in AMHS staff in managing young people and different cultural approaches in service delivery may also impede the transition process.^{18,46}

Improving transition through specific interventions

Some of the above-mentioned challenges provide directions as to what should be done in clinical practice and at policy level to improve the transition process. On the other hand, effect studies are lacking and there is a need for longitudinal research about different transition trajectories and health outcomes.^{16,47} Although care trajectories, transition experiences and quality of transition have been investigated within the UK,¹ Ireland,^{28,46} the USA and Australia,¹⁶ no research has been performed about the care and transition trajectories (both the experiences and the quality) in relation to their effects on mental health in the long term. The MILESTONE project contains a prospective study on the longitudinal outcomes and experiences of young people reaching the transition boundary within eight different European countries, taking into account differences in the organisation of mental health systems, the age at which transition takes place and the available services.^{43,44} The MILESTONE study will result in evidence- and practice-based guidelines that clinicians can follow to support their decision-making and direct their actions.

To prevent young people from falling through the care gap and to tailor services to their specific needs, new service models have been developed. Examples include mental health services in Australia, Canada and some European countries that target the age group of 0–25 years. Besides solely focusing on mental health, these services take into account all aspects of psychosocial functioning.^{48–50} Despite the aim of trying to solve the problem of a shortage of tailored services for this target group, some of these services are faced with an additional transition boundary: the first around 12 years of age and the second around 25 years of age, both of which need to be optimally managed. At the current time, it is too early to conclude if these models provide an answer to the longstanding problems of transition barriers.

An alternative approach to bridge the transition gap is by improving the liaison between CAMHS and AMHS, but keeping services as they currently exist. To achieve this, diverse models to enhance joint-working between services, including transition clinics and transition coordinators have been suggested.^{51–54}

Improving clinical practice

Policy makers should consider implementing the topic of transition in the training program of clinicians as 94% of European psychiatric trainees indicated further training regarding transition is necessary.²³ Furthermore the distinct split between CAMHS and AMHS should be revised as well as the separate funding, which may hamper collaborative efforts.^{13,42}

To ensure that the transition process is better managed, the transition should be mentioned to the young person well in advance,^{17,41,42} whereby the young person should be involved in the decision-making during all phases of the process.^{22,42,55} Guidelines and criteria regarding optimal transition can guide clinicians during their clinical practice.^{4,41,42} Furthermore, standardised assessment of the young persons' needs when approaching the transition boundary should become routine, although it is rarely done nowadays.¹³

Conclusion

The transition from CAMHS to AMHS is an important process for young people with mental health problems. Literature shows that continuation of care is a complex process, with important players at policy and organisational levels, service level and at the level of individuals: patients, their families and healthcare providers. At the moment, specific programmes for young people are being developed. However, research such as the MILESTONE project is needed to support these interventions in an evidence-based manner.

We would like to thank Marc Hermans, past president of the European Union of Medical Specialists (UEMS) board of psychiatry, for inviting us to join the UEMS working group regarding transition. We are also very grateful for the whole UEMS working group on transition for their interest and plans to make transition part of the training of psychiatrists throughout Europe. Furthermore, we would like to thank all members of the MILESTONE consortium.

The MILESTONE project has received funding from the European Union's Seventh Framework Programme for research, technological development and demonstration under grant agreement no. 602442. This paper reflects only the authors' views and the European Union is not liable for any use that may be made of the information contained therein.

The funding body has had no role in the study design, in the writing of the protocol or in the decision to submit the paper for publication.

1.3.56 Management measures for non-medical staff on psychiatric hospital wards during the COVID-19 pandemic

- *Management measures for non-medical staff on psychiatric hospital wards during the COVID-19 pandemic*

A notice issued by the National Health Commission in China on 18 March 2020 highlighted the need for psychological counselling for those affected by COVID-19, vulnerable groups, health workers and those fighting the virus on the frontline.¹ Data shows that 323 patients with severe mental disorders had been diagnosed with COVID-19 across the country as of 19 February 2020.² The development of an epidemic poses great challenges for psychiatric hospitals.

There are visitors and non-medical staff who work in hospitals, such as cleaners, who have no medical experience or knowledge about prevention of infectious diseases. In order to ensure the safety of in-patients and staff, it is necessary to formulate management measures for non-medical staff.

First, there needs to be strict implementation of a system for non-medical staff to sign in and out of the ward. The following details should be entered into a table: name, date of going out, time of going out, reason for going out, estimated return time, actual return time, temperature at return, exact location of outing, etc. They can leave the ward only after a nurse has signed it.

Second, it is essential to follow procedures formulated by the wards and service providers. Wards should undertake temperature monitoring of non-medical staff at least twice a day. Wards should be responsible for monitoring the non-medical staff's work, including the wearing of protective clothing and ensuring that proper hand washing is carried out. Cleaners are required to clean and disinfect tableware and dining tables after meals. Staff need to strictly implement management regulations when transporting patients' specimens. Unless essential, wards and service providers should not replace permanent staff with temporary or agency staff. There must be epidemiological screening of new recruits to ensure that these personnel do not have a history of epidemiological exposure, fever or any respiratory symptoms.

Third, wards need to provide training and guidance. The ward's head nurse needs to consider the different educational levels of non-medical staff when developing and undertaking training regarding epidemic prevention knowledge and skills to ensure all training is appropriate. The training needs to focus on disinfection, isolation, hand hygiene and wearing protective clothing. The responsible nurse is in charge of daily guidance for non-medical staff. When problems are identified with epidemic prevention they should correct issues without delay.

Fourth, wards and service providers need to work together on management supervision. The ward's head nurse needs to evaluate the impact of training on non-medical staff daily. Service provider managers need to check the results of training and keep corresponding records. The head nurse of the department needs to supervise the work of non-medical staff in wards under their jurisdiction. Then, they need to check the preventive knowledge and skills of the non-medical staff members and report the results to the director of nursing. The chief manager needs to undertake special inspections to assess the mastery of epidemic preventive knowledge, skills and the quality of work in the hospital on a weekly basis.

Finally, it is important to keep an eye on the psychological status of non-medical staff on wards. On account of the long-term exposure to a dangerous environment, coupled with patients' uncooperative attitudes, loud yelling or violent behaviour, their visitors and caregivers are prone to psychological difficulties.³ As cleaners frequently enter or leave wards, the exposure risk increases. If there are any signs of anxiety or panic, non-medical staff should receive psychological interventions to help them properly handle negative feelings.

Recently, the number of cases of COVID-19 outside of China has become very serious. This letter aims to formulate epidemic prevention and control measures for non-medical workers in psychiatric hospitals. It is hoped that these measures will be of value for both domestic and foreign epidemic prevention efforts.

1.3.57 Section 12 approval: fit for purpose?

Darryl Ballantyne-Watts

date

2020-06

Contents

- *Section 12 approval: fit for purpose?*

I read this article¹ with some interest, and with some alarm. Yes, striving for ‘evidence-based improvements’ in the Section 12 approval/reapproval process is an understandably good thing. However, basing recommendations on a 21.7% (5/23) return rate for a questionnaire is never going to change much behaviour. Not even when this information is ‘triangulated ... with other sources’ are many heads going to be turned.

I believe that those of us who carry out Section 12 assessments in the real world are all too aware of the lack of hospital resources and are thus inclined to seek out every community solution for disposal, given the availability of ‘alternative to hospital’ teams these days. Particularly when we are considering complex mental illness and mental disorder matters in a social context coupled with a healthy assessment of risk, the decision to detain to hospital for assessment cannot be taken easily or lightly.

Knowing the precise wording of mental health law is important, and we all want to ‘do things right’. But in a complex, sometimes heated, community situation we are required to complete the harder additional task of ‘doing the right thing’, which takes time, thought, experience and some element of wisdom. I am not at all sure that the solutions proposed in this paper will take many in that direction.

Aims and method

To compare and contrast the burden of comorbidity in a population receiving in-patient treatment for substance misuse with that of a cohort admitted to the same unit 4 years previously. The Charlson Comorbidity Index (CCI) was used to quantify patients' comorbidity and predict 10-year survival.

Results

There was a marked reduction in predicted 10-year survival: in 2014, 22% of patients had a predicted 98% chance of 10-year survival, whereas only 2% in the 2018 cohort had a predicted 98% chance. Additionally, in 2014 only 9% of patients had a <20% 10-year predicted survival chance, whereas 28% in 2018 had a predicted 10-year survival chance of <20%. In this time, funding for services was cut by 23% and the 12-bed unit was reduced to 8 beds. This resulted in an increase in the average waiting time from 30 to 65 days. In 2018, more patients were admitted for alcohol detoxification, rising from 79% to 93% of admissions. Chronic respiratory disease remains the most prominent comorbidity; however, there is also an increase in the percentage of patients with liver disease.

Clinical implications

In-patient substance misuse units are known to serve individuals with complex illnesses. With service funding cuts, subsequent bed reductions and increased waiting times, this complexity is increasing, with a considerably higher burden of comorbidity. The consequential increased mortality risk highlights the ongoing need for adequate community and in-patient services with integrated care of mental and physical health alongside social work.

 - * *Limitations*
 - * *Implications*

It is widely accepted that there are social, psychological and physical harms associated with chronic substance misuse.¹ It has also been identified that drug and alcohol misuse are independent risk factors for physical illness in people with pre-existing mental illness.² Furthermore, the World Health Organization (WHO) found alcohol consumption to be the third highest risk factor, in high-income countries, for disease burden, superseded only by smoking and hypertension.³ Specialist in-patient units offer drug and alcohol detoxification and stabilisation to individuals with complex problems, whose substance misuse needs cannot be met in the community. Despite this, there have been significant funding cuts for alcohol and drug prevention, treatment and support services in Scotland in recent years.⁴ This study seeks to

describe and evaluate the burden of comorbidity carried by a current population of in-patients in a substance misuse unit in Edinburgh. It was anecdotally noted among the staff of this unit that in-patients were requiring more medical intervention. We therefore sought to compare the disease burden of a patient cohort in 2018 with that of a 2014 cohort in order to identify any developments in the prevalence or character of comorbidity carried by this population. These data provide invaluable insight into a high-risk population and aim to recognise any areas of developing trends within this group, to identify possible areas for intervention in the future.

Method

We conducted a retrospective study of in-patients over a 6-month period in 2018. We sought to explore the population's characteristics and compare these with the data collected by Mogford & Lawrence for their primary study conducted in the same unit in 2014.⁵ To quantify comorbidity, cumulative disease burden scales are used. These are calculated by attributing scores to specific diseases, health behaviours and medications, which are weighted according to their impact on morbidity and mortality. These scores are combined to assign an overall index of comorbidity, which can be used to compare, contrast and track change in individual patients or patient groups. The Charlson Comorbidity Index (CCI) has previously been used across a wide range of clinical settings and a variety of patient populations, including the 2014 cohort. To allow a direct comparison of patient cohorts, the same CCI was implemented to quantify comorbidity in the repeat patient cohort in 2018. There is a strong base for using the CCI, which has been deemed valid and reliable for estimating the burden of comorbidity in clinical research.⁶ The index records 16 diagnoses, including chronic respiratory disease and congestive heart failure. These details are all obtained as part of the routine documentation completed on admission to the unit. These 16 diagnoses have validated predictive value when calculating projected 10-year survival. The impact of age on predicted survival is accounted for by the addition of an age-based score to the raw CCI. The version of the CCI used is an extended one that includes four additional items that predict healthcare cost, but are excluded from the calculation of predicted 10-year survival.⁷ This version held the additional benefit of including a greater breadth of conditions/factors, specifically hypertension, skin ulcers or recurrent cellulitis, treatment with warfarin and the presence of depression. The individual patient scores could then be used to calculate their predicted 10-year survival.

We assert that all procedures contributing to this work comply with the ethical standards of the relevant national and institutional committees on human experimentation and with the Helsinki Declaration of 1975, as revised in 2008. Ethics approval was not required.

Participants

There were a total of 138 participants, who were admitted over a 6-month period to the Ritson Clinic at the Royal Edinburgh Hospital in Scotland. All the patients who were admitted to the unit were included in the data-set. The Ritson Clinic is a specialist unit that provides in-patient detoxification, stabilisation and replacement therapy for people with alcohol, opiate and other drug dependencies such as benzodiazepines, stimulants and novel psychoactive substances. All of the patients have complex psychiatric and social needs that are best met in an in-patient setting. Referrals are received from a range of community teams, including general practice and substance misuse services as well as some acute services such as the regional infectious diseases unit. These are all within the local National Health Service (NHS) health board of Edinburgh and the Lothians, with a population of over 800 000. The participants included in the study were 'recruited' retrospectively from the 6-month period immediately prior to the start of data collection. The period covered was from 19 April to 22 October 2018. The original study recruited patients from 26 May to 27 November 2014 in a prospective manner.⁵

Data collection

All collected data had been gathered during the in-patient admission clerking that was part of routine practice at the unit. As with the data collection in 2014, a brief paper recording tool was used for standardised collection of data. The authors, A.B. and A.M., completed the brief paper recording tool, retrospectively, that was created for completion during admission in the 2014 study. This information included a full psychiatric history, substance misuse history, medical history, physical examination and appropriate investigations, including a routine set of blood tests. To provide collateral information, a full range of data sources were used to complete the summary. These sources included a verbal report from the patient, electronic patient records, out-patient letters, previous discharge letters and general practitioner clinical summaries. The CCI provides detailed and specific descriptions of the inclusion criteria for each diagnosis, allowing for objectivity and repeatability in assessment so that each diagnosis was given the appropriate score. This data collection was conducted in the same manner as the data collected from 2014 cohort had been, as provided by Mogford & Lawrence, to allow for direct comparison.⁵

Results

In total, 138 patients were admitted during the repeat 6-month period of data collection. This compares with 175 patients admitted during the original period of data collection in 2014. The profile, number of patients admitted for alcohol detoxification, substance misuse diagnosis, the presence of a diagnosis and prevalence of cigarette smoking are shown in *Table 1*. The average age of patients for treatment has increased from 44 years to 49 years. There has been an increase, from 80% to 93%, in the number of patients who were admitted for alcohol detoxification. There has been a slight fall, from 80% to 76%, in the number of patients who were smokers at the time of admission. At the time of data collection for the 2018 study, 14% of the 2014 cohort was deceased and 2% of the current cohort was already deceased. *Table 1* Study group characteristics

	2018 cohort	2014 cohort
Age, years: mean (range)	49 (23–70)	44 (19–73)
Male, <i>n</i> (%)	60 (43)	111 (63)
Female, <i>n</i> (%)	78 (56)	64 (37)
Patients admitted for alcohol detoxification, <i>n</i> (%)	128 (93)	139 (80)
Comorbid depression diagnosis, <i>n</i> (%)	100 (72)	82 (47)
Cigarette smoker, <i>n</i> (%)	105 (76)	138 (80)
Patients deceased at 2018 data collection point, <i>n</i> (%)	3 (2)	25 (14)

The proportions of patients with each of the CCI items are summarised in *Fig. 1*. Within both cohorts, the condition with the highest prevalence was depression. Of note, however, this has shown a marked increase, from 47% in 2014 to 72% in 2018. Depression is the only psychiatric condition included in the CCI. There was a small reduction in the percentage of patients with chronic obstructive pulmonary disease (from 26% in 2014 to 22% in 2018), which we would expect with the reduction seen in the percentage of smokers over this period. In the 2018 cohort there is an increase in prevalence of both mild liver disease (from 19% to 21%) and moderate to severe liver disease (from 6% to 14%). This is in the context of an increased number of admissions for the purpose of alcohol detoxification. There is also a marked increase in the percentage of patients who met the criteria for diagnosis of dementia (from 6% in 2014 to 16% in 2018). *Fig. 1* Comparison of comorbid diagnoses/factors recorded for the 2014 and 2018 study cohorts. COPD, chronic obstructive pulmonary disease; TIA, transient ischaemic attack.

Table 2 presents the comparison of the distribution of CCI scores and associated 10-year mortality. The percentage of patients with a predicted 10-year survival chance <20% has increased from 9% to 28%. In 2014, 63% of patients had a predicted 10-year survival chance >90%, whereas in 2018 this was only 16%. *Table 2* Comparison of Charlson Comorbidity Index (CCI) scores and predicted 10-year survival for 2018 and 2014 cohorts

CCI score	Predicted 10-year survival chance	2018, <i>n</i> (%)	2014, <i>n</i> (%)
>5	<20%	38 (28)	16 (9)
2–4	20–49%	17 (12)	13 (7)
0–1	50–74%	24 (17)	12 (7)
3–7	75–90%	37 (27)	24 (14)
>8	>90%	22 (16)	110 (63)

As shown in *Fig. 2*, in 2014 only 7% of patients were predicted to have no chance of survival at 10 years, compared with 15% in 2018. There were just 2% of patients with a 10-year predicted survival chance >98% in 2018, whereas this was 22% in 2014. The interaction between age and predicted survival is demonstrated in *Fig. 3*. The number of younger patients carrying a high burden of comorbidity has increased. *Fig. 2* Comparison of predicted 10-year survival for the 2014 and 2018 study cohorts. *Fig. 3* Comparison of age and predicted 10-year survival for the 2014 and 2018 study cohorts.

Discussion

The Ritson Clinic and government policy on drug and alcohol services

The Royal Edinburgh Hospital site is currently being redeveloped, with the Ritson Clinic being one of the last areas of the hospital to undergo service redevelopment. This has led to considerable discussion about whether the unit would be best placed at a medical hospital or on a psychiatric site and about level of intervention the in-patients require. In addition, on a wider scale, there is ongoing debate regarding the allocation of resources to fund specialist in-patient treatment of drug and alcohol problems within NHS Lothian. The original study⁵ helped make the case for the ongoing availability of a medically supported in-patient unit for the treatment of alcohol and drug use disorders within NHS Lothian. In the intervening period, service pressures have increased and available bed numbers have decreased. Between 2016 and 2017 direct Scottish Government funding for alcohol and drug partnerships (ADPs, local partnerships between health boards, local authorities, police and voluntary agencies to tackle alcohol- and drug-related problems) fell by 22%.⁴ In Lothian, the ADP funding allocations for alcohol and drug prevention, treatment and support services was cut from £11 469 680 in 2015–2016 to £8 887 133 in 2016–2017.⁸ As a consequence of this reduction in national funding, by January 2018 the number of beds in the Ritson Clinic was reduced from 12 to 8. These changes have occurred in the context of changes in public health policy, which increasingly focuses on the preventability of drug- and alcohol-related deaths. The average waiting time for an admission to the Ritson Clinic has increased from 30 days for the 2014 cohort to 65 days in 2018. The average length of admission was 8.9 days for the 2018 cohort. The unit receives referrals from community addiction services, general practices (including practices for those without fixed accommodation), in-patient and out-patient hepatology teams, alcohol liaison nurses and the regional infectious diseases unit. These are screened using admission criteria originally based on Scottish Intercollegiate Guidelines Network (SIGN) guidelines.⁹ This ensures that admission for in-patient treatment is limited to those who could not have their needs met in the community; by its very nature, this predisposes them to carry a higher burden of comorbidity.⁸ It is worth noting that there are other factors that may contribute to increased morbidity in this patient group that were not accounted for in the study, such as poor nutrition and blood-borne viruses such as hepatitis B or hepatitis C. This study did, however, look at the prevalence of smoking in the patient group. Evidence suggests that the prevalence of smoking in the Scottish population is falling. In 2017, it was estimated that 18% of the Scottish adult population smoked.¹⁰ Despite showing a small improvement between 2014 and 2018, the in-patients included in our study still have a considerably increased prevalence of smoking; 76% of the 2018 cohort were current smokers, which will contribute to their overall increased morbidity and mortality.

Reductions in 10-year predicted survival

Data from the Office for National Statistics for 2011–2013 estimated the predicted 10-year survival chance for a 45-year-old Scottish male to be 96.6%.¹¹ Comparatively, in the original cohort, among patients aged between 45 and 55, the mean predicted 10-year survival chance was 68.6%. In the 2018 cohort, this had reduced to 55%. There are multiple likely contributing factors to the increase in predicted mortality over the 4 years. The increased waiting times and reduced bed numbers have certainly played a role. When screening referrals to the unit, the patients with the greatest need are given preference, with those with highest immediate risk to physical well-being taking precedence. This is also likely to explain why there is an increase in the number of patients admitted for treatment of alcohol dependence over the 4 years, as the risk to physical health from alcohol withdrawal is usually greater than that of drug stabilisation or detoxification, therefore these patients are admitted preferentially. As per the SIGN guidelines any patient who is confused, has a history of seizures or hallucinations, has an acute physical or psychiatric illness, including multiple substance misuse, has previously failed home-assisted detoxification or has a home environment unsupportive of abstinence is deemed to require in-patient detoxification.⁹ These broad inclusion criteria cover much of the patient population that would require alcohol detoxification and also go some way to explain why the large majority of admissions, in both 2014 and 2018, were for treatment of alcohol dependency, despite the Ritson being a unit that treats both drug and alcohol problems. With increased waiting times and pressure on beds, the triage of referrals requires ever more challenging clinical decision-making.

Increasing burden of comorbidity

The Ritson Unit currently forms part of the Royal Edinburgh Hospital site, which provides only psychiatric care and is not a medical hospital. Anecdotally, among the multidisciplinary team, it was felt that the patients being admitted to the unit had increasingly complex medical problems, requiring more medical intervention beyond the capabilities of the unit. Patients admitted to the unit who become acutely medically unwell often require transfer across the city to the medical hospital, as their physical health needs cannot be safely managed within the psychiatric hospital setting. Our data have supported this impression that patients are indeed carrying a higher burden of comorbidity. In quantifying this burden, the study demonstrates the ongoing and growing demand for in-patient facilities to treat this unique population of patients, whose needs intersect mental and physical healthcare services. To improve outcomes for these patients, a more collaborative and proactive approach in the development of these services is required. This is in accordance with the recommendation of increased funding and an emphasis on better integrated care made by NHS England in its NHS Long Term Plan.¹²

Limitations

The study was conducted using the CCI, which is a useful tool for comparison of predicted mortality. We have compared two groups, admitted over the same length of time. However, because the capacity of the unit was reduced between the two studies, we compared a smaller, of an already small, sample (138 patients in 2018, compared with 175 in 2014). This meant that we used percentages for data analysis rather than gross numbers of patients. The CCI does not give an indication of the impact of morbidity on quality of life, nor does it demonstrate causation. A further limitation of the study is that the data were collected retrospectively. The initial study was carried out prospectively and by different clinicians, so there may have been a resultant difference when scoring the patients. However, the CCI is based on objective measures, so variability should be limited. The score is predicted over 10 years, and we have repeated the study after 4 years. We are therefore unable to compare the predicted mortality with the actual mortality. Furthermore, one cannot extrapolate the current number of deceased patients to draw any conclusions about the accuracy of the scoring in this patient group. In addition, although the score demonstrates a declining trend in health outcomes in this patient population, it does not provide any indication of quality of life or functionality of patients.

Implications

The original data collected in 2014 showed a high burden of physical illness carried by those admitted for in-patient treatment for substance misuse. The data collected in 2018 confirm what was suspected from observations made by the healthcare professionals working within the service: that patients being admitted have an increasing burden of comorbidity, requiring more intervention from specialties, and ultimately are likely to have worse long-term health outcomes. At 4 years, 14% of patients originally audited were deceased. It is recommended that the study is repeated after 10 years, to assess the accuracy of the score at predicting mortality in this population with complex, specialist care needs. The intersection between physical healthcare requirements and psychiatric and substance misuse needs continues to present a unique challenge in caring for this group of patients. Although the current trend is to move towards a more community-based healthcare model, the increased comorbidity and growing waiting lists identify the ongoing need, within this population, for in-patient services. There is clearly a requirement for healthcare providers and facilities that can provide safe and effective treatment of the combined conditions and substance misuse needs of these patients. Quantifying the degree of comorbidity within this population remains valuable for the allocation of resources and development of services with an emphasis on integrated care.

Daniel V. Mogford and Rebecca J. Lawrence, both consultant psychiatrists with NHS Lothian, Edinburgh, UK, conducted the 2014 data collection and provided non-financial advice and support for the current study.

A.M. has met all four ICMJE criteria with regard to her contribution. She helped follow up the previous cohort of patients and contribute to the collecting of new retrospective data. She placed the data in the spreadsheets for analysis. In collaboration with A.B. she contributed to the drafting, editing and review of the final paper. A.B. has met all four ICMJE criteria with regard to her contribution. In her role as ward doctor she gathered retrospective data and contributed to the analysis and interpretation of the data. This involved using spreadsheets to input the data and attributing

the score. She formulated the formulae to analyse and compare the results. She contributed to the drafting, editing and review of the final paper. Both authors agree to be accountable for the work and to answer any questions regarding the work.

Alice Bradley, BMBS (Peninsula College of Medicine and Dentistry) is a Junior Clinical Fellow in general surgery at NHS Fife, and she was a foundation year 2 (FY2) doctor in NHS Lothian at time of writing. **Amy Martin**, MBChB (University of Aberdeen) is a general adult higher psychiatry trainee in NHS Lothian (ST4) and was a core psychiatry trainee (CT3) at time of writing.

1.3.59 Clozapine and COVID-19

Edward Silva Siobhan Gee Shubulade Smith Fiona Gaughran

date

2020-08

Contents

- *Clozapine and COVID-19*

The COVID-19 pandemic presents psychiatrists prescribing clozapine with complexities over and above the general difficulties already described among Chinese psychiatric in-patients.¹ Some common initiation effects of clozapine: isolated fever, tachycardia or a mildly raised C-reactive protein² may be difficult to differentiate from intercurrent infection, including COVID-19.³ Other laboratory anomalies may add to confusion. Given COVID-19 infection deaths that are not the result of acute respiratory distress syndrome are often from fulminant myocarditis, for which a raised troponin is a poor prognostic feature, troponin levels taken routinely during clozapine initiation will need to be interpreted carefully. However, while leucopenia is a reported blood dyscrasia with COVID-19, to date neither neutropenia nor agranulocytosis is.

In the absence of an antibody test for COVID-19⁴ we rely on reverse-transcriptase polymerase chain reaction COVID-19 testing, which does not have 100% sensitivity in the initial phase of infection, so a single negative test does not exclude infection. Once an antibody test becomes available it will be a useful addition to pre-clozapine investigations.

Comorbidities such as diabetes, hypertension, respiratory illness and cardiovascular disease are very common in patients taking clozapine but are associated with adverse outcomes in the event of COVID-19 infection, including increased mortality rates. It is not known whether the antibody deficiency described in patients taking clozapine will further compromise this vulnerable group.⁵ These are not, however, indications to stop clozapine, which itself has serious adverse consequences. Rather patients need clear advice and, if possible, assistance regarding self-isolation and other precautions advised. Obesity and sleep apnoea may also contribute to poor outcomes and continuous positive airway pressure treatment, which can be an aerosol-generating procedure,⁶ may be a risk to staff.

Individuals already established on clozapine and managed in the community may require changes to their management. In view of recommendations for social distancing, the use of clozapine clinics for routine blood testing should be reconsidered. Instead, blood tests may be better performed in patient's homes, with staff using personal protective equipment and at, or near, the maximum intervals permitted. While the standard blood monitoring frequencies are at weekly (weeks 1–18), fortnightly (weeks 19–52) and four-weekly (over 52 weeks) intervals, clozapine can still be dispensed and administered with satisfactory monitoring at 14-, 21- and 42-day intervals, respectively.

Inevitably many patients taking clozapine will present with flu-like symptoms. An urgent full blood count will be required to exclude neutropenia with appropriate action. Many, however, will have another cause and so the evolving National Health Service recommendations regarding isolation and hopefully testing for COVID-19 infection should be followed. The combination of flu-like symptoms, chest pain and shortness of breath will, as community prevalence of COVID-19 increases, be much more likely to be because of COVID-19 than clozapine-induced myocarditis, except perhaps within the first 60 days of treatment.⁷ However, such a presentation will still need investigation and cessation of clozapine may on occasion be required as well as urgent general medical assistance. Careful documentation of symptom

profiles and investigations will aid subsequent decisions regarding clozapine re-challenge. In the event of COVID-19 infection the acute-phase reaction may result in reduced activity of cytochrome P450 1A2, raising clozapine levels and so an urgent trough clozapine level will be needed with a reduction in clozapine dose if required. This effect may be amplified if hospital admission is indicated necessitating abrupt change in smoking habits.

In summary; COVID-19 presents us with extreme difficulties regards clozapine initiation, the risks of COVID-19 are insufficient to justify stopping clozapine, an action which presents its own serious problems, precautions must be taken now to help protect our high-risk patients as COVID-19 infection may jeopardise both their physical and mental health.

1.3.60 Social media, self-harm and suicide

Allan House¹

Correspondence

Abstract

Use of social media by people with mental health problems, and especially those who are prone to self-harm, has potential advantages and disadvantages. This poses a dilemma about how and by how much the form and content of social media sites should be regulated. Unfortunately, participation in the public debate about this dilemma has been restricted and high-profile discussion of necessary action has been focused almost entirely on how much suppression of content is justified. Professional bodies, including the Royal College of Psychiatrists, should be doing much more than they are to shape how the debate is conducted.

- *Social media, self-harm and suicide*
 - *The dilemma*
 - *The public debate*
 - *The missing element: clinical and academic leadership*

The dilemma

There are, broadly speaking, positive and negative accounts of how people with mental health problems, and especially those with a history of self-harm, experience social media.^{1,2} Negative accounts have been emphasised in mainstream media,³ with social media presented as places where you are drawn into an immersive atmosphere of depressive messages and images that act as enticement to self-harm and suicide. More positive accounts from young people suggest that social media can also offer a space where you can come out of hiding, share otherwise secret fears with peers, and gain an element of support and advice.⁴

In the former view, risk of suicide is increased by the mood-lowering effect of the content and by a sort of creeping familiarity with the idea of self-harm or suicide – called sometimes desensitisation or normalisation – and greater awareness of the methods involved. In the latter view, the social or networking function creates opportunity for reducing the sense of disconnection or lack of belonging, and the sharing of detail allows some alleviation of the burdensomeness of feeling uniquely troubled (these and other ideas about risk of suicide are discussed by Joiner⁵). This Janus-faced nature of social media is well outlined in a report by Barnardo's about young people, social media and mental health – *Left to Their Own Devices*.⁶

The natural conclusion is that different people are likely to be affected differently by their online experiences, and the same person may be affected differently on different occasions. Which raises the question – how to minimise risk without at the same time suppressing useful content? This is a dilemma that requires a careful public debate involving as many interested parties as possible in coming to a solution that considers all the competing demands of the situation.

There are three issues that contribute to the complexity of the problem.

First, examination of online material about self-harm reveals substantial diversity in form and content.⁷ Those who post and those who respond to posts are engaged in conversations not just about the manifest topic of self-harm and suicide, even when the relevant posts are explicitly tagged as self-harm: content is also about emotional problems more generally, about relationships, fitting in or belonging, and about attractiveness, sexuality and body image. The mixture of textual and visual messaging leads to communication the ambiguity and irony of which can be missed by reading one without the other.

Second, much of this may be regarded as helpful by those who access it,⁴ even when the content includes direct communication about self-harm with images of self-injury. Such images can help an isolated person (anything up to a half of people who self-harm do not seek help for their problems⁸) feel less alone. The images may come with messages about self-care or harm minimisation. It is reasonable to conclude that content which some people find unhelpful is found helpful by others, and that whether particular content is found to be helpful or unhelpful by a particular individual depends on the immediate circumstances in which it is accessed.

Third, it is not clear what the putative pathway to harm is, following exposure to self-harm material online. Words such as graphic, explicit or glamorising are in themselves not tightly defined, but they imply that the underlying mechanism is an invitation to copy the behaviour. Linking this argument to suicidal behaviour is problematic – for example most online images of self-harm are of self-injury (cutting or burning) and yet these are extremely rare methods of suicide, especially in young people. If the putative pathway to suicide is not by copying then presumably it is by exposure leading to low mood and hopelessness – in which case it is not clear that images of self-injury are more problematic than other mood-influencing content.

These sources of ambiguity raise the serious possibility that clumsy, excessive or inconsistent intervention – in the name of reducing harmful exposure and (by implication) habituation or normalisation – may have the unintended

damaging consequence of increasing the sense of disconnectedness and burdensomeness experienced by people with mental health problems who self-harm.

The public debate

In the UK, this public debate has centred recently on the suicide of teenager Molly Russell, not least because her father has pressed forcibly the case for the damaging effect of social media and the need to suppress content that might (in his view, definitely does) encourage suicide. The BBC opened their coverage with an aggressive interview⁹ of Steve Hatch, the managing director of Facebook in Northern Europe, by Amol Rajan, who is the BBC's Media Editor rather than somebody with expertise in self-harm or suicide. Not long afterwards the government produced a White Paper – *Online Harms*¹⁰ – that bundled encouraging self-harm or suicide with incitement to terrorist activities, dissemination of child pornography, and drug dealing on the dark web. The main direction has not therefore been about self-harm and suicide prevention, but about steps to regulate the tech giants.

The response from the principal player in this case – Facebook/Instagram – has been dispiriting. After an attempt to use Nick Clegg as a front man, they announced earlier this year a ban on images of self-harm described as graphic or explicit¹¹ – with no definition of either offered by way of clarification. Now Instagram has announced a ban on drawings or cartoons depicting self-harm.¹² There is again lack of clarity about exactly what this means: in the cited article the specific example is of text linked to an innocuous drawing. What is happening, in the absence of serious discussion of the pros and cons, is a piecemeal suppression of visual content of social media postings.

The missing element: clinical and academic leadership

Where is the commission-like meeting of organisations, clinicians, academics and people with personal experience, that should be leading the debate and informing the decisions? Neither the social media companies nor the government has shown an interest in organising such an activity. The mainstream media, as one might expect, just want a story to tell, sentimental or sensational if possible. Samaritans has an interest¹³ but progress is painfully slow.

What is striking in all this is the absence from the debate of the professional bodies – the Royal College of Psychiatrists, the British Psychological Society, the Royal College of Nursing, the Health and Care Professions Council. Although members of the Royal College of Psychiatrists may have an online presence, and although the College has issued (rather one-sided) advice to its members¹⁴ and further guidance about professional standards of online behaviour is forthcoming, the College has conspicuously not been organising the high profile, mature debate that is needed to replace what is going on now. The absence of professional bodies from that role represents a failure of leadership in an area of public health where they should be at the forefront of educating the general public about self-harm and suicide, and modelling how intelligent decisions should be made on complex and important topics. It is time our College took the lead, initiating the establishment of a joint working group with the key professional bodies, third-sector organisations and people with personal experience. The role of such a body is not to establish the practicalities of regulation or control of content, but to offer the best available advice about what such content should be. The group should have a strong policy related to communication and dissemination of its discussions and not just await the production of a report – the aim is as much to model how discussion should happen as it is to achieve any other outcome.

Allan House is Professor of Liaison Psychiatry at the Leeds Institute of Health Sciences, School of Medicine, University of Leeds, UK. He is author of *Understanding and Responding to Self-Harm: The One Stop Guide* (Profile Books, 2019), which offers practical advice for anyone affected by self-harm.

1.3.61 Adjustment to short-term imprisonment under low prison staffing

Abstract

Aims and method

To understand experience of early imprisonment in one prison under low staffing levels. A researcher, independent of the prison, interviewed each prisoner soon after reception and 3–4 weeks later. The first question of the second interview was: 'I'd like to start by asking you about your experience of the last 3–4 weeks in prison'. Data are verbatim answers to this. Narratives were brief, so responses from all 130 participants were analysed, using grounded theory methods.

Results

The core experience was of 'routine' – characterised by repetitive acts of daily living and basic work, and little reference to life outside prison – generally resolved passively, towards boredom and 'entrapment'.

Clinical implications

This 'routine' seems akin to the 'institutionalism' described in the end days of the 1960s' mental hospitals. In an earlier study of similar men at a similar stage of imprisonment, under higher staff:prisoner ratios, experience was initially more distressing, but resolved actively and positively, suggesting that staff loss may have affected rehabilitative climate.

More men are imprisoned in England and Wales than in any other Western European country.¹ Many prisoners have at least one mental disorder,² but few are transferred to a healthcare setting for treatment, so most treatment and most programmes for offending behaviour are delivered in prison. Any impact of these is likely to be affected by the prison milieu. Studies have shown that people seem to be particularly vulnerable during early imprisonment, especially to self-harm,^{3,4} although there is widespread evidence of adjustment, including improvement of mental state over 4–6 weeks.^{5,6} Since these studies, however, there have been substantial cuts to prison staffing in England and Wales – about 40% in publicly run prisons since 2013.⁷ Over the same period, prisoner suicide, self-harm and violence rates have risen.⁸ Austerity in public service delivery is far from unique to the UK, so it is important to understand day-to-day prisoner experience and adjustment under reduced staffing. In one prison in public management, for example, prison officer numbers had been cut from 200 in 2013 to 148 in 2016, while the number and type of prisoners had remained more or less constant; there were 763 prisoners, of whom 52% were unsentenced or serving sentences of less than 6 months, in 2013, compared with 770, of whom 57% were similarly short-term, in 2016.^{9,10} Our research question was: How did new receptions in this prison affected by staff cuts experience day-to-day living during the first 4–5 weeks of a new imprisonment?

Method

Overview

Applying a grounded theory approach, a researcher employed independently of the prison recorded prisoners' responses to an open question about experience of the current imprisonment. This study was designed to stand alone, although it was embedded in a larger study, a randomised controlled trial of a 9-group intervention for alcohol misusing prisoners.

Ethics

The overarching study, including the qualitative components, had ethical approval from the National Health Service Health Research Authority National Research Ethics Service (NRES) Committee East of England – Essex (IRAS ref. 140458; REC ref. 14/EE/0046). Information leaflets about the research were made available to all prisoners on reception. Each potentially eligible prisoner was approached by the researcher, who explained the research to each man in private, assured him that neither his treatment in the prison nor in the criminal justice system more widely would be affected by a decision to participate or not and answered any questions about the research. Confidentiality was assured, except with reference to any specific information about intent or plan to harm self or others or to escape from the prison. Consenting men were asked to sign a consent form. Each man had at least 24 h to reflect before full participation and could withdraw at any time if he changed his mind about the research. The rate of refusal to participate was below rates reported in similar studies (P. J. Taylor, personal communication, 2019), but still about one in five men approached for screening refused and 27 (11%) of the eligible men initially agreeing to participate subsequently withdrew.

Sample

Participants were recruited between June 2014 and August 2016, from men newly received into one UK prison. In a two-stage screening process, the first stage was to identify, from records, all men likely to be in prison on this occasion for under 12 months (short-term prisoners) but to remain in this prison for at least 1 month, thus likely to acquire sufficient experience of the environment to be able to describe living in the prison and adjusting to it rather than talk about receiving a prison sentence *per se*. About 1 week after reception, a researcher invited these men to meet her to explore willingness to participate, to take formal consent from those willing and to complete a second, face-to-face screen for alcohol¹¹ or drug¹² misuse. All 238 consenting men screening positive for substance misuse were included; 197 remained for interview on a subsequent day up to a week later about pre-prison life experiences and their mental state. Between 3 and 4 weeks later, those still in prison and consenting were interviewed about their experience of this imprisonment and their mental state was re-evaluated. Data from the opening of this second interview are analysed in the study we report here.

For the trial, the men were randomised to receive either standard prison regime alone or prison regime and a 3-week group programme between these two interviews. The group programme included motivational work and self-management skills development, delivered by clinical psychologists from a local health board. Both intervention and treatment-as-usual men were included in this qualitative work.

Procedures

All interviews were conducted in private, by the same researcher on both occasions for each man. The data for this study were responses to the opening question of the second interview: 'I'd like to start by asking you about your experience of the last 3–4 weeks in prison'. After this, only simple, neutral prompts were used to encourage the men to talk freely about this, for example 'go on', 'tell me more'. Each prisoner's responses were documented contemporaneously and any abbreviated words or phrases written up in full immediately after the interview was complete. The interviews were not audio-recorded; audio-recording is commonly discouraged in grounded theory work and external researchers are not generally permitted to take recording equipment into prisons. Once each man had said everything that came to his mind, unprompted by us, about this imprisonment, he was asked some specific, supplementary questions about aspects of the imprisonment, including how much time he spent out of his cell, whether he had work, education and/or outside visitors, and whether he got on with prison staff and other prisoners. In turn, we were able to access independent reports on this prison from Her Majesty's Inspectorate of Prisons.^{9,10} These two separate sources of data allowed some *post hoc* consideration of the extent to which reported experiences fitted with actual activities on the one hand and general prison conditions on the other.

Data analysis

Anonymised, free narrative data were analysed in two batches – control- and intervention-arm men – by researchers blind to trial-arm membership and without reference to answers to specific questions about this imprisonment. This was to allow for the possibility that participating in groups as part of the trial affected the standard prison experience. The narratives tended to be short, a third of them not more than three sentences, so we decided to analyse all of them rather than defining the sample size by data saturation as would be more usual in a study of this kind. We used a grounded theory approach to analysis.^{13,14} The first narrative was examined, and categories of information contained in it extracted into a table, as far as possible labelling each category with a word or phrase used by the participant, with the supporting evidence of the full quotation. The second narrative was analysed in a similar way, using already identified categories where possible and adding new ones as appropriate. Two of us analysed the first 10 narratives masked to each other, then compared the ratings. Differences between us lay only in the extent to which we had listed each item as a separate category of routine – for example ‘having food’ as a common term for taking meals rather than listing each meal as a separate category. It was agreed that even the smallest of categories would be listed initially, after which both extractions were in full agreement.

We then completed first-level category identification from each batch separately (see Supplementary Tables 1 and 2 available at <https://doi.org/10.1192/bjb.2020.2>). It was apparent that very similar categories of experience were emerging, regardless of trial arm, so data from all the men were combined for further analysis. Using constant comparative analysis, higher-order categories were allowed to emerge, and then a core category, which best encompassed all the other categories.

Results

Sample characteristics

In total, 130 men provided valid interviews. Given the sample size, we have not tabled each man’s personal characteristics for context but provide the following summary. Their mean age was 30 years (s.d. = 7.9). Most (101/130) had been in prison before, with a mean total time spent in prison, after adding their various remands and sentences together, of just over 5 years (5.17, s.d. = 5.65). Two-thirds had mental health concerns (87/130), over a quarter physical health concerns (36/130) and screening confirmed that all were struggling with problem substance use.

The core experience of this imprisonment

The core category or concern was of ‘routine’ within the prison. The most repeated elements were activities of daily living (‘got up’, ‘made a cuppa’, ‘food’, ‘fag’, ‘nap’, ‘TV’, ‘association’ (when prisoners are allowed to mingle freely out of their cells), ‘cleaning’), with most men making some reference to at least one of these. Most of these activities were just listed to us – without further comment – but in a few cases comments were explicitly negative – ‘do a bit of work, well I say work, fuck around on the computer. I’m wasting time [...] really’ (141); ‘I’m fed up of TV’ (230) (the number shown in parentheses indicates the particular man making the statement). A few men mentioned going to the gym or taking other forms of exercise, and a few were explicit about not doing so. Other activities sought by the men as part of a healthy routine but which required more initiative met mostly with limits and frustration. These activities were work, education and courses. Few men reported attending education or courses, but most were preoccupied with seeking work – ‘my brain needs to focus on something’ (217). More than half reported actually working, although often repetitive cleaning or prison maintenance, with some explicitly objecting to this: ‘I don’t want to just work for the prison’ (154). Others were explicit about the frustrations of trying to get ‘real work’: ‘I’m frustrated because I didn’t get a job’ (217). Many seemed accepting, coming back to the concept of routine: ‘You get into a routine and tell yourself it’s not forever’ (215).

This dreary routine also seemed to encompass the men’s experience of the outside world. Few men volunteered reference to family or friends, and most of these only in terms of ‘routine visits or phone calls’. The few men who referred to outside events with emotion were all negative: ‘they wouldn’t let me go to my Dad’s funeral; I was a bit upset’ (120);

'Nan passed away [...] someone came from the chapel [...] he asked if I was alright and if I was going to do anything stupid while I was in here' (211).

The model of adjustment to this imprisonment

The men all felt some sense of movement over the 3 weeks in relation to this 'routine'. Two directions of resolution were apparent. The stronger was passive movement towards feeling ever more trapped or 'banged up'. The weaker, experienced at all by very few, was of 'being busy' and even of 'time flying'.

Passive resolution was characterised by comments such as: 'The same stuff, day in day out, it just does your head in' (100); 'spend all my time sweltering in my cell' (219); 'banged up most of the time' (109). For a few, though, even this restrictive routine provided a kind of stability: 'I'm settled now. Been in 10 times and got my routine now' (128); 'I like the routine of prison' (253).

The very few men who described more active movement towards 'being busy' and 'time flying' were not only looking for 'new opportunities', but considered that they had found them: 'it's busy, and I like to keep busy' (106); 'time goes quicker now I'm doing stuff' (117). Just two men stood out as different because they specified that they themselves were trying to help others, which gave them a sense of purpose: 'I'm also the smokers' champion – I give people advice on coping strategies, just like being a listener really' (134); 'I've been cleared to be a prisoner listener. History of self-harm, so surprised, didn't ever think I would. Look forward to starting that' (153). Further, when these more positive things happened, prison staff were invariably also seen in a positive light and as helping them to move in a positive direction.

Barriers to and facilitators of adjustment

In this model of adjusting to imprisonment, the men volunteered particular barriers and facilitators as affecting direction of movement towards being trapped and bored or towards being busy. These broadly fell into two types – personal or prison issues.

Personal issues

The few personal issues raised relating to life outside prison were almost invariably described as problems, leaving the men feeling more restricted and trapped: 'I'm stressing a lot, thinking I'm a parent, shouldn't be here, I should be out there looking after my missus and kids' (102).

Reports of the impact of relationships in prison were more mixed. Some liked their relationships with other prisoners and thought they helped pass the time positively: 'chill out with the boys and have a chat, the boys are all good in here' (103). Most were more negative, with 'routine irritations' beyond their control promoting a negative path towards an increasing sense of entrapment: 'me and my cell mate just end up bugging the shit out of each other' (100); 'It's hell in here – kicking doors, bunch of kids' (207). There was an occasional report of loss of an in-prison attachment as a stressful 'outside-prison' issue: 'I was in with my other mate, but he went to [another] prison. I'm gutted. I won't be seeing him for three years – that's how long he's got left. I'll have to do another sentence to see him' (141).

Another major personal issue frequently referred to was ill health. Most comments indicated that this was a real barrier to progress and left individuals feeling restricted. Occasionally, these were in the form of a simple statement of fact: 'my liver is fucked' (112); 'I got a diagnosis. PTSD' (230). Sometimes state of health was a more explicit barrier: 'Won't let me go to the gym because of my blood pressure' (101); 'Sleeping mostly. My head is shot' (223). Six men, though, thought prison was helping or could help their health specifically: 'No, it's brilliant. I feel better and put a bit of weight on' (138); 'I've seen mental health today – let them know my frustrations. She is going to help me' (134).

Prison system issues

The prison system issues that most felt frustrated by were the 'routine blocks', or barriers, to their efforts which left them trapped in their poor health, boredom and numbing routine. Very occasionally, this was attributed to staff personally – 'Staff don't care' (238) – but mostly to the system. This was of particular concern in relation to health: 'I'm waiting to see the dentist. Remember I had toothache last time you came [3 weeks before]? Well I've got an abscess now. I asked to see the dentist, but I've not heard back' (147); 'I still haven't seen mental health' (222); 'I was pissing blood and passed kidney stones on Monday. There is no help in here' (148). Prison issues posing barriers to occupation were commonly described, with most wanting to be productive but being frustrated in their efforts: 'I've applied for everything, I'll do anything' (262); 'You read the prison policies and they say you must work and I'm here begging for it. I've spoken to the officers [...] I've put three apps [applications] in so far. I said I would kick off in a week if I didn't get something but my partner said it's not worth it' (217); 'You don't seem to get anywhere when you put the applications in – we made a complaint but I haven't heard anything about that either' (247); 'I think the system is designed to break you' (156). Prison-system problems were thus generally seen as frustrating recovery and a direct barrier to progress.

Discussion

'Routine' is, by definition, made up of a series of repeated, expected actions. In some form, it is ubiquitous among human beings. It may be imposed in order to influence behaviours. Institutions, almost by definition, impose routines, whether deliberately or otherwise, so it may seem unsurprising that men put routine at the core of their experience of being in prison. The routine that most men reported, however, was impoverished and seemed comparable to reports from the end days of the big 'asylums' for people with mental disorder, in which the patients tended to become as impoverished as their environment.^{15–17} Wing¹⁸ subsequently emphasised that this could happen in the community too if resources were limited. A difference between the patients described by Wing and colleagues and these prisoners is that none of these prisoners had enduring psychotic illness, so it is possible that they were less vulnerable. A few prisoners welcomed the basic, limited repetitiveness of the experience and a very few found positive ways through the system. Most were explicit about finding the limitations frustrating and being unable to affect their situation. To what extent, however, could we rely on these accounts from, perhaps, disgruntled men and to what extent is this a consistent experience?

Other evidence on the experience of being in this prison

There is an independent inspectorate of prisons for England and Wales (HM Inspectorate of Prisons), which conducts reviews of individual prisons as well as occasional thematic reviews of needs and services in them (<https://www.justiceinspectorates.gov.uk/hmiprisons/>). Fortunately, an unannounced inspection of this prison took place in 2016, more or less at the same time as this research. The resultant report, despite referring to 'a decent, hard-working staff group who had maintained good relationships with the men in their care, and had done well to keep the prison stable through some challenging times' (p. 5), highlighted how low staffing levels had affected the responsiveness of staff to the needs of the men in the prison.¹⁰ In 2016, for example, only 16% of prisoners' call bells were responded to within 5 min, compared with 39% in 2013; timetabled activities were run less often, application response rates fell from a 59% within 7 days in 2013 to 31% in 2016, and only 5% of men reported spending more than 10 h out of their cells in 2016 but 10% in 2013, all significant differences. This all fits with the limitations that the men in our sample were citing. It indicates that the prison milieu may be subject to substantial changes over time. This has implications for all prisoners and their chances of 'reform'. From a trialist's perspective, it is clear that 'treatment as usual', the traditional standard against which psychosocial interventions are evaluated, must be measured in some detail in order to understand its meaning and potential impact. For clinical and criminal justice system practice, staff should be aware of the potential impact of the milieu on what they can deliver.

How prisoner experience after staff cuts compares with experience at a better staffed time

We were able to consider the model of prisoner experience and adjustment for the years 2014–2016 in the context of data we collected in a similar way from similar men in this prison (and another in South Wales) in 2007–2008, before the prison staff cuts.¹⁹ In that study, narratives were much longer and richer, to the extent that we had clear data saturation (no new categories of information emerging) after just 20 cases. This in itself fits with the possibility that the later sample of men were, indeed, already so restricted by their ‘routine’ that they were less engaged in thinking and talking about themselves and their experiences. The core concern of these similar men in prison during the better staffed period was of the losses inflicted by the imprisonment and how awful the experience was. Although, even then, there was some passive resolution of this concern by ‘getting used to it’, most invoked a sense of active movement towards becoming ‘alright’, which meant feeling and getting better, making positive changes and developing good relationships. The men in the earlier sample spoke much more about how much they were missing people, freedom, information and other resources, whereas those in the current sample were much more focused on prison *per se*. The study samples were of different men, but as their age, sentences, prior experience of imprisonment and rates of reported mental health difficulties were so similar (the earlier sample is described in Taylor *et al*, 2010⁵), it is reasonable to consider that the difference in prison milieu and experience has had an impact.

Souza & Dhami,²⁰ in a quantitative study of men in two English prisons at about the same time as our earlier study, also cited losses of family, friends and freedom as the hardest experiences reported by first-time and recurrent male prisoners, but also some resolution of problems through improving health and having opportunities for rehabilitation. They then argued that positive engagement or not was better explained by aspects of life before imprisonment and overall exposure to imprisonment than by prison security or regime. They could not envisage the extent of imminent cuts, and we must now question whether, for most prisoners, impoverished regimes force their focus onto prison conditions *per se* and limit capacity for concern about others and/or reflection and development.

The advantages of richer routines

Behan²¹ examined the specific prisoner experience of educational programmes. Although some prisoners wanted to ‘better themselves’, gain new skills and prepare themselves for work on release, some used these programmes as a way of coping with their imprisonment, saying that it took their mind off their experience in prison and ‘killed time’. This use of education to better oneself or as a coping strategy resonates with the narratives given by our sample of men, some of whom were clearly wanting to develop their skills and abilities, whereas others just wanted to get out of the cell or the wing or simply fill the time. Behan suggests that attendance for experiences such as education may also give a greater sense of agency in being able to control their prison routine. Our men commonly found themselves frustrated and without agency because they wanted to be at education or, more likely, work and could not get there.

Nurse *et al*²² found, in a qualitative study of prison environment and mental health of prisoners and prison staff, that understaffing and a lack of activities led to increased stress and frustration among prisoners. The men in their sample, like those in ours, viewed any activity as important to ‘stimulate your mind’. Nurse and colleagues, however, found more tension between prisoners and staff than in either of our studies. Their data were, however, collected through focus groups rather than individually. It may be that prisoners feel more need to complain about staff when other prisoners are listening than when they can talk in private.

Reiter *et al*²³ were wide ranging in their inquiries about prison experience, covering a broader range of prisoners and prison conditions than we did. All our prisoners were living in ‘ordinary locations’ within the prison during the study. Nevertheless, it is striking that in the relatively well-staffed Danish prisons of the Reiter study, men’s experiences had more in common with those in the earlier of our studies. The Danish prisoners too seemed very aware of what they were missing by being in prison and, although making references to in-prison conditions, did not appear so mentally bound by their routine as the men in our ‘austerity prisoner sample’.

Limitations

This was a qualitative component of a wider study and not set up as a primary open inquiry in its own right. Nevertheless, the question about experience of imprisonment was planned, open ended, consistent and posed before any other questions at the second interview after the men had had about a month of experience of imprisonment. The interviews were not audio-recorded, so the notes and final written record of the responses could not be checked except against each other, but as responses were generally not long or complex, we think it extremely unlikely that any key word or phrase was missed. The researchers collecting the data experienced some of the same frustrations in accessing the prisoners as the prisoners did in their daily living, which could have coloured data recording, but consistency on some key issues with the report published by HM Inspectorate of Prisons¹⁰ mitigates against this.

We have suggested that the dull, restricted, almost institutionalised experience of the men, so different from that of an earlier cohort, related to staff cuts. It is impossible to rule out other explanations completely, but the reduction in prisoner officer numbers from about 200 to fewer than 150 was the main observable change. Numbers and types of prisoner overall remained the same and there were only modest differences between research cohorts in likely key measures. Although all of the men in our later cohort screened positive for substance misuse so did 84% in the earlier cohort; 74% of the men in the earlier cohort had had prior experience of imprisonment, but so did 80% in the later cohort.

Summary and implications

Focus on prison ‘routine’, which tended to leave prisoners feeling trapped, dominated short-term prisoners’ accounts of their time in this one UK prison at any time between July 2014 and August 2016. They did not raise concerns about the awfulness of the losses of family, friends and freedom incurred by imprisonment, as men in an earlier cohort had done, and hardly referred to the outside world. They rarely reported any positive resolution, which had been prominent among the men in the earlier study. The large change in staffing levels made a difference to the environment, and it seems that the core experience and adjustment of prisoners cannot be assumed to be a constant in such a context. Indicators that the later men were experiencing ‘institutionalism’, not apparent in an earlier, better staffed time, should concern those who fund and commission prisons.

Our warmest thanks to the staff of Cardiff prison, who facilitated the work under the most difficult circumstances, and to the prisoners themselves. Many others contributed substantially to the study, including: Michael Robling and Rebecca Playle, grant co-applicants; Rachel McNamara, all of the Centre for Trials Research, and Hannah John-Evans, who completed some of the data collection; Anna Kissell and Gemma Plant, who provided additional research support in the Division of Psychological Medicine, Cardiff University; and clinical psychologists from Abertawe Bro Morgannwg University Health Board, who provided the group work: Ruth Bagshaw, Bronwen Davies, Leigh Gale, Thomas Hoare, Lynwen Mallows, Sara Morgan, Chris Stamatakis and Samantha Vine.

The trial of which this study is a part was funded by Health and Care Research Wales and the Welsh Assembly Government under the Research for Patient and Public Benefit (RfPPB) scheme (grant number RfPPB-1028).

S.O’C. completed qualitative analysis of all cases and co-led the drafting of the paper. Z.B. completed most of the interviews with the prisoners and contributed to drafting the paper. Y.M. provided independent qualitative advice and contributed to drafting the paper. N.K. completed independent analysis of a proportion of the cases from each group and contributed to drafting the paper. P.J.T. designed the study, analysed data for half the cases, co-led paper drafting and completed revisions.

date

2020-06

Abstract**Aims and method**

To assess physical health needs of adolescent in-patients by routine monitoring. A retrospective analysis of case notes was conducted on a 6-month intake to generic and secure adolescent mental health units in Greater Manchester, UK.

Results

Fifty individuals were admitted (52% female, average age 15.84 years). Diagnoses varied and 66% were prescribed medications before admission. All had a physical health assessment, which identified various physical health risk factors. Average body mass index was 25.99 (range 15.8–44), and increased during in-patient treatment for 84% of individuals who had their body mass recorded more than once. A total of 28% of individuals smoked. Lipids and prolactin levels were elevated across the sample.

¹ **Declaration of interest:** None.

Clinical implications

This evaluation strengthens the argument to optimise physical healthcare for adolescent in-patients and develop physical health interventions, particularly given that we observed elevated lipids and prolactin. Physical health and well-being may not be prioritised when assessing and managing young peoples' mental health, despite their increased vulnerability for comorbid conditions.

People with serious mental illness (SMI) experience poor physical health, resulting in an estimated loss of life of 30 years.¹⁻³ This is because of unhealthy lifestyles, medication side-effects and inadequate physical healthcare.^{1,2,4} It occurs early, often preceding the onset of illness, thus offering the opportunity to intervene to prevent comorbid conditions.^{5,6} Young people with mental health disorders are a vulnerable group requiring additional physical healthcare.^{1,7} Adolescent in-patients are particularly at risk, given the 'obesogenic' environment.^{8,9} This refers to additional restrictions and barriers to living a healthy lifestyle, such as reduced opportunities to exercise, lack of control over dietary intake and increased access to highly calorific snack foods. It may also be their first contact with mental health services, and affords the opportunity to intervene on an individual level through treatment access, and on a wider scale. For example, ensuring the environment encourages a healthy lifestyle and reduces the chance of iatrogenic harm. However, the precise physical health needs of adolescent in-patients is still unclear. A previous Australian study found that physical health problems are common in adolescent mental health settings, yet often go undetected and untreated.¹⁰ Previous evaluations suggest physical healthcare is inconsistent across services, including in-patient units, neurodevelopmental clinics and community services.¹¹⁻¹³ Therefore, indicators of poor physical health are missed. However, this issue has not been evaluated in UK generic/secure adolescent in-patient services, where individuals present with a range of disorders on a variety of medications. Therefore, we aimed to evaluate the physical health needs of adolescent in-patients by routine monitoring in services in Greater Manchester, UK.

Method

A retrospective analysis was conducted on electronic files of individuals admitted to generic and secure adolescent in-patient units over 6 months in Greater Manchester, UK (August 2018 to February 2019).

Setting

The service is made up of units Junction 17 (generic) and Gardener (male secure). Junction 17 is a 20-bed, mixed-gender, generic adolescent in-patient service that provides various evidence-based treatments for young people with complex mental health needs. The young people admitted to the unit present with mental health symptoms that are of a severity such that they are unable to keep themselves safe, or require intensive treatment above and beyond the scope of community mental health teams. Individuals have a range of diagnoses and mental health needs, yet all are experiencing a high level of psychological distress. It also has a day service to provide alternatives to in-patient care (patients attending this were excluded from this evaluation). Referrals are received via regional child and adolescent mental health services and adult mental health services for adolescents aged 13–18 years with needs that cannot be met safely within the community. They receive intensive therapies and treatment in line with National Institute for Health and Care Excellence (NICE) guidelines and have access to a range of psychological therapies (individual and group), occupational therapy based activities and family interventions. The Gardener unit is a specialized, ten-bed, national medium secure in-patient service for adolescent males with complex health needs that cannot be met safely within the community or by standard mental health services. It is one of seven nationally commissioned services by National Health Service (NHS) England for adolescents. Referrals are received from mental health teams via a national referral process. There is also an onsite educational facility for young people provided by the Bury Educational authority. Multidisciplinary teams consist of consultant psychiatrists, psychiatric trainees and colleagues from nursing, psychology, occupational therapy, family therapy, dietetics, social work and advanced practitioners with non-medical prescribing and physical health monitoring skills.

Although ethical approval and informed consent were not sought, the evaluation was considered necessary by the clinical leads within the trust who are responsible for approving audit and service evaluations. The audit and evaluation team at Greater Manchester Mental Health NHS Foundation Trust was informed of the rationale for this evaluation and reviewed the data that was to be extracted, along with the clinicians' approval. They approved this process and provided the research team with a list of patient identification numbers to be used to extract the data. No identifiable information was extracted from the patient files and the process was conducted in line with the local guidance for service evaluations.

Outcome measures

A structured audit tool was developed with Microsoft Excel. The following demographics were collected: gender, ethnicity, employment and living status, legal status and age on admission. Clinical variables included primary diagnoses, length of stay, discharge status and medication. Medication was recorded at two time points; the first was upon admission (this included any pre-existing prescriptions before their admission) and the second included medications prescribed at the time of discharge, or any current medications if the individual remained an in-patient at the time of the search. To maintain patient confidentiality no identifiable information was recorded.

The Physical Health Improvement Tool (PHIT) is a standardised measure developed within the service to collect physical health data for individuals upon admission. It is an electronic document that enables clinicians to record physical health assessments (blood tests, electrocardiogram (ECG), body mass index (BMI)), body composition, physical health observations, and lifestyle factors such as smoking habits, alcohol use (Alcohol Use Disorders Identification Test; AUDIT¹⁴), substance use, physical activity and diet, sexual health and referral to other services, e.g. sexual health services. BMI was recorded on the PHIT tool shortly after admission; some individuals also had their BMI recorded at subsequent time points, which enabled change in BMIs to be calculated.

The standard procedure for physical health monitoring is set according to the local physical health and well-being policy (Greater Manchester West Mental Health NHS Foundation Trust Physical Health and Wellbeing Policy, 2011).¹⁵ The policy recommends a PHIT¹⁶ assessment within 24 h of admission, and all individuals are to be offered appropriate

lifestyle interventions in line with NICE guidelines.⁷ The PHIT tool enables clinicians to select whether individuals were offered lifestyle interventions such as smoking cessation, diet and exercise advice, and referral to drug, alcohol and sexual health services.

Data extraction and analysis

A manual search of patient files was conducted from 12 to 19 February 2019 for the previous 6-month intake across generic and secure services (August 2018 to January 2019). Descriptive analysis was conducted with SPSS version 22 for Windows (IBM Corp., 2013) and Microsoft Excel 2016 for Windows.¹⁷

Results

Sample

Fifty individuals were admitted between August 2018 and January 2019 to the generic and secure services (52%, $n = 26$ females, 76% White British; *Table 1*). The average age at admission was 15.84 (range 13–21, s.d. 1.46) years. Average length of stay was 49 (range 2–169, s.d. 44.1) days. Nine (18%) were detained under the Mental Health Act 2007.¹⁷ *Table 1* Demographic information

Diagnoses and medication

Individuals had a range of diagnoses, primarily mood disorders (e.g. moderate depressive episode) ($n = 9$, 18%), adjustment disorders ($n = 8$, 16%) and mixed anxiety/depressive disorders ($n = 7$, 14%) (see *Table 1* for full list of diagnoses). Thirty-three (66%) were prescribed medication on admission and 32 (64%) received medication upon discharge or at the time of the search. A total of 38% ($n = 19$) were prescribed antidepressants, 18% ($n = 9$) were prescribed antipsychotics and 2% ($n = 1$) were prescribed anxiolytics at discharge or time of the search. A range of non-psychotropic medications were also prescribed to individuals for physical comorbidities such as digestive complaints and dermatological issues (see Supplementary Tables 1 and 2 available at <https://doi.org/10.1192/bjb.2019.68>).

Physical health assessments

All new admissions received a physical health assessment, recorded on the electronic records with the PHIT tool. However, the extent to which the assessments were completed in full varied for each variable, and some information was missing at the time of the search either because of a delay in paperwork processing or patient or staff non-adherence.

² MHA, Mental Health Act 2007.

Smoking and alcohol use

Smoking rates were higher than the general population as 28% currently smoked, compared with the average of 12% for young people in the UK.²⁰ The amount of cigarettes smoked daily varied ($m = 11$, range 2–40, $n = 7$) and two individuals reported the age they started smoking (9 and 11 years). Nine smokers used cigarettes (64%) and three used roll-ups (21%). Six (42% smokers) individuals received nicotine replacement therapy as part of their routine care (Table 3). Table 3 Lifestyle assessments Physical lifestyle assessment Yes, n (%) No, n (%) Not reported, n (%) Reports a diet high in fat and salt 30 (60%) 20 (40%) Lives a sedentary lifestyle 8 (16%) 42 (84%)—Aware of the risks of a sedentary lifestyle 44 (88%) 6 (12%)—Referral made to physical activity advice 1 (2%) 18 (36%) 31 (62%) Smoking status Non-smoker (history unknown) 23 (46%) Current smoker 14 (28%) Never smoked 10 (20%) Ex-smoker 3 (6%) Alcohol use Completed, n (%) Mean (s.d.) Range Units of alcohol consumed per week 49 (98%) 1.02 (4.44) 0–30 AUDIT total 49 (98%) 0.81 (2.40) 0–14 Frequency of alcohol consumption Yes, n (%) Weekly (4 or more) 1 (2%) Weekly (2–3 times) 1 (2%) Monthly (2–4 times) 4 (8%) Monthly or less 3 (6%) Never 40 (80%) Not recorded 1 (2%) Quantity of drinks on typical day None 40 (80%) 1 or 2 4 (8%) 3 or 4 3 (6%) 10 or more 1 (2%) Not recorded 2 (4%) Times consumed 6 (female) or 8 (male) drinks on a single occasion Daily or almost daily 1 (2%) Weekly 1 (2%) Monthly 0 Less than monthly 4 (8%) Never 42 (84%) Not recorded 2 (4%) Substance use Yes 6 (12%) Yes previous 3 (6%) No 39 (78%) Not recorded 2 (4%)⁵

As part of the initial PHIT assessment individuals were screened for alcohol use with the AUDIT tool.¹⁴ Alcohol consumption was low, and most individuals abstained ($n = 40$, 80%). Individuals were also screened for substance use ($n = 48$, 96%). Six (12%) used substances on admission and three (6%) used substances previously, including cannabis, cocaine, ketamine, LSD and aerosols.

Sexual health

Sexual health was discussed with ten individuals. This included whether they practiced safe sex ($n = 10$, 20%) or used contraception ($n = 9$, 18%). For females, relatively few files contained information on human papillomavirus vaccination status ($n = 9$, 35%), whether they experienced amenorrhoea ($n = 6$, 23%) or if they were pregnant ($n = 5$, 19%; no pregnancies). For males, the presence of symptoms such as erectile dysfunction were discussed with some individuals ($n = 5$, 21%). One referral was made to sexual health services.

Discussion

The entire sample received routine physical health monitoring, and multiple various health recordings were conducted as part of these assessments. Individuals had a range of diagnoses, and displayed evidence of physical health issues requiring some form of assessment, monitoring and intervention. This is consistent with adult in-patient populations. Individual risk factors for poor physical health included high levels of obesity upon admission, subsequent weight gain, high levels of self-reported sedentary behaviour, increased smoking rates and some evidence of increased levels of lipids and prolactin. For some young people prescription of medication with metabolic side-effects included increased sense of hunger. Therefore, some of the antipsychotic medications may also be a risk factor, although only 18% of young people were prescribed antipsychotic medications in this cohort. Further information is needed to establish the dietary intake of young people and there is a need to introduce standardised measures for physical activity and diet. This evaluation highlights the vulnerability of young people admitted to in-patient wards and emphasises the opportunity this presents for physical health to be monitored, assessed and treated routinely. Although many risk factors for physical

health may predate the admission, contact with health professionals during an in-patient stay affords the opportunity for healthcare provision.

Clinical implications of findings

Our findings have important clinical implications for adolescent in-patient settings.

The ‘obesogenic’ environment

The ‘obesogenic’ environment of in-patient wards has frequently been discussed in the literature.^{8,9} This has been attributed to higher energy intake through increased access to high-calorie foods, reduced energy expenditure through inactivity and fewer opportunities to engage in exercise.^{8,9} Our evaluation adds further evidence to this as individuals had high BMI values, which rapidly increased with duration of stay. Weight gain in mental health services is often attributed to side-effects of antipsychotic medication; however, only a small proportion of young people were prescribed antipsychotics and those who were not also gained weight.

Unhealthy lifestyles were often reported by the clinicians. Although many received advice on living a healthy lifestyle, research has consistently shown that advice alone is insufficient to result in meaningful behaviour change.^{21–23} Clinicians should be aware of using proactive approaches to implementing lifestyle interventions and encouraging uptake of routinely offered physical health activities, such as occupational therapy groups (e.g. walking). People with SMI experience significant barriers to living healthily, such as low mood and anxiety, poor motivation, lack of social support, reduced opportunity, lack of knowledge and skills, financial barriers and employment difficulties.^{24,25} This group also has additional restrictions of being on secure and adolescent in-patient wards, living in a contained environment with relatively reduced access to facilities and outdoor opportunities. Therefore, interventions taking these additional barriers into account need to be explored, and these difficulties should be considered when attempting to promote health and well-being in this setting.

Because of the limited data available on food intake on the in-patient wards, we were unable to assess the adolescents’ diet. At the time of this evaluation, routine dietary assessments were not yet conducted upon intake. This is an important and valuable opportunity to collect information on young people’s eating habits and identify appropriate interventions to promote healthier diets. Systematic ways of recording food choices and dietary intake will need to be developed to facilitate this process. This could include simple charting of meal options on patient files, and conducting routine diet assessments with individuals, such as 24-hour recall to include any other foods consumed outside of regular mealtimes. Monitoring of diet will allow appropriate interventions to be targeted to those who are most in need to prevent the likelihood of weight gain.

Other physical health issues

Many patients were prescribed medications to alleviate physical health problems upon admission. There was also evidence of dysregulated blood metabolites and elevated levels of prolactin in over half of this sample, which is common in people with SMI.²⁶ Hyperprolactinaemia can have serious consequences, such as hormonal disturbances causing sexual dysfunction, facial hair and acne, disruption to usual pubertal development in young people and increased risk of developing cancers such as breast cancer.^{26–28} This is addressed appropriately within the service and monitoring of bloods is conducted routinely. It is important for clinicians and healthcare teams to maintain routine monitoring of blood metabolites and endocrine markers as there are often no obvious symptoms to indicate individuals are at risk. Ensuring blood tests are conducted routinely, regardless of medication or diagnosis, is important. Additionally, information about sexual health screening was variable, and at the time of the search only 10% had discussions about their sexual health. This is a common issue across adolescent services. For example, a previous review found that only 37% of young people had sexual health screening upon admission to an in-patient unit.²⁹ This represents a missed opportunity for management of sexual health in a high-risk group.

Importance of monitoring

We add to the growing evidence that physical health monitoring in mental healthcare is necessary, particularly for adolescents.^{11–13,30–32} Previous research also shows that metabolic abnormalities are common in adolescents receiving mental healthcare, but often go unnoticed and untreated.^{6,10,13,21} Individuals admitted to generic and secure mental health wards have a wide range of difficulties and non-specific mental health needs, and may or may not be prescribed psychotropic medication. It is therefore important to develop clear guidelines and policies that focus on adolescents in mental healthcare, regardless of their diagnosis or physical health status. Senior clinicians should acknowledge this when developing the standard operating procedures for their units and ensure that physical health is a fundamental part of individuals care when staying on adolescent in-patient units.

Recommendations and future work

There is a pervasive need to explore health interventions for this group and identify the best way to deliver these within in-patient settings. Future work should focus on developing physical interventions to reduce the cardiometabolic risk associated with the in-patient environment. Hayes *et al* reviewed non-pharmacological interventions delivered on in-patient wards and found psychosocial programmes, such as therapy-based activities, family interventions and mindfulness-based activities, were common.³² Yet, few studies have been conducted offering physical health interventions within this setting, or even those across the general population, despite the benefits of exercise for adolescents.³³ Further, a recent review showed that despite being recommended by NICE, lifestyle interventions are not consistently offered across mental health trusts in the UK.³⁴ Standardised guidance also needs to be developed to guide clinicians and ensure adolescents are receiving high-quality physical healthcare regardless of diagnosis and in-patient status. This includes introducing formal assessments of diet and physical activity to better quantify adolescents' needs. Ensuring access to interventions alongside continued monitoring of physical health is imperative to improving outcomes for adolescents.

Strengths and limitations

To date, this is the first evaluation of adolescent in-patient generic and secure services that assesses routine monitoring of physical health. The findings carry significant implications for service development. This work has only been made possible because of the high levels of work happening within the unit to record all of this data, and the importance placed on ensuring the physical health assessments are conducted for all young people on admission to the units. However, this clinical audit taken from a cross-section of this population is only representative of one specific area, and the trans-diagnostic nature of the service means that physical health issues identified may change over time given the rapid turnover of young people, particularly within generic in-patient services. However, it is likely that the issues and difficulties identified here will be prevalent across mental health trusts. There is potential that some assessments identified as missing had indeed been conducted, and the data may have been uploaded after the files were searched. There is also potential for the data to exist in paper format within the service, or exist elsewhere in the electronic files rather than the physical health tool, thus resulting in some missing data. As with all routinely collected measures, they are subject to human error and reliant on accuracy of the clinicians completing the forms.

In conclusion, this evaluation strengthens the argument for optimising physical healthcare for adolescent in-patients. Adolescents admitted to generic and secure in-patient services show increased cardio-metabolic risk in the form of weight gain, obesity and dysregulated blood metabolites. We suspect that our findings are not unique to this unit and there is a need to consider physical health in adolescent in-patient services across the UK. There is a need to implement standardized routine monitoring guidelines for physical healthcare for adolescent in-patients, given their increased vulnerability, and also develop appropriate interventions in collaboration with young people to tackle the physical health disparities experienced by this group.

We acknowledge the work of all the clinicians and staff at the adolescent generic and secure in-patient services at Greater Manchester Mental Health NHS Foundation Trust to which this service evaluation would not have been made possible.

(lalexand@tcd.ie)

date

2020-02

Abstract

Aims and method

To apply process mapping, a component of lean management, to a liaison psychiatry service of an emergency department. Lean management is a strategy that has been adapted to healthcare from business and production industries and aims to improve efficiency of a process. The process consisted of four stages: individual interviews with stakeholders, generation of process maps, allocation of goals and assessment of outcomes.

Results

There was a significant reduction in length of stay of psychiatric patients in the emergency department (median difference: 1 h; $P = 0.015$). Five of the six goals were met successfully.

¹ Declaration of interest None.

Clinical implications

This article demonstrates a management intervention that successfully reduced length of stay in an emergency department. Further to the improvements in tangible (quantitative) outcomes, process mapping improved interpersonal relations between different disciplines. This paper may be used to guide similar quality improvement exercises in other areas of healthcare.

Lean management is a process that has been adapted for use in healthcare from business and production industries. Its usefulness has been demonstrated in medical settings, where it generates enhanced staff understanding and improved, coordinated delivery of care.¹⁻³ Research indicates similar benefits in behavioural crisis units⁴ but its use in an emergency department liaison psychiatry setting has not been demonstrated. Although psychiatric patients comprise a minority of emergency department presentations, they require a disproportionate amount of time and resources, which can frustrate emergency department staff and cause negative attitudes towards such patients.^{5,6} Myriad factors underlie this, such as lengthy waiting times, interpersonal difficulties and procedural ambiguity. These factors are often long-standing and resistant to change, but lean management processes, when executed appropriately, are an accessible and effective way of effecting meaningful change.

Prolonged length of stay was a recurrent source of contention and discontent in this emergency department before the process was undertaken. Boarding or lodging of psychiatric patients awaiting admission to psychiatric units is common and, for various reasons, these patients spend longer in the department than their medical and surgical counterparts.⁷ The requirement for 'medical screening' is contributory, but avoidable non-clinical factors, such as health insurance or lack of transport, are known to play a significant role.⁸ In addition to straining resources, patients who spend longer in

an emergency department are more likely to suffer adverse outcomes or incidents, such as medication errors.⁹

Workplace incivility is a further stressor that is reportedly commonplace in emergency departments,¹⁰ and is compounded by the phenomenon of ‘silo working’, whereby different departments operate in isolation from each other.¹¹ In addition to contributing to an unpleasant work environment, interpersonal conflicts interfere with provision of collaborative and efficient care. Efficient and coordinated delivery of care is essential to optimising the quality of treatment provided.¹²

Aims

To execute and describe a quality improvement process consisting of: mapping the psychiatric patient’s journey through the emergency department, using data from all involved healthcare professionals (stakeholders) identifying weaknesses in the system, such as duplication of work, role confusion, communication errors and unnecessary delays(iii) generating immediate and short-, medium- and long-term goals to improve service provision.To evaluate and quantify outcomes of the quality improvement process, including: (i) length of stay of patients in the emergency department before and after the quality improvement intervention(ii) attainment of goals after intervention.

Method

Setting

This quality improvement exercise was executed in the emergency department of an urban university tertiary-referral hospital, processing in excess of 55 000 patients per year. This is a 24-hour emergency department that receives on average 29 psychiatric referrals per week. Mental health assessments are carried out by the consultation liaison psychiatry service during working hours and on-call psychiatry out-of-hours.

The process was executed in four stages: stage I – stakeholder interviewsstage II – generation of process mapsstage III – interdisciplinary meetingstage IV – assessment of outcomes.

Over a period of 3 months, we conducted interviews with 11 staff working in the emergency department.

Selection of participants

The proposal for this project was submitted at an in-house Emergency-Psychiatry Management Meeting. We applied to interview 11 stakeholders – staff members from different disciplines who are routinely involved in providing care for mentally ill patients in the emergency department. They were: one emergency department triage nurse, one emergency department nurse, two emergency department doctors, one liaison psychiatry registrar, two liaison psychiatry nurse specialists, one psychiatry registrar on-call, one social worker, one healthcare assistant and one security staff. The data were to be collected by a senior member of the psychiatry team not routinely involved in first-line care in the emergency department.

Ethical approval

Exemption from ethical approval was granted by the Ethics Committee in St Vincent’s University Hospital, Dublin, on the basis that there was no direct patient involvement in this study.

Stage I: stakeholder interviews

The purpose of stage I interviews was to elicit details of individual staff members' management of psychiatric patients in general, in order to map a generic template of the interaction, from beginning to end, between psychiatric patients and specific disciplines, such as social work.

Duration of interviews was 40–60 min, concluding when no new data were being generated.

In an individual face-to-face meeting, the stakeholder was invited to describe their involvement with psychiatric patients in the emergency department, beginning from the point at which they first become aware of the patient and concluding with their last contact with the case. The participants were asked to describe interactions with psychiatric patients in general, rather than specific issues that had arisen with individual patients.

The purpose of the interview (stage I) was explained to each participant. They were informed that they would be invited to participate in stages II and III at a later date. They were advised that the interviewer would redirect them if they began to engage in stage II or III discussion.

Participants were first asked open questions, such as 'Tell me about your first contact with a psychiatric patient in the emergency department', followed by more closed questions, such as 'How long does this component take?' Further questions were raised to identify specific weaknesses, such as duplication of work, role confusion, communication errors and unnecessary delays.

To reduce bias from the interviewer, the participant was allowed to speak without interruption except when redirection or clarification was required. Participants were redirected back to the routine care pathway if they began to discuss problem-solving.

Stage II: generation of process maps

A working flow diagram of each participant's involvement was drawn up during the interview and the participant was asked to make any comments or changes before the meeting ended.

The information was transformed into an overview process map showing the patient journey and maps representing the role of each individual stakeholder (*Figs 1 and 2*). Fig. 1 The overview process map, detailing the pathway of psychiatric patients through the emergency department. (a) Baseline map; (b) map with problem areas superimposed (marked by 'no access' symbol). ED, emergency department; SW, social work; GP, general practitioner. Fig. 2 An individual process map representing the role of the liaison psychiatry nurse specialist: 3–4 h pathway of patient assessment and management in the emergency department (ED). HCA, healthcare assistant; OPD, out-patient department; ED, emergency department; GP, general practitioner.

Stage III: post-interview stakeholder focus group and goal-setting

All stakeholders and heads of departments (medical, nursing, liaison psychiatry, social work, security) were invited to participate in a focus group. The focus group consisted of ten individuals.

The overview (integrated) map and individual maps (*Figs 1 and 2*) were scrutinised for weaknesses or pinch points. No solutions were suggested or elicited at this stage. Weaknesses were itemised into four groups: role confusion, duplication of work, unnecessary delays and communication deficits. A problem list was collated and distributed. Stakeholders were asked to categorise items according to priority (1, low priority; 2, medium priority; 3, high priority) and to mark a timeline for implementation (immediate, less than 1 month, more than 1 month). After consensus was reached on target areas (items that scored >20), stakeholders were invited to generate potential solutions. Responsibility for each target area was allocated (*Table 1*). *Table 1* Results of six targeted areas for change, including action prescribed, individual assigned and projected timeline

Proposed improvement	Weakness targeted	Action	Person responsible	Timeline
At 6-month follow-up ^a	Efficient handover after psychiatric assessments	i, ii, xiii, xiv	Designated emergency department staff members (team leaders A and B)	to be the contact for psychiatry staff about all psychiatric patients in the emergency department
	Psychiatry consultant to inform psychiatry staff;		emergency department clinical nurse manager	to

inform emergency department nurses Immediate Target met on projected timeline Emergency department staff access to liaison psychiatry team at morning shift-change i, ii, iii, xiii, xiv, xvii Priority discussion for emergency department nurse manager or social worker or emergency department doctor at liaison psychiatry handover meeting at 09.00 h Psychiatry consultant to restructure handover meeting Immediate Target met on projected timeline Refine referral pathway (emergency department to psychiatry) v, vii, viii, ix, x, xi Default referral to psychiatry is by emergency department medical staff, not triage or emergency department nurse. MITT to reflect this Emergency department consultant to change MITT protocol. Emergency department nurse manager to inform triage nursing staff. Immediate Target met on projected timeline In limited circumstances, as defined, direct referrals are possible Emergency department and psychiatry consultants to agree criteria for direct referral pathway between emergency department and psychiatry Immediate to 1 month Target met on projected timeline Define medical screening vii, x, xi Emergency department and psychiatry consultants to collaborate on medical screening requirements Emergency department and psychiatry consultants 1 month Target revised and excluded at clinical meetings (see section IV: attainment of outcomes) Prevent or manage acute agitation in psychiatric patients v, vi Implementation of psychiatric medication chart for patients awaiting transfer to approved psychiatric unit. Psychiatry will prescribe 'as required' medication and give advice proactively and preemptively Psychiatry consultants to inform psychiatric registrars Immediate Target met on projected timeline Formalise the role of security staff vi, xv Clarity about legal obligations and safeguards in relation to restraint and detention Psychiatry consultants to provide formal written guidance and training for security staff 1 month Target met on delayed timeline (3 months)²³

Stage IV: assessment of outcomes

Outcomes were evaluated 6 months after completion of stage III. Outcomes were patient length of stay in the emergency department and attainment of goals (*Table 1*).

Statistical analysis

Lengths of stay of samples of patients referred for psychiatric assessment were measured over a 3-month period before commencing the process (January–March 2017) and over a 3-month period 6 months after the intervention (January–March 2018). In total, 190 pre-mapping patients and 190 post-mapping patients were compared. Distribution of data was calculated using the Shapiro–Wilk test. Statistical significance was calculated using the Mann–Whitney test and effect size was calculated by the difference between median lengths of stay in the pre-mapping and post-mapping groups. This was a convenience sample that represents over half the total number of psychiatry consults in emergency department over the 3-month post-mapping period. This was a convenience sample that represents over half the total number of psychiatry consults over a 3-month period, chosen from cases that were labelled as psychiatry consults on the emergency department's patient-processing software.

² MITT, Mental Illness Triage Tool.

³

a. Five of the six targets were met, one on a delayed timeline. One target was discarded at subsequent clinical meetings.

Results

Stage I: stakeholder interviews

Each of the 11 interviewees described their involvement with psychiatric cases, which were mapped onto individual maps (*Fig. 2*). The difficulties encountered were also elicited and categorised into four problem areas and 17 targets (i–xvii). Delays: on-call psychiatry doctors reported delayed handover of updates from emergency department staff(ii)emergency department nursing reported delayed handover from psychiatry team following assessments(iii)social work reported that the patient stay was prolonged by delays in referral from emergency department and psychiatry staff(iv)social work reported that medical and psychiatric assessments were delayed by failure to assess patients in tandem with social work assessment.Role confusion: the discipline responsible for the management of acute agitation (emergency department doctors or psychiatry doctors) was unclearthe role of security staff in the care of psychiatric patients, in particular the statutory limits of their interventions, was unclearthe medical discipline responsible for ‘medical screening’ (emergency department, psychiatry or general medical), and the definition of ‘medical screening’, were unclearit was unclear which medical discipline (emergency department or psychiatry) was considered to be the treating team of patients following completion of psychiatric assessmentconsequent to role confusion (viii), it was unclear which discipline was responsible for further referralsconsequent to role confusions (vii) and (viii), it was unclear which discipline was responsible for further investigations, such as blood tests/ECG/urine toxicology.Duplication of work: the emergency department nurse and triage nurse both reported routinely making phone contact with psychiatry doctors to inform them of the arrival of psychiatric patients, in addition to the referral that was made by the emergency department doctor after their assessment; the expectation from these phone contacts was unclearsome disciplines reported carrying out overlapping assessments, e.g. social work and psychiatry.Communication difficulties: emergency department nurses reported a failure by psychiatry to keep emergency department staff updated on psychiatric management planspsychiatry staff reported a difficulty identifying emergency department staff to receive updatessecurity staff reported failure of medical staff (psychiatry and emergency department) to update the security team, leading to a longer security intervention than needed in some casesthe healthcare assistant reported delayed updates after change of treatment plans, leading to a longer healthcare-assistant intervention (1:1 special) than needed in some casesthe social worker reported delayed referrals of child welfare issues to social work.

Stage II: generation of process maps

Individual process maps (*Fig. 2*) and an overview process map (*Fig. 1*) were developed for discussion at stage III.

Stage III: post-interview stakeholder focus group and goal-setting

Following presentation of maps and completion of worksheets, the highest-ranked problems were targeted for intervention and a projected timeline was assigned. The consensual goals were: to ensure efficient and comprehensive handover between liaison psychiatry and emergency department staff following psychiatry assessments (targets i, ii, xiii, xiv)to facilitate emergency department staff accessing the liaison psychiatry team for updates at morning shift-change (09.00 h) (targets i, ii, iii, xiii, xiv, xvii)to refine the referral pathway (emergency department to psychiatry) in order to clarify the role of each individual and the appropriate timing of referrals and to prevent staff making repeated and redundant contacts about the same patient (targets v, vii, viii, ix, x, xi)to establish a definition of ‘medical screening’, the process of medical assessment before psychiatry referral (targets vii, x, xi)to prevent or effectively manage acute agitation in psychiatric patients (targets v, vi)to formalise the role of security staff in the management of psychiatric patients, including education about statutory obligations and limitations (targets vi, xv).

Stage IV: assessment of outcomes

Length of stay

A statistically significant Shapiro–Wilk test indicated a non-normal distribution of data (2017 $P < 0.001$; 2018 $P < 0.001$), indicating suitability for non-parametric analysis. There was a statistically significant improvement in the median length of stay between the pre-mapping group and the post-mapping group (median difference: 1 h; $P = 0.015$). The median length of stay pre-mapping was 8 h (interquartile range, IQR = 8) and post-mapping was 7 h (IQR = 7). There was a particular improvement in the number of psychiatric patients spending over 24 h in the department: length of stay exceeded 24 h for 5% of psychiatric patients in the pre-mapping group and 2% in the post-mapping group.

Attainment of goals

Five of the six targets were attained to the satisfaction of stakeholders, four on the projected timeline and one on a delayed timeline (*Table 1*).

One of the targets – ‘define medical screening’ – was revised and excluded at a subsequent clinical meeting, after concerns were raised that the implementation of such a definition could lead to a rigid clinical approach to screening psychiatric patients.

Discussion

Process mapping, a component of lean management (‘lean’), is one of a number of management tools that aim to improve efficiency and eliminate ‘waste’.¹³ Lean was originally applied to the motor industry in Japan but the underlying philosophy lends itself to many types of organisation, including healthcare. Lean scrutinises and evaluates each component of a process so that ineffective, inefficient or potentially harmful elements (‘waste’) can be fixed or discarded.

Lean processes have been applied to other healthcare services, including ambulatory care settings¹ and interventional radiology.² Process mapping has been successful in these settings in identifying problems, reducing errors and generally improving efficiency; however, the outcomes in most of the previous studies have taken a qualitative approach rather than quantitative. Some studies have measured patient satisfaction before and after implementation of this method, but found no statistically significant difference.¹⁴ To our knowledge, the benefits of this method have not been studied in liaison psychiatry. The differences that exist between liaison psychiatry and other services, in particular the inherent unpredictability of an emergency department liaison psychiatry service, make it a unique setting that warrants particular attention. Lean methods have been applied to acute emergency settings³ and behavioural health crisis settings,⁴ both more similar to our service, but those studies did not assess the function of an emergency psychiatry service within a general emergency department, as is commonly the setting for the provision of emergency psychiatric care in Ireland and the UK. One such study of a stand-alone crisis centre found a significant improvement in door-to-door dwell time, but, as a disparate service to ours, without comparable interdisciplinary challenges, the findings are difficult to relate to a hospital setting.⁴

The use of process mapping in the present study afforded us the opportunity to visualise the journey of the psychiatric patient as they interacted with each individual stakeholder (*Fig. 1*) and as they were processed through the interdisciplinary department (*Fig. 2*). Doing so, we were able to set realistic, practical, timely and finite goals, thereby measurably improving efficiency. Further to this, we hoped that this process might help to improve the quality of working relationships between individuals and departments.

Lengthy waiting times of mentally ill patients in an emergency department exert stress on resources and increase the risk of adverse incidents.⁹ Before undertaking this quality improvement project, their median length of stay in this department (8 h) significantly exceeded the national target of 6 h. The National Emergency Medicine Programme in the jurisdiction of Ireland aims to ensure that 95% of patients are processed within 6 h.¹⁵ Process mapping and the series of interventions that followed led to a significant reduction in length of stay (median 7 h), with a particular reduction in the number of lengthy waiting times (5% exceeding 24 h pre-mapping, 2% exceeding 24 h post-mapping). This

outcome, we postulate, was achieved by improving staff relations and agreeing on a series of low-burden and low-cost practical changes.

One such practical change was the management and prevention of acute agitation in mentally ill patients in the emergency department. The application of process maps enabled the stakeholder group to deconstruct the chain of events leading up to acute agitation: delayed handover following psychiatric assessment caused ambiguity about management (*Table 1*, proposal (a)) psychiatric registrars reported being unable to identify the appropriate person in the emergency department to receive handovers (*Table 1*, proposals (a) and (b)) the head of emergency department nursing observed that delays in administration of oral medication in the early stages of behavioural disturbance precipitated escalation of the behavioural disturbance, requiring emergency administration of intramuscular medication (*Table 1*; proposal (e)) healthcare assistants observed that long periods spent in the contained environment of the emergency department led to patients becoming more irritable, but the assistants did not feel equipped to supervise time out of the department security staff were willing to supervise breaks with the healthcare assistant, but were unclear about their legal obligations and safeguards in relation to restraining and detaining patients (*Table 1*; proposal (f)).

Consensus on such solutions could not have been reached in the absence of this process, as non-clinical security staff and healthcare assistants – who provided important information and insights that were key to implementing solutions – are not routinely consulted by senior clinical and management staff. These types of solution, especially in cases such as this, reduce risks to patients and staff and reduce the burden on resources, thereby allowing the department to run more efficiently.

Further to these measurable benefits, process mapping facilitated progression from silo working to a cohesive team approach. The phenomenon of silo working leaves individual staff members feeling isolated and unsure about what to do or where to find help,¹¹ especially in highly stressful situations such as a patient's acute agitation. Clarification of departmental policies and pathways, paired with improved individual flexibility and collegiality, empowered individuals to navigate difficult situations as a team so that interdisciplinary solutions were generated with minimal conflict. Process mapping provided a structure for this conversation to take place, thereby enhancing collegiality and collaborative care.

Limitations

For process mapping to be successful in creating a consensus of opinion, the interviewer must remain objective. This process-mapping exercise was led by a senior registrar on the psychiatry team. Ideally, the lead role would be undertaken by an external participant, to avoid introducing interviewer bias (or the perception of interviewer bias by the stakeholders). This was not possible within the limits of our resources. This did not emerge as an obstacle in this study, probably because of the considerable trust between the specialties, but an independent interviewer would be essential if relationships were more fractious.

Compounding this, participants in this project were vulnerable to recall and reporting bias due to the retrospective nature of the interviews and the fact that they were asked to consider the pathway common to the majority of psychiatric cases, rather than specific cases.

Having evaluated the success of this process, it appears that neither of these limitations was prohibitive.

Recommendations for utilising process maps in healthcare

Adhering to structure

We found that both the interviewer and stakeholders were tempted to offer personal conclusions and suggestions in stage I, which could have led to individual maps being contaminated by an individual's personal agenda. It was important throughout this process to remind the stakeholders that any useful solutions must be raised through the focus-group meeting in stages II and III.

Completing the full process

Change management requires energy and motivation and we found that sustaining momentum was a struggle at times. Process mapping does not serve its function if it ends after stage I, so persistence through stages II and III is needed to enable meaningful change to be made. It can be a challenge to convince busy professionals to sacrifice valuable time, but the value of participation en masse cannot be matched by only one or two people. Active involvement of consultants and heads of department from the outset is vital.

A word of caution

Not all situations are amenable to process mapping, so this method should be carefully considered before applying it to a problem situation.

Process mapping is a tool developed to examine a process, not a population. It is not designed to mediate interpersonal conflicts. Although we observed an improved sense of trust and collegiality, process mapping cannot enhance trust in a relationship where none exists.

The problems described herein are particular to our liaison psychiatry service, and may not mirror the challenges faced by other specialties or services; however, the general challenges encountered in the day-to-day provision of healthcare (e.g. inefficient use of resources and a tendency to resort to silo working) are ubiquitous across all settings. We have identified a method of overcoming these pitfalls. This experience can provide a blueprint for undertaking this kind of work in other fields of healthcare. We have found it a useful tool for enhancing working relationships and implementing immediate, lasting and meaningful change.

Contents

- *Section 12(2) MHA approval process is fit for purpose*
 - *Declaration of interest*

Rigby and McAlpine¹ have confusingly conflated criticism of Section 12 Mental Health Act (s12 MHA) approval courses, attendance at which is only one of several statutory criteria for s12 approval, with criticism of the overall process of s12 approval. This letter addresses some of the limitations of the article, which in hindsight I'm sure Rigby and McAlpine would prefer to have entitled: 'Are s12 approval courses fit for purpose?'

Before reading further, readers should understand the following. •A s12-approved doctor is legally defined as 'a medically qualified doctor who has been recognised under section 12(2) of the MHA as having specific expertise in the diagnosis and treatment of mental disorder' and has had training in the application of the MHA.²•The criteria for s12 approval are contained within the statutory instructions³ and represent the Government's requirements regarding the

work experience, training and qualifications doctors need to possess before they can legally be considered to have the 'specific expertise in the diagnosis and treatment of mental disorder' required to be an s12-approved doctor. •Regional s12 approval panels have robust governance structures and procedures in place, including audit, that ensure that only those doctors that meet the statutory criteria are approved. •Doctors require only a basic working knowledge of the MHA to be involved in MHA assessments (MHAAs). •Doctors do not need to be s12 approved to be involved in MHAAs. If they are not s12 approved then it is preferable that they have personally treated the patient in the past or have some previous knowledge of the patient's case. •S12 approval courses are not courses on which doctors learn about the MHA, or how to conduct MHAAs, for the first time. The courses serve to reinforce and enhance attendees' knowledge of the MHA and of the MHA Code of Practice. They offer valuable time for discussion among clinicians, with a solicitor present, with debate often focused on the intricacies of the MHA as opposed to the basics. •Not all s12-approved doctors are actively involved in detaining patients under the MHA. Examples include medical members of the first-tier tribunals (mental health), Second Opinion Appointed Doctors (SOADs) and doctors who produce independent expert reports for court.

Aspects of Rigby and McAlpine's article that need highlighting include the following. •Rigby and McAlpine imply that s12 doctors may not be 'equipped with the knowledge and skills', particularly knowledge of the MHA, to consider detention of patients under the MHA and that this may have contributed to a rise in detentions over the past decade. There is no evidence to support their view, which in any case has not considered that the decision to apply to detain a person under the MHA does not lie with s12 doctors but with, usually, an approved mental health professional (who makes the application). •Rigby and McAlpine declare that a 'lack of formative assessment [in relation to s12 course objectives] is particularly concerning considering that there is evidence to indicate that there are inadequacies in many psychiatrists' understanding of the relevant [MHA] legislation'. Once again, this is an eye-catching assertion for which they offer no convincing evidence. The two papers they cite are more than 20 years old, from 1999 and 1997 respectively, and pre-date the introduction of routine s12 approval courses, which commenced around 2002. •Rigby and McAlpine state that international applicants with MRCPsych may not be aware of the UK MHA as 'the MRCPsych does not assess UK mental health law'. However, they neglect to mention that s12 legal instructions require that 'if the applicant has completed all or a substantial part of their training outside England or Wales, that the applicant must provide evidence of 'steps the applicant has taken to familiarise themselves with psychiatric practice and the organisation of psychiatric services in England or Wales, including the practical application of the 1983 Act'.³ Furthermore, the MRCPsych curriculum is different to the requirements for core training (e.g. Workplace Based Assessments (WBPA)), and the knowledge and skills pertinent to s12 approval are mostly gained outside preparation for the MRCPsych examination. •In criticising references for s12 approval, Rigby and McAlpine fail to appreciate that references for s12 approval are not restricted to commenting on an applicant's ability to undertake an MHAA but also require referees to be able to comment on, for example, the applicant's report writing and attendance at legal hearings, or that referees are, as always, bound by General Medical Council guidance in that references must be honest, objective and include all information relevant to a colleagues' competence, performance and conduct.⁴ •The response rate of their survey was only 21.7% (5/23), which is far too low for the results to be usefully interpreted regardless of triangulation.

In summary, Rigby and McAlpine offer no convincing evidence that attendees of s12 courses do not have a working knowledge of the MHA sufficient to undertake MHAAs, or that the introduction of an additional requirement for s12 approval, to pass a multiple choice question (MCQ) and clinical examination, essentially on the MHA and on conducting MHAAs, is required.

We would also argue that, other than theoretically, Rigby and McAlpine provide no evidence that s12 courses, as they are currently delivered, fail to fulfil their core objectives or require major revision, or that the s12 approval process is anything but fit for purpose.

It is always important to consider how training may be improved; in relation to s12 courses, as Rigby is aware, the London Approval Panel have suggested that benchmarking MCQ course material and content across s12 courses nationally might support the development of improved course material and potentially of a 's12 course MCQ self-assessment revision aid' focused on the essential aspects of mental health law and the Code of Practice akin to mandatory training on the MHA recommended by the MHA Code of Practice and monitored by the Care Quality Commission.⁵

The development of continuing professional development material relevant to building or maintaining the skills and knowledge required to act as an s12-approved doctor, and support from employers to evidence experience pertinent to s12 approval and reappraisal in annual appraisals, are areas that those interested in supporting doctors to improve

practice in relation to their s12 work might also wish to focus on.

Abstract

The Royal College of Psychiatrists' Parliamentary Scholar Scheme gives higher trainees in psychiatry the opportunity to spend 1 day a week in the House of Lords working alongside a peer with an interest in health. This article describes the work of the House of Lords and Parliament using examples from the experiences of 2017–2018 scholars and outlines ways doctors can get more involved in policy and politics.

- *Conclusions*

The Royal College of Psychiatrists set up its Parliamentary Scholar Scheme in 2017 with Professor the Baroness Hollins, who is a cross-bench peer in the House of Lords. Professor the Baroness Hollins, a former Consultant Psychiatrist and College President, spends much of her time in the Lords campaigning to improve services for people with learning disabilities, which is one of her specialist areas of interest. The Parliamentary Scholar Scheme, now supported also by the BMA Foundation, gives higher trainees working in psychiatry the opportunity to spend 1 day a week, as a special interest session, in the House of Lords working alongside a peer with an interest in mental health. Peers on the scheme come from across the political spectrum; in the 2017–2018 cohort there were peers from the Conservative, Labour and Liberal Democrat parties as well as from the cross-benches.

The scheme gives trainee psychiatrists hands-on experience of working in the field of health policy as well as wider politics. The psychiatric higher trainee curriculum requires the development of ‘effective leadership skills’ and ‘an understanding of organisational policy and practice at a national and local level in the wider health and social care economy’.¹ The scheme clearly allows participants to develop such skills but it aims to go further – to enable the trainees to develop skills in influencing the mental health agenda.

There are other schemes available to support trainees to develop leadership skills, for example the National Medical Directors Fellowship Scheme² and the Darzi fellowship scheme.³ However, as far as we are aware, the Parliamentary Scholar Scheme is the first programme to give trainees experience of working in the House of Lords. Given the current recruitment and retention problems within the mental health workforce,⁴ this scheme is certainly something that makes psychiatry training stand out from other specialties and may help encourage more doctors into the profession.

This article aims to guide readers through the work of Parliament, mainly focusing on the House of Lords, using examples from our experiences as 2017–2018 scholars.

What the House of Lords and Parliament do

The UK Parliament is made up of the House of Commons, House of Lords and the monarch. Members of the House of Lords, known as peers, are appointed by the Queen (the monarch) on the advice of the Prime Minister and are unelected. The House of Lords has three main roles: making laws, debating public policy and holding government to account. Members of Parliament (MPs) have the power to overrule the Lords, but the Lords can still be very influential in terms of making/changing legislation and policy.

Members of the House of Lords

Peers are often experts with experience from outside of Parliament, for example, the peers we worked with had experience of working in psychiatry, nursing, surgery, trade unions and the civil service. Most are ‘life peers’, although 92 (at the time of writing) sit by virtue of a hereditary title. Life peers are appointed by the monarch on the advice of the Prime Minister to serve for life; the title is not transferable when they die.⁵ Peers are nominated either by their political parties or by the House of Lords Appointments Commission, which recommends people for appointment as non party-political life peers.⁶

Work of the House of Lords

Making and changing laws (legislation)

Bills (draft laws) are introduced to Parliament and then repeatedly reviewed, debated and amended by both the Lords and the Commons. There is a process known as ‘ping-pong’ where the Bill goes back and forth between each House as amendments are made and agreed or rejected. When the Bill is agreed by both Houses it is given Royal Assent and becomes an Act of Parliament.⁸ An example of a Bill that was going through Parliament while the 2017–2018 scholars were in post was the Mental Health Units (Use of Force) Bill, otherwise known as ‘Seni’s Law’. The Bill was proposed by Steve Reed, MP for Croydon North, following the death of one of his constituents, Seni Lewis, in 2010. Seni died aged 23, after being restrained on a mental health ward by 11 police officers. The Bill started in the Commons, went to the Lords, amendments were considered in both Houses and then it became an Act in 2018. The new legislation means that mental health units will have to take steps, including better training for staff, to reduce the use of force against patients. Robust data on the use of force will be collected and police will have to wear body cameras when called to mental health settings; recordings from these cameras can be used in evidence.^{9,10}

Another example is the Mental Capacity (Amendment) Bill, which is now enacted¹¹ and lays out a new legal framework to replace Deprivation of Liberty Safeguards. Some of the 2017–2018 scholars were able to research the framework, liaise with experts and organisations with interests in the area, and contribute to topics such as the role of care home managers in overseeing the safeguards and the central importance of a person’s wishes and feelings when decisions are made about them. Many peers spoke on this Bill as it passed through the House of Lords and some of the 2017–2018 scholars were able to support their peers in drafting speeches using their own experience of working in mental health services and research briefings.

One peer put down an amendment to the EU Withdrawal Bill when it passed through the House of Lords in 2018. The amendment focused on the mutual recognition of professional qualifications, which is about ensuring that professional qualifications (e.g. medical degrees) continue to be recognised in the EU and UK after Brexit. The 2017–2018 scholar attached to this peer undertook some research in this area using a briefing from the Parliamentary library and liaising with relevant organisations, such as the British Medical Association (BMA) and legal firms to seek their perspectives. The scholar then used this information to draft a speech for their peer for the debate on the Bill.¹²

Debating public policy

Alongside debates on specific legislation there are also debates on topical issues and public policy. It is during these that members are able to give speeches, giving their opinions and arguments and the relevant government minister has to respond. Members may speak because they have a particular interest in the area of debate or particular expertise. The 2017–2018 scholars had the opportunity to contribute to a variety of speeches for their peers on topics related to mental health, for example for debates on access to mental health services for people from Black and minority ethnic groups¹³ and to debates on wider healthcare system issues such as long-term NHS sustainability and global nursing.^{14,15}

Checking and challenging the work of the government (scrutiny)

Select committees

MPs and peers hold the government to account. One way of doing this is through the select committees run in the Commons and the Lords. The most important one for health is the House of Commons Health and Social Care Select Committee, which conducts inquiries on a range of topics. Anyone can submit a proposal to a select committee and, as a group of scholars, we submitted a proposal for an inquiry into the state of drug and alcohol services in England. An inquiry we followed during our time in Parliament focused on the impact of Brexit on medicines, medical devices and substances of human origin. Experts (including doctors), interested organisations and members of the public can submit written evidence to inquiries, for example in this one, the BMA and the Academy of Medical Royal Colleges both submitted evidence. The committee also took oral evidence from a range of expert witnesses, including the Rt Hon Jeremy Hunt (the then Secretary of State for Health and Social Care) and Dr Ian Hudson (Chief Executive, Medicines and Healthcare products Regulatory Agency), which some of the 2017–2018 scholars were able to watch. The committee used this evidence to write a report with a series of recommendations. For example, one of the recommendations was that the government should ‘produce a comprehensive list of all the issues relating to the supply of medicines, medical devices and substances of human origin which require contingency planning for the UK leaving the EU [...] with evidence that plans are in place to address identified risks to patients’.¹⁷ The government has to respond to each published select committee report and to consider its recommendations, which may or may not influence government policy. The government published its response to this Brexit report in July 2018 and in answer to the recommendation above it said, ‘At this stage we do not have plans to publish a comprehensive list of the issues relating to medicines, medical devices and substances of human origin. We will continue to be as transparent as possible, but whilst we are engaged in on-going negotiations it is vitally important that we manage information carefully in order to not disadvantage the UK’s position’.¹⁸

Written and oral questions

Members also hold the government to account by asking oral or written questions that the government is required to formally answer on the record. Questions on health and social care are answered by the Ministers for Health and Social Care. At the time of writing, Matt Hancock MP is Secretary of State for Health and Social Care. However, there are other government health ministers to be aware of, for example Jackie Doyle Price MP is currently the Parliamentary Under Secretary of State for Mental Health, Inequalities and Suicide Prevention and, in the Lords, the Parliamentary Under Secretary of State (Lords) for Health is Baroness Blackwood. As part of their role, the 2017–2018 scholars drafted oral and written questions that could be used by their peers to put to House of Lords ministers. Ideas for questions came from recently published reports, government announcements and stories in the media.

Oral questions are posed each day in both Houses. In the House of Lords, there is a 30 min slot for four oral questions, which peers have to submit in advance. The peer stands up for their slot and puts their question to the minister for the appropriate department, who has to respond; there is then time for other peers to ask the minister supplementary questions on that topic. The 2017–2018 scholars also identified upcoming oral questions in the chamber that could be of interest to their peers and drafted supplementary questions to be used in the brief debate to further clarify or challenge the government’s position. An example of an oral social care question asked by one of the peers we were working for during our time on the scheme was ‘To ask her Majesty’s Government what steps they are taking to support (a) the care sector, and (b) those receiving care, in the light of the retrospective change in guidance on the application of the national minimum wage to sleep-in shifts for care workers’.¹⁹ This question was asked following a widely publicised media story about sleep-in carers being able to claim minimum wage for overnight shifts and was answered by Lord O’Shaughnessy, the then Parliamentary Under Secretary of State (Lords) for Health.

Peers and MPs can submit written questions to government departments that ministers have to respond to within certain time frames. Peers can table up to six questions each day and can expect an answer within 14 days. For example, when the report by the Parliamentary and Health Services Ombudsman on NHS eating disorder services²⁰ was published, one of the shadowed peers asked a series of questions about improvements that could be made to medical training and funding, one of which was, ‘To ask Her Majesty’s Government, following the conclusions of the Parliamentary

and Health Services Ombudsman, *Ignoring the alarms: how NHS eating disorder services are failing patients* (HC 634), published on 6 December, what assessment they have made of the recommendations set out in that report; and what discussions they have held with the General Medical Council on reviewing the eating disorders training for junior doctors'. This was answered by Lord O'Shaughnessy.²¹

Other work of peers

All-party parliamentary groups (APPGs) are informal cross-party groups that have no official status within Parliament. They are run by and for members of the Commons and Lords. Many choose to involve individuals and organisations from outside Parliament in their administration and activities. Examples are the Acquired Brain Injury APPG, the Mental Health APPG and the Psychology APPG.²² The 2017–2018 scholars were able to attend meetings and contribute to the work of some of the APPGs. In 2017–2018 the APPG for Mental Health was chaired by Helen Whately MP and its secretariat was provided by the Royal College of Psychiatrists and Rethink. Some of the 2017–2018 scholars had the opportunity to work on the APPG for Mental Health's inquiry into the Five Year Forward View for Mental Health.²³ One of the scholars went on a visit to see some of the new services set by Central and North West London NHS Foundation Trust as a result of the Five Year Forward View and to understand the challenges and opportunities involved. We helped with reviewing evidence and recommendations for the report using our clinical expertise.

Day to day, most peers have meetings with a wide range of people, such as politicians, representatives from charities, think-tanks and NHS organisations, journalists and lobbyists. The 2017–2018 scholars had the opportunity to shadow peers and also contribute to some of these meetings. There are always events taking place in Westminster, for example we were able to accompany our peers to events such as the launch of the report by the Lancet Commission on Liver Disease, the launch of the Schizophrenia Commission report and the Parliamentary Conference on Mindfulness.

Peers also receive correspondence from a wide variety of sources, including members of the public, interested organisations and other politicians. The 2017–2018 scholars were able to help their peers with responding to enquiries and drafting letters.

The role of the College

Our links with the Royal College of Psychiatrists were invaluable, and the advice from its Public Affairs team enabled us to navigate what can be a complex parliamentary process. They were also able to support us with our parliamentary research on specific topics related to mental health. More broadly, the Public Affairs team works with parliamentarians, arm's-length bodies and other political stakeholders to campaign and influence mental healthcare. It sends out written briefings to parliamentarians on mental health topics which are coming up in debates, oral questions or Bills to give an overview of the topic but also to give the College's perspective (for example with the Mental Capacity Bill). Team members regularly meet with politicians face to face about different mental health issues. The Public Affairs team, alongside Rethink, coordinates the APPG on Mental Health and helps to plan their activities and inquiries for the year. The team also sends out a weekly email to College members entitled 'Political Week', which gives an overview of any mental health topics that have come up in Parliament.

What we learnt and skills we developed

Our 1-year scholarship was an exciting and unique opportunity to learn more about the interface between politics and healthcare and how Parliament works. As trainees it gave us a better understanding of the wider mental health system and its interactions with government. We developed skills in leadership, policy analysis, speech writing and influencing the mental health agenda, all of which will be helpful for us as consultant psychiatrists. Within the Healthcare Leadership Model,²⁴ these skills correspond to the 'connecting our service' domain, as we were able to develop an understanding of how different services connect to the broader health landscape, how complex relationships form and how decisions are made. It also corresponds to the 'influencing for results' domain, as we were able to develop our communication skills and our ability to influence people.

During our time, we were able to meet with a number of MPs and peers who are influential in healthcare to learn more about how they got into politics, their day-to-day work and what their priorities are. In return, we were able to share with them our experiences of working in front-line mental health services. Some of us took our peers to visit our clinical teams so that they could get an in-depth understanding of what it is like to work in psychiatry.

All of us have been able to share our learning with colleagues through teaching sessions, blogs and conference presentations. At present there are no objective data to examine the impact of the scheme, but this could be gathered after further cohorts of scholars have completed the placement.

How doctors can get involved

There are lots of different ways doctors can get involved in healthcare policy and politics. One way is to join a political party, which will allow you to develop an understanding of the political system and to become politically active. You can write to your local MP, or a peer in the House of Lords with an interest in your issue. Politicians' interests are listed on their Parliament webpage. The select committees regularly run inquiries and, as a doctor, you can submit evidence, propose a topic or go to watch the evidence sessions. You can follow what goes on in the Houses of Commons and Lords by reading Hansard (<https://hansard.parliament.uk>), watching Parliament TV (<https://www.parliamentlive.tv/Commons>) or listening to the BBC Radio 4 programme 'Today in Parliament' (<https://www.bbc.co.uk/programmes/b006qtqd>), which provides a 30 min summary of the day's events.

If you have an interest in a particular topic you can campaign for it on social media, write blogs or articles for newspapers or go on TV or radio. The difficulties with the revised NHS junior doctor contract a few years back led to many more doctors becoming politically active. There are also roles for doctors in organisations that lobby government, for example the BMA. Many medical Royal Colleges have a policy and/or parliamentary committee which will influence policy and you may be able to get involved with this. The Royal College of Psychiatrists produces a weekly political update that you can sign up for. This will keep you up to date with forthcoming parliamentary business.

Of course, if you are a psychiatry higher trainee you can apply to the Parliamentary Scholar Scheme, which (at the time of writing) is in its third year. It is advertised on the Royal College of Psychiatrists website usually in the spring.

Conclusions

Our participation in the 2017–2018 Parliamentary Scholar Scheme was a unique opportunity for us as trainee psychiatrists to learn more about healthcare policy and Parliament. It has enabled us to develop skills in leadership and influencing that will stand us in good stead for our future careers as consultant psychiatrists.

The idea of the medical profession turning to soft power to influence policy has been proposed recently.²⁵ Our experience of working in Parliament has demonstrated the many areas where policy is made, challenged and communicated. The scope for those with first-hand knowledge of the healthcare system to have input into the areas where policy is influenced is there, but it requires knowledge of the system and a willingness to suggest solutions, not just to criticise the end product.

We thank Olivia Clark, Jonathan Blay, Rebecca Couper (Royal College of Psychiatrists) and Professor the Baroness Hollins and the other peers associated with the scheme.

We confirm that we meet all four ICMJE criteria for authorship. J.P., P.L., F.T. and K.M. designed, drafted and revised the article. S.H. designed and revised the article.

Jen Perry is a consultant psychiatrist with Camden and Islington Mental Health Trust, London, UK; **Paul Lomax** is a specialty trainee with South West London and St George's Mental Health NHS Trust, UK; **Fiona Taylor** is a consultant psychiatrist with Camden and Islington Mental Health Trust, UK; **Susan Howson** is a consultant psychiatrist with Devon Partnership Trust, Exeter, UK; **Kathleen McCurdy** is a consultant forensic psychiatrist with Oxleas NHS Foundation Trust, Dartford, UK. All five authors were higher trainees on the 2017–2018 Parliamentary Scholar Scheme.

1.3.66 Standing with our medical colleagues

Sarah Castle

2020-08

Contents

- *Standing with our medical colleagues*

Like many of us I am increasingly concerned about the possible effects of coronavirus on myself, my family and our community and patients. With family in Italy, I am mindful of the need there for other medical professionals to be brought in to work alongside their acute medical colleagues. This has included those more distant from acute medical work now, such as pathologists and even in some cases psychiatrists.

Little has been spoken about our role in regards to COVID-19 should we see similar scenes here in the UK and what our possible involvement might be. It would be easy to adopt a ‘protectionist’ attitude and leave the messy stuff to ‘real doctors’.

As a psychiatrist, I am a doctor of the mind and body. Of course, I would never advocate working beyond our professional competencies; however, I feel we have a strong duty to stand beside our medical colleagues be it pushing trolleys, taking blood or sweeping floors if the need arises. We spend so much time and energy trying to reduce the splitting that occurs between ‘medicine’ and ‘psychiatry’; surely we cannot hide behind this very split now when our colleagues and indeed our communities may need us if an outbreak worsens to the degree that many fear. Surely then we must stand together as one profession.

None.

1.3.67 Quality improvement in mental health services

Billy Boland¹

¹

Declaration of interest B.B. is the faculty lead for quality improvement for the Faculty of General Adult Psychiatry at the Royal College of Psychiatrists; is on the advisory board of the Money and Mental Health Policy Institute; and periodically writes a blog on matters relating to leadership and quality improvement for The BMJ. As part of leadership development he visited GlaxoSmithKline to learn about its approach to quality improvement. GlaxoSmithKline has developed its own approach and did not specifically adopt lean or the Model for Improvement discussed in this article.

Abstract

Quality improvement (QI) approaches are becoming increasingly important in the delivery of mental healthcare internationally. They were originally developed in the manufacturing industry, but the principle of having a systematic approach to improvement has spread to many other industries, not least to healthcare. Quality improvement approaches in healthcare were pioneered in the USA at organisations such as Virginia Mason and the Institute for Healthcare Improvement. In recent years, they have become firmly established in mental health services in the UK's National Health Service (NHS). There are a number of different approaches to quality improvement, but two leading models have taken root: 'lean thinking' (also known as 'lean methodology' or simply 'lean'), which arose out of Virginia Mason, and the 'Model for Improvement', which came out of the Institute of Healthcare Improvement. This article describes these two quality improvement approaches, critiques their philosophy and explores how they can apply in the provision of mental healthcare, particularly with reference to the use of data, evidence and metrics.

Lean thinking

Getting to the essence of ‘lean’ is made challenging by the ambiguous language and definitions in the field. Hallam captures this well in observing that the term ‘lean’ has been used interchangeably to describe four different dimensions, specifically ‘the operating philosophy, the tools, the activities, and the state of the manufacturer’ (cited by Stone¹). In his review on the science of lean, Kyle Stone defines the lean thinking paradigm as the ‘operational philosophy’ of the organisation’ which ‘differentiates between waste and value’.¹

Muda (Japanese for waste) is defined by Womack & Jones as ‘any human activity which absorbs resources but creates no value’² (p. 15). The ‘powerful antidote’ to tackling waste, they argue, is lean thinking. Five ‘lean principles’ are proposed. Data, evidence and metrics, and their application are not specifically addressed within the principles, but their use in realising the principles is clearly important. Definitions of the principles exist, but there are challenges in engaging with them and applying them to healthcare. The next section considers these challenges in relation to the key concept of each principle.

Challenges engaging with the lean principles

Specifying value

Womack & Jones argue that value can only be specified by the ‘ultimate customer’² (p. 16), but fall short of clarifying who that is. They make a compelling argument that those who design and deliver the business can never truly know the value that customers seek and must work hard to understand the customer’s wants and needs in building their product. How one defines or identifies the ‘ultimate customer’ is not made clear. Instead, readers are encouraged to maintain a dialogue with a broad customer base and continually evolve their product. They offer a number of lenses through which one can see value, such as ‘challenging traditional definitions of value’ (p. 31), defining value in terms of the ‘whole product’ (p. 32) and tackling the ‘target cost’ (p. 35), yet crucially they do not define what value actually is.

Specifying value is key to making best use of data, evidence and metrics, as all efforts should be directed towards improvement aimed at achieving the target ideal value. Having a robust definition of value is necessary in order to demonstrate, using data and evidence, whether or not value has been achieved. Progress towards achieving ideal value can be measured using metrics.

The value stream

Liker & Ross define the value stream as ‘core customer-focussed business processes’³ (p. 241). Womack & Jones offer a more granular explanation: “‘The Value Stream is the set of all the specific actions required to bring a specific product (whether a good, a service, or, increasingly, a combination of the two) through the three critical management tasks of any business: the problem-solving task running from concept through detailed design and engineering to production launch, the information management task running from order-taking through detailed scheduling to delivery, and the physical transformation task proceeding from raw materials to a finished product in the hands of the customer.’² (p. 19)”

Both definitions are inadequate as they fail to get to the heart of the matter and they leave important questions unanswered. The Liker & Ross definition is narrow and wholly business oriented. Why should the value stream only regard ‘core’ business processes, and how are these defined? The mass production examples given in both texts do not fully translate to a complex multiservice industry such as healthcare. Which business processes in healthcare are ‘core’? Does that mean ‘non-core’ services do not deliver value?

In contrast, the Womack & Jones definition is too verbose and meaning is obscured as a result. It is also internally incoherent, as although it begins by explaining that a product can be goods or services, later parts of the definition are articulated only in terms of goods, for example ‘the physical transformation task proceeding from raw materials to a finished product’² (p. 19).

In establishing the value stream, obtaining information (data and evidence) from those involved in delivering the work is crucial to truly understanding what is happening. Evidence from customers (such as patients and carers) is important in understanding what value is actually delivered at relevant points through the stream. Metrics can be used to indicate whether value has been delivered, provided that the value has been clearly specified. For example, in mental health services patient-reported outcome measures (PROMS) and patient-reported experience measures (PREMS) can give some insight into patients' experience of services and service impact.⁴

Flow

Frustratingly, a 'lean' definition of flow is hard to come by, and most authors appear to have resorted to explaining what it is not. Womack & Jones explain that it is not batch processing or doing tasks in batches that inherently cause waiting and queuing² (p. 50). In their analysis of lean in an emergency department in an NHS hospital in Nottingham, Timmons and colleagues talk of the lean principle in the healthcare setting in terms of 'ensuring that there is a continuous flow throughout the process. Standardising processes around best practice allows smooth running, which frees up time for creativity and innovation'.⁵

Flow can be quantified with respect to value and so can be amenable to the generation of metrics. Indirect measures of waste (*muda*) are useful data and evidence proxy indicators for flow. For example, measures of defects, overproduction or waiting can all give useful insights into the performance of flow⁶ (pp. 82–84).

Pull

Pull also seems to be defined by what it is not. For example, Womack & Jones offer: 'you can let the customer pull the product from you as needed rather than pushing products, often unwanted, onto the customer'² (p. 24) and 'pull in simplest terms means that no one upstream should produce a good or service until the customer downstream asks for it'² (p. 67). Although, on the face of it, pull seems a wholly transactional concept, Liker & Ross emphasise 'even a well-designed pull system does not automatically solve all our problems and is dependent on human judgement and discipline'³ (p. 177). Once more in these definitions we see a focus on goods rather than services, and so aspects of the human nature of pull are obscured. For example, in their new study of lean in a Finnish healthcare service, Hihnala and colleagues state that, although work and workflow can be ordered to create pull, 'It emerged [...] that a common set of values that respects human dignity came [sic] more important'.⁷

Pull too can be amenable to metrics to help maximise value. Measures of demand can be a useful source of data, which can be used to evidence how to manage the flow. Qualitative sources of evidence can include customers' (patients' and carers') accounts of their experience and motivations to make use of the service⁶ (p. 96).

Perfection

This is yet another concept with a shadow side. Womack & Jones once again avoid defining it, but talk of it as being the continuous application of the previous four principle concepts to strive to continue achieving better products² (p. 25). Perfection is never achieved, but there is always room for improvement. Actually, what they are truly referring to is the continual pursuit of identifying and eliminating waste (*muda*).

Metrics are important here as perfection needs to be defined. Perceptions of perfection can change over time, so descriptions need to be clear and revised regularly. Perfection may be best approached incrementally (monitored through metrics) and is never reached. Evidence demonstrating approaching perfection can be quantitative (e.g. in consistency of data) or qualitative (e.g. in having a culture free of fear that promotes quality improvement).

Lean in practice: a case example

Tees, Esk and Wear Valleys NHS Foundation Trust (TEWV) were supported by Virginia Mason in the USA in adopting lean.⁸ Virginia Mason's own lean processes were adapted from the Toyota Production System, with a strong focus on eliminating waste (*muda*) and the use of metrics to measure improvement.⁹ TEWV have made a number of high-impact changes to the way their processes operate that have had benefits (brought value) to patients. One of these, the purposeful in-patient admission (PIPA) model, which was trialled on two adult wards, saw their original bed occupancy of 106% reduce by 22%, a 57% reduction in length of stay, a 72% reduction in reports of violence and aggression, and a 100% reduction in complaints (p. 62).¹⁰

Lean techniques they used to achieve these changes included: a move from a weekly ward round to daily multidisciplinary team meetings – to remove 'batching' of decision-making (to improve *flow* of the *value stream* of clinical decisions and interventions) visual control boards on the wards – to map the patient journey (*flow*) removal of waste (*muda*) from the office and patient literature – ensuring that only necessary literature were on the ward creating standard processes for each step of the patient journey and changing the layout of the ward environment (to improve *flow*).

The Health Foundation is now exploring how other organisations might benefit from lean and is conducting research into the effect a partnership with Virginia Mason would have on five other NHS organisations.¹¹

Lean thinking – evidence of impact

Although there are countless books and journal articles on the subject, Stone¹ identifies three 'voids' that lean research is yet to adequately tackle: the relationship between planned organisational change and human resource development intervention the relationship between planned organisational change theories and lean theories the 'human' factor – by this he means how best to engage staff in lean.

In contrast, in *The Toyota Way*, Liker defines the tenth of the 14 management principles of Toyota as 'develop exceptional people and teams who follow your company's philosophy'¹² (p. 184) and explains that at the company the Toyota Production System was originally called the 'Respect for Humanity System'¹² (p. 186). Nevertheless, other than his own observations, and a critique of theories of behaviour, Liker offers no empirical evidence for human resources and the human factor.

The Model for Improvement

Don Berwick, the improvement champion who has led the Institute of Healthcare Improvement (IHI) in the USA and who was called on by the then Prime Minister David Cameron to help make the NHS safe for the future¹³, writes an impassioned introduction for *The Improvement Guide*, a key text that describes the Model for Improvement.¹⁴ Notably though, the authors of the guide, who Berwick says he is still learning from, are largely statisticians by training. This is important, as the focus in lean is on waste and flow, whereas data, and the use of data, are at the heart of the Model for Improvement.

Berwick calls the model the 'most useful single framework' he has encountered¹⁴ (p. xiii). Founded on the work of Deming, also a statistician, the 'System of Profound Knowledge' is fundamental to the Model of Improvement. The system asserts that, through developing appreciation for a system, understanding variation (data, evidence and metrics are clearly important here), building knowledge and getting to grips with the human side of change, one is better equipped to make improvements¹⁴ (p. 76). Applying the Model for Improvement to an improvement challenge helps the leader organise an approach by guiding them through the following key questions. 'What are we trying to accomplish?' is about being specific and defining the problem. This makes it measurable and potentially subject to metrics. The question is also used as a call to arms, by clearly describing what is expected, and to create ownership, through encouraging others to contribute to creating this definition or 'charter'¹⁴ (p. 89). There are some darker sides to how this statement is used to motivate change, of the stick rather than carrot variety. For example, Langley and colleagues¹⁴ suggest choosing goals that are clearly unachievable using current practices, being explicit that previous tools will be removed whether change happens or not, or simply stating that the current service will no longer be provided if change does not happen. Thus, although values of addressing the 'human side' of change are espoused, the

authors are not shy of using traditional ‘machine metaphor’ classic top-down management theory¹⁵ (p. 18) if they think it will help towards achieving the goal. This seems to be in contrast to the approach Berwick advocates in his work on patient safety for the NHS, where he says, ‘Fear is toxic to both safety and improvement’.¹³ ‘How will we know that a change is an improvement?’ is sometimes abbreviated to ‘measures’. This is all about how to demonstrate the impact of change using data, evidence and metrics. Three different types of measures are encouraged: outcome measures that observe the outcome in question, process measures that monitor whether activity to achieve the outcomes is performed, and balancing measures that look at whether there are any unintended consequences of change¹⁴ (p. 96). One could argue that the model encourages only superficial engagement with the ‘is the change an improvement?’ part of the question by focusing on measures. For example, in a healthcare system where increasing discharge is the aim, is there enough challenging of the assumption that discharge is the right thing? ‘What change can we make that will result in improvement?’ is often abbreviated to ‘changes’ and is about identifying initiatives that could bring about change¹⁴ (p. 93). Methods for developing change are promoted, including ‘logical thinking about the current system, benchmarking or learning from others, using technology, creative thinking and using change concepts’¹⁴ (p. 120). ‘Changes’ can be opportunities to put evidence into practice, and could be an application of evidence-based medicine, such as the implementation of National Institute for Health and Care Excellence (NICE) guidance.¹⁶ Dozens of change methods are proposed that can be used in the Model for Improvement and many of these, such as ‘use pull systems’, ‘eliminate things that are not used’ and ‘match the amount to the need’, have clear roots in lean thinking¹⁴ (p. 358). Langley and colleagues acknowledge the overlap with other improvement approaches: ‘Several of the concepts are included in other approaches to improvement, such as Total Quality Management, Reliability, Safety, Six-Sigma, and Lean’¹⁴ (p. 358).

With the three Model for Improvement questions answered, improvers are ready to make use of the ‘plan–do–study–act’ (PDSA) cycle. PDSA can be used to ‘turn ideas into action and action into learning’¹⁴ (p. 97). There are four distinct phases to PDSA: the intervention or test should be planned, the plan should be executed and data recorded, data are analysed, and reasonable action is taken on the findings (essentially action is based on evidence).

The cycles of PDSA can be used to ‘build knowledge’ both of the improvement challenge faced and potential solutions.¹⁷ PDSA cycles are recommended by NICE to bring about improvements through implementing NICE recommendations.¹⁶ A model akin to ‘plan–do–study–act’, called ‘plan–do–check–act’, has been used in lean in, for example, work on patient safety.¹⁸

The Model for Improvement in practice: case examples

East London NHS Foundation Trust (ELFT) adopted the Model for Improvement, supported by the IHI. The trust’s work to reduce violence on in-patient wards saw a 40% reduction in violence across six wards and reduced costs related to violence by £181 296 (data are for 2015–2016).¹⁹ The Care Quality Commission (CQC), the UK’s healthcare regulator, has rated the organisation as ‘outstanding’ and commented: “‘ELFT has invested over the previous two years in a wide scale quality improvement programme. This has been embraced by staff. The methodology has successfully encouraged innovation and improvement which CQC inspectors were able to see throughout the inspection. There was a genuine passion to ensure that the services provided are the best possible.’²⁰”

The teams used the Model for Improvement questions to define and drive their work. They agreed what they wanted to *accomplish* (to reduce physical violence by 30%) and the *measures* to determine whether a change was an improvement (the main outcome measure used was ‘rate of incidents of physical violence per 1000 occupied bed-days’). In generating ideas for change, the team worked with staff and patients, and then used PDSA cycles with wards from across the trust to test the favoured change strategies. Staff came together at 6-weekly intervals to learn from each other and review data to consider whether improvement was happening.²¹

Hertfordshire Partnership University NHS Foundation Trust has also employed the Model for Improvement, launching it in 2015. Subsequently, the 2016 national NHS staff survey reported that the percentage of staff in the trust who said they were able to contribute to improvements had increased to 76%, from 70% the previous year. The Picker Institute, which analyses the data for the NHS, reported this as a statistically ‘significant improvement’ and above the national average for mental healthcare.²² The trust was also rated ‘outstanding’ by the CQC in May 2019. It said: “‘The delivery of innovative and evidence based high quality care was central to all aspects of the running of the service. There was a true sense of desire to drive service improvement for the benefit of patients, carers, and the wider

system, evident throughout the inspection. Staff included patients in service improvement and used their feedback to change practice.’²³”

Model for Improvement – evidence of impact

Evidence for PDSA in a UK healthcare context is varied. A systematic review of quality improvement methodologies carried out by NHS Scotland found that the evidence for PDSA in the NHS was ‘mixed’. It found that, in large projects taken forward by the NHS Modernisation Agency, work often did not proceed beyond ‘plan–do’. Other initiatives, such as work on the 4-hour emergency department (A&E) waiting target, could lead to problems elsewhere in the system (such as the patient waiting in a medical assessment unit instead). Success can be context dependent, with ‘striking differences’ between organisations using PDSA in quality improvement collaborations.²⁴ Furthermore a multisite cluster-randomised study comparing the effectiveness of different change initiatives within healthcare services in the UK found no difference between standard dissemination of guidance versus standard dissemination plus PDSA in the implementation of the guidance.²⁵

Conclusion – the essence of theories of improvement science

Considering these two approaches to quality improvement, a number of factors emerge as the essence of these theories: They aim to be pragmatic, seeking to clearly describe the problem and bring about real-world change. Although they draw on scientific theory, they are about implementing and applying scientific method to bring about improvement. The sensible use of data, evidence and metrics is essential in order to demonstrate change. They are about both processes and people. Automation can enhance productivity, but it is people that bring about change. They are sensitive to context. The evidence base demonstrates that improvement methods can succeed and fail, but identifying win factors can be a challenge. Leadership, engagement and culture are all extremely important. They are not discrete. The various improvement methods have considerable degrees of overlap and borrow from each other, for example lean can employ a ‘plan–do–check–act’ cycle, the Model for Improvement can use lean concepts.

The Health Foundation has summarised a similar list of ‘underlying principles’, which include understanding the problem, understanding the processes and systems, analysing demand, capacity and flow, choosing tools for change and evaluating change²⁶ (p. 11). In September 2018, the CQC published a report into what it had learned about embedding a quality improvement culture within healthcare organisations. It states, ‘We would expect that a hospital trust committed to delivering high-quality care should be embedding a systematic and effective approach to QI’.²⁷ Regardless of the provenance of the approaches and their evidence base, in the UK at least, it looks like they are here to stay for the foreseeable future. Clinicians will benefit from understanding quality improvement and could do much to shape how it is received and applied in their context.

1.3.68 Do foundation doctors meet the mental health competencies in the foundation programme curriculum?

Jack Haywood

date

2020-02

Contents

- *Do foundation doctors meet the mental health competencies in the foundation programme curriculum?*

In recent years, the UK Foundation Programme has been adapted in order to meet the changing demands of patients, as well as those of foundation year doctors. A broadening of the Foundation Programme in 2014 stipulated that 100% of foundation year doctors should undertake a placement including community care from August 2017.¹ Further to this, in 2015, Health Education England set a target that 45% of foundation year trainees should complete a psychiatry placement to gain exposure to mental healthcare.² However, it is important to recognise that mental health problems do not present just in the psychiatry setting. General practice (GP) and accident and emergency (A&E) are arguably 'gateways' to accessing mental healthcare in the National Health Service.

The Foundation Programme Curriculum 2016 outlines the expectations for what foundation doctors should learn. With the changes to community placements outlined above, I conducted a study to assess whether doing a foundation year placement in psychiatry, A&E and/or GP affects trainees' ability to meet the Foundation Programme mental health competencies. I used a cross-sectional questionnaire to ask foundation year 2 (FY2) and CT1/ST1 trainees whether they felt they had met 17 mental health-related competencies from the curriculum.³ This was sent electronically via Foundation Schools.

A total of 360 trainees took the survey. Of all the trainees, only 29.7% (n = 107) were aware that there are specific mental health competencies in the Foundation Programme curriculum that they should have met. Fourteen of the 17 competencies were self-assessed to have been met by trainees who completed a placement in psychiatry, compared with 15 out of 17 in A&E and 13 out of 17 in GP. By comparison, only nine competencies out of 17 were met by those who did not have a placement in any of the three specialties. Interestingly, in all groups, the competencies that should have been met by the end of FY1 were more successfully met than those for FY2.

These results were for trainees who may have taken one, two or all three specialties in their foundation year training. When considering each specialty uniquely, ten out of 17 competencies were met in psychiatry, whereas only six were met in A&E and nine in GP.

These results suggest that a combination of these three specialties may be more beneficial than one specialty alone, or none at all, in order for trainees to feel they have met the mental health competencies. There is also a case to be argued that trainees should be educated about the curriculum, as many were not aware they had the competencies to meet.

Further research should involve asking assessors to make the same competency assessments about the foundation year trainees, moving away from self-assessment to a work-based assessment.

1.3.69 Section 12 approval: fit for purpose?

Nidhi Gupta William Calthorpe

date

2020-06

Contents

- *Section 12 approval: fit for purpose?*

We compliment Rigby and McAlpine on a well-written editorial on Section 12 approval.¹ The authors raise several pertinent issues about Mental Health Act (MHA) detentions and note that there has been a 47% increase in the rate of detentions countrywide. They are of the opinion that the increase in detentions is mainly attributable to clinicians not being equipped with the necessary knowledge and training. Rigby and McAlpine suggest more rigorous evidence-based training reinforced by appropriate assessment, including summative assessment using criteria-referenced methods with pass marks determined by the Angoff method. The authors also feel that the approval and revalidation processes need to be more robust.

We, however, are of the opinion that the authors have taken an Occam's razor view by largely attributing the problem to clinicians' training. In our opinion, increases in detention rates are due to multiple factors, and the 'fix' is not as binary as upgrading training of clinicians or making the approval and revalidation processes more robust. The process of MHA assessment requires two doctors, of which one has to be an independent Section 12 doctor, and an approved mental health professional (AMHP), who is usually (but not invariably) a social worker. All three have to agree to detain a patient with a mental disorder. It is pertinent that the final responsibility for detaining someone under an MHA belongs to the AMHP, who then submits an application to a local hospital for an in-patient bed.

We quote verbatim from the 2018 Care Quality Commission report² on the use of the MHA to detain people: "1. The apparent rise in rate of detention since 2010 is in part due to the national data return being more complete.2. More people are being detained on more than one occasion during a calendar year than was previously the case.3. Bed numbers have fallen and more people with severe mental health problems are living outside of a hospital setting, and so are at greater risk of being detained.4. Some people are being detained under the MHA who would previously not have been detained. This is because clinicians are applying the criteria for detention differently to people with certain types of disorder (such as dementia or personality disorder). It could also be because more people with mental health problems are coming to the attention of mental health care workers (for example, through schemes that divert people from the criminal justice system).5. People who need admission and who would previously have agreed to informal admission are now refusing and are being admitted as detained patients.6. Admissions (some of which would be formal) that could in the past have been prevented are now not being prevented because less restrictive alternatives in the community are not available.7. There has been an increase in the total size of the population of England and an increase in the size of those sections of the population that are more at risk of detention.8. There has been an increase in the prevalence of risk factors for detention, such as social exclusion and problematic, untreated drug and alcohol misuse."

Glover-Thomas, in a recent review, notes that the availability of mental health beds has decreased, thereby delaying the 'preferred option' of voluntary admission of patients. Therefore, in circumstances when clinicians deem a patient to be in need of care in hospital, resorting to detention 'may be the quickest means of opening up services'.³ This factor – in our view – is consequential in 'bumping up' detention rates.

The number of appeals to mental health review tribunals (MHRTs) in England and Wales has risen steadily, from 904 in 19804 to 31 469 in 2014.⁵ This reflects the parallel increase in the number detained. However, the percentage of patients who are successful in obtaining discharge at MHRT hearings is relatively low (only 9% of all hearings in 2013–2014 resulted in discharge⁶), suggesting that patients have been detained appropriately. This, in turn, suggests that training for Section 12 approval is not a factor. However, we agree with Rigby and McAlpine that improvements in training would be beneficial to clinicians in terms of increasing their confidence and knowledge.

1.3.70 Improving patient flow in acute psychiatric wards: enhanced bed management and trusted assessment

Douglas Turkington Steve Moorhead Gordon D. Turkington Carla King Leigh Bell Denise Pickersgill¹

Correspondence

Douglas Turkington

(douglas.turkington@ntw.nhs.uk)

date

2020-08

Abstract**Aims and method**

In three localities in a mental health trust in England, an enhanced bed management team was established to improve patient flow and reduce out-of-area placements. Trusted assessments were provided to support risk management and conflict resolution. Two measures of flow were compared before and after the team was established.

Results

The trusted assessment recommendation was for discharge in 70% of cases. The number of out-of-area placements was significantly reduced ($P < 0.05$), saving £616 876 over a 12-month period. Patient flow was significantly improved in one of the three localities as measured by patients/bed/6-month period ($P < 0.05$). In one of the other localities increased use of trusted assessment input and reduced numbers of patients being transferred in are recommended to improve flow.

Clinical implications

Mental health trusts should consider the establishment of an enhanced bed management team, including trusted assessment, as a safe and cost-effective approach to improving patient flow and reducing the need for out-of-area placement.

NHS England's Five Year Forward View for Mental Health¹ mandated that access should be increased to high-quality community care, avoidable admissions should be prevented and treatment delivered as close to home as possible (recommendation 22). Out-of-area placements were to be completely eliminated by the financial year 2020–2021. 'Financial incentives and levers' were to be deployed to deliver on the key outcomes anticipated in recommendation 22. Consequently, mental health trusts working under contracts where these levers were being deployed had been losing substantial amounts of non-returnable funding through the use of out-of-area placements at a cost of £608/day. It is known that patient outcomes when admitted out of area are significantly worse than for those admitted locally.² The Five Year Forward plan, however, set targets without acknowledging that many mental health trusts were already 'under-bedded' in relation to their population size and level of social adversity and under-resourced in terms of community provision. Also, critical indicators for admission/discharge and estimated discharge dates were being underutilised by crisis teams and ward staff, leading to unnecessarily prolonged in-patient stays.³ Meanwhile, since the plan was written and distributed, a number of factors have come together to increase the pressure on scarce in-patient bed resources.⁴ In particular, the percentage of patients admitted under the Mental Health Act 1983 has increased, as has length of stay. Intellectual disability ('learning disability') beds were being reduced for both the forensic and working-age adult populations. One possible explanation was put forward that clients are declining informal admissions as the acute wards are perceived as stressful and end up eventually being admitted for a longer period under the Mental Health Act.⁵ This is paralleled by nursing staff opinion that acute in-patient wards are now best viewed as 'mini-PICUs'. Reduction in the use of the Mental Health Act 1983 is an objective of the Independent Review of the Act (which was completed in December 2018 and for which a white paper is proposed in the next session of parliament), and this could potentially improve flow through acute admission beds. Over the past 5 years there has been a 50% increase in accident and emergency (A&E) department attendances for mental health problems.⁶ This has led to increased pressure on crisis and liaison specialist services and, at times, perhaps unnecessary admission under the Mental Health Act. Presentations with intoxication from alcohol and other substances have been rising. We have also seen a surge in the use of 'gate sections' from Her Majesty's Prisons. This occurs when a prisoner has been mentally ill, was not transferred to prison under section 38 but is detained under the Act 'at the gate' at the time of their release. People whose primary diagnosis is a personality disorder are frequently kept too long under assessment in in-patient units, where risk may

increase rather than decrease. Their difficulties have often arisen from prolonged or repeated traumatising experiences in childhood or adolescence, and they may be better supported with effective community psychological management programmes,⁷ avoiding off-licence use of psychopharmacology and potentially further traumatising coercive in-patient treatment under the Mental Health Act.⁸ Any such admissions should be brief and require a team or pathway-based attitude supporting positive risk management. Risk averse practice has been rising owing to the negative consequences ensuing if the discharge and community plan are not effective in preventing a serious adverse outcome. All of these factors have combined to make the current in-patient experience of care potentially a stressful one for patients and staff alike.

There is no doubt that the spiralling development of specialist teams (while a good thing for their target populations) has significantly weakened the generic community mental health teams. Waiting lists for key worker allocation are lengthening and, at times, individuals are discharged too soon, removing ongoing support with well-being activities (including medication concordance support). Another factor that has driven admissions up is that nobody 'owns the flow'. Sector and integrated psychiatric services would facilitate a discharge if an admission was needed. However, 'split' in-patient and out-patient consultant psychiatrist posts have contributed to impairing pathway ownership of the flow of patients into and out of acute units as well as causing patient dissatisfaction with perceived lack of continuity of care.⁹ As a result of this accumulation of factors, many trusts across the UK have found themselves in great need of a solution to the problem of lack of available admission beds that arises as they do not have 'the right patient at the right place at the right time' on their care pathway. Cumbria, Northumberland, Tyne and Wear NHS Foundation Trust (NTW), which covers a population of approximately 1.5 million, decided that effective and prompt discharge to the correct treatment pathway needed to be facilitated and the trust board mandated a director to take responsibility for this crucial area. The enhanced bed management (EBM) service was created as one of a number of interlinking strands to deal with rising demand for in-patient admission. The other strands included the establishment of a personality disorder hub, improving crisis assessment and home treatment teams and improving rehabilitation flow. This paper reports early findings from evaluation of our EBM service.

Method

In response to the above pressures, NTW decided to implement the EBM approach across all acute psychiatric wards in three localities. The EBM team included three discharge facilitators and five bed managers. There were also one nurse manager, one part-time administrator, one part-time social worker, one research assistant and two part-time consultant psychiatrists (both 0.4 full-time equivalent). A system of linked detailed electronic bed boards was introduced in all acute wards trust-wide to regularly update critical indicators, estimated discharge date, mental health cluster and Mental Health Act status. Discharge facilitators attended all multidisciplinary team (MDT) meetings and clinical bed managers were available for consultation on a locality basis. 'Trusted assessments' were made available on request by the MDT with the agreement of the responsible clinician. The purpose of the trusted assessment was to complete a full review of the history, interview the patient and all pertinent staff and give an independent and comprehensive opinion to all parties on diagnosis, treatment and management. Trusted assessments began in January 2018, continued throughout that year and are ongoing. The impact of EBM on out-of-area placements (adult acute) was calculated by comparing a proxy of flow (number of out-of-area placements/month) between the calendar years of 2017 and 2018. The impact on flow as measured by patients/bed was compared between the first 6 months and second 6 months of 2018 (the second reflecting the period when the full team was operational). Unpaired *t*-tests were used to compare the periods in question.¹⁰ All other statistical analyses were performed using IBM SPSS Statistics (for Windows), release 24.0.0.2. Further exploration to understand the impact of internal transfers examined length of stay data for all patients discharged from adult acute wards in the trust during the financial year 2018–2019. Outcomes and recommendations from the first 50 trusted assessments were determined by case note review in March 2019.

Ethical approval was not sought as this project was a service evaluation and there was no randomisation and no treatment being tested.

Results

Out-of-area placements

The number of out-of-area placements was reduced by over 60%: in 2017 the monthly mean was 5.25 (65 placed in the year); in 2018 the mean was 2.4 (29 placed in the year) ($P < 0.05$). This equated to a saving of £616 876 in otherwise lost revenue (the figure given for savings does not include the cost of the EBM team).

Patient flow

Flow (patients/bed/6-month period) showed a significant improvement in one locality ($P < 0.05$) in the period of full operation of EBM, compared with the preceding 6 months: 4.83–5.5 (167 admissions rising to 246, with 56 transfers reducing to 52 over that period). In the other two localities one already had acceptable levels of flow and these did not change significantly (5.2–5.36; 253 admissions rising to 260 and 56 transfers reducing to 35). In the other locality flow remained lower, at 4.6–4.65 (284 admissions reducing to 253 and 46 transfers increasing to 71). The three localities had 57, 70 and 54 acute beds respectively. Patient flow is locality specific and deemed acceptable in two NTW localities, because if all three localities were hitting the same flow targets of 5.2–5.5 patients/bed/6-month period then there would have been no out-of-area placements and only infrequent admissions into leave beds.

Trusted assessment uptake

To examine the potential impact of trusted assessment uptake on locality patient flow, a *post hoc* correlation between number of trusted assessments provided and proportionate increase in flow was calculated. In locality 1, where 9 trusted assessments were requested, the proportionate change in flow was 0.13. The flow figures for locality 2 were 0.02 (with 14 trusted assessments) and for locality 3 they were 0.13 (with 19 trusted assessments). A correlation between proportionate change in patient flow and number of trusted assessment requests was significant, with a two-tailed Spearman's rho of 1.0; $P < 0.001$.

Length of stay

A more detailed exploration of the factors affecting flow data was undertaken. Initial flow data indicated that flow was noticeably low on one ward in particular. The consultant body suggested that looking after relatively more intra-trust, cross-locality 'transfers in', who would, by implication, be more ill, might explain the lower flow. Examination of data for 1 year of patients who had been discharged showed that intra-trust, inter-locality transfers indeed stayed significantly longer than those who were admitted and discharged from the same ward (mean stay 70 days compared with 32 days; $P < 0.001$). If short-stay patients (in for less than 20 days) are removed from this analysis, a statistically significant difference remained (83 v. 59 days; $P < 0.001$). Overall then, intra-trust transfers stay significantly longer than those remaining on the ward on which they land and this ward had a much greater proportion of transfers in. However, both male wards in this locality had, proportionately, a considerably greater number of transfers in, contributing to lower flow data for the whole locality. Clarity, then, about the greater numbers of transfers in and their associated length of stay initially suggested an explanation for this low flow (many more transfers in, who stay longer). However, further analysis of the pathway indicated that these patients had remained on initial wards before the transfer for a mean of 18 days. If the same group of short-stay patients are again removed, the mean rises to 21 days, corresponding almost exactly to the difference in mean of total length of stay between the groups of those transferred and those remaining (24 days) once the short-stay group was removed from the data. Thus, the length of stay on the wards on which the patients land after the initial stay was examined. This showed that male transferred-in patients in this locality as a whole stayed significantly longer after their arrival on the destination ward than male transfers in in the other localities (means: 38, 46 and 71 days; one-way ANOVA, d.f. = 2; $F = 4.6$; $P = 0.01$) indicating a difficulty with the male pathway as a whole in this locality rather than just one ward.

Trusted assessment recommendations

Examination of 'the first 50' outcomes showed that the trusted assessments recommended discharge for 35 (70%) of patients they were asked to assess and, of these, 19 were discharged within 2 weeks; 25 of the 35 were discharged within 4 weeks. There were no untoward incidents in the follow-up period after discharge (which was obviously different for each patient, depending on the timing of trusted assessment provision): the mean was 149 days (range: 89–355). This amounted to 3730 people-days among 25 people. Thirteen of this 25 experienced a readmission (eight had one readmission, four had two and one had three readmissions) for a median of 9 days in total. Considering the impact of the trusted assessment on overall care, this 25 had experienced a mean of 7321 days as in-patients since their very first admission and 21 863 days living in the community (ratio 0.33). In the intervening 3730 people-days, these 25 patients experienced a mean of 35.4 days as in-patients and 251.5 in the community, a ratio of 0.14.

Discussion

These results show that, by investing in an enhanced bed management (EBM) service, improvement in quality of care and substantial financial savings can be achieved by preventing unnecessarily long hospital stays.¹¹

Trusted assessments

Although the clinical bed managers, discharge facilitators, EBM social worker and research assistant were broadly welcomed by in-patient teams, the role of the trusted assessment was viewed initially with some suspicion, as the exact nature of the role was not understood for some time. The initiation of the concept of trusted assessment required the agreement of the responsible clinician. There was not a uniform uptake across the three localities. This might indicate ambivalence on the part of the MDT or the responsible clinician. We are not aware of any vetoing of a trusted assessment by the responsible clinician when it was requested by the MDT. In a parallel project to build consensus there was 89% agreement with the following statement among a multiprofessional consultant staff group: 'Given consensus that the needs of current in-patients should be balanced with the needs of those waiting admission, a trusted assessment is helpful in contributing a view that explicitly takes account of the wider needs of the system and when such needs are incorporated into the trusted assessment thinking these should be explicitly articulated in the report'. A trusted assessment is only undertaken at the request of the MDT and with the full consent of the responsible clinician. Trusted assessments were able to support the MDT in relation to difficult discharge situations.

The trusted assessments recommended prompt discharge in 70% of cases and were able to support MDTs in terms of mediation between different views and positive risk management to achieve prompt discharge.

Specific locality-based analysis of patient flow highlighted difficulties that required detailed analysis of data on length of stay to fully understand local problems, ensuring that possible solutions could be developed. Rather than showing that transfers in alone explained the problem on one ward, this analysis revealed that there were whole-locality pathway problems. A number of patients were waiting for a rehabilitation bed and there were fewer discharge options in terms of supported accommodation in that locality. Further, the locality in question did not make use of trusted assessments, whereas the locality that optimised flow was a heavy user of trusted assessments.

Trusted assessment has been operating in acute hospitals for some time but with a slightly different role, where a number of different providers agree that the trusted assessment will decide on the most appropriate discharge package once that discharge has been decided on.¹² Our model of trusted assessment, within mental healthcare, is that the various teams within the trust agree to clinical mediation, positive risk management or other care strategy with the contribution of an experienced clinician working within EBM. This team can be consulted in relation to EBM establishment and working practice, and the multimodal linked bed boards viewed. If the important targets of the Five Year Forward plan are to be achieved within a system of suboptimal bed provision, our findings show initial support for the contention that EBM, incorporating trusted assessments, is a safe and viable option.

Study limitations

This is the first publication of the impact of such a service. Different comparison periods were used for out-of-area placements and flow because trusted assessments began in January 2018 but the full EBM team was not functioning until mid-2018. It is likely that the impact on out-of-area placements when next measured will be further enhanced. A further limitation of this report is that the case note review of the impact of the first 50 trusted assessments was done by a non-masked team member.

Implications for other mental health trusts

This service development took place in a mental health trust that already had an ‘outstanding rating’ from the Care Quality Commission. In-patient beds, rehabilitation beds, community and other resources were all close to the median in the NHS benchmarking document.¹³ The Five Year Forward plan, however, set targets without acknowledging that many mental health trusts were already ‘under-bedded’ in relation to their population size and level of social adversity and under-resourced in terms of community provision. It is certainly the case that there are mental health trusts where much higher numbers of out-of-area acute beds are chronically in use. If the important targets of the Five Year Forward plan are to be achieved within a system of suboptimal bed provision, our findings show initial support for the contention that EBM, incorporating trusted assessments, is a safe and viable option. The generalisation of these findings to other trusts and settings will depend on an adequate number of acute psychiatric beds being funded and a number of other locality-specific factors. These include the level of social deprivation and adequate funding of crisis/home treatment teams and other community mental health provision. Mental health trusts might consider appointing a senior clinician or director with responsibility for pathway synchronisation and ownership of patient flow. This model may also prove beneficial for older adult and rehabilitation services.

All authors contributed in a substantial manner to the design of this project or the acquisition/analysis or interpretation of the data and drafted or critically revised the manuscript and approved the final version. All authors also agreed to be accountable for all aspects of the work in insuring that all questions relating to accuracy or integrity are appropriately investigated and resolved.

- *Authors’ reply*

We are delighted that the publication of our article has generated a debate around the Section 12 approval process and welcome the opportunity to respond to the three letters. Before responding to some of the criticisms of our article, we think that readers would benefit on some narrative on why we chose to publish this article. At a similar time to attending a Section 12 approval course, the first author had also attended an advanced life support (ALS) course. These

courses have some similarities in that they are 2-day events with teaching on performing specialised tasks which are required in order to work in certain specialties or positions of seniority after accreditation from a respected body.

However, the author's experience of the two courses also had notable differences. To name a few: the ALS course came with an extensive manual, knowledge of which was tested in a multiple choice question; the large majority of the course was spent undertaking simulations of the tasks in which the course was accrediting competence; and IDs were checked and significantly late arrivals would have resulted in course failure, and therefore the course was promptly attended.

By contrast, the Section 12 course had several late arrivals and some early leavers. There were no ID checks. Teaching, although of a high standard, was mostly lecture based and didactic and, most worryingly, a significant minority of attendees spent large amounts of time using their phones during the course. There was no simulation training on performing Mental Health Act assessments (MHAAs) in the course.

Although anecdotal, these differences should cause concern to those with responsibility for Section 12 approval. As we demonstrated in our article, our belief that the difference in engagement in these two courses is due to lack of assessment in the Section 12 approval process is based on pedagogical research that shows that students will not engage in effective learning when they are not assessed.

We accept Dr Khwaja's criticism that we do not have contemporaneous evidence of a lack of knowledge or skills in Section 12-approved doctors but argue that – in contrast to the current situation – the onus should be on Section 12 approval courses to establish through assessment that participants have in fact acquired appropriate knowledge and skills.

We note Dr Khwaja's suggestion to change the title of our article, but we stand by our original title as we believe that there are concerns in multiple domains of the Section 12 approval process. For instance, many National Health Service trusts only allow Section 12-approved doctors to perform MHAAs. The MRCPsych exams do not assess knowledge of mental health law. Therefore, it is entirely possible for a doctor to receive Section 12 approval who has never performed an MHA, simulated or real, or who did not attend the approval course, instead asking a colleague to sign in, or attended the course but chose to engage with their phone rather than the course content. Essentially, UK doctors receiving Section 12 approval will not have had any formal assessment in their knowledge and skills in relation to performing an MHAA.

Dr Khwaja notes that international candidates are required to have evidence of having undertaken supervised MHA assessments. Surely this disparity should be corrected and extended to all Section 12 approvals in the UK? He also notes that only a basic working knowledge of the MHA is required to conduct an assessment, but this should not negate responsibility for assessing Section 12 doctors for any knowledge of the MHA.

The authors are aware that Section 12 approval is not required to take part in an MHA but argue that this is even more reason to ensure that Section 12 doctors have the appropriate knowledge and skills to undertake assessments if they are to be relied upon as one of two doctors with specialist skills. At the time of writing this letter, proposals to amend the MHA to allow only one doctor to detain a patient were under consideration owing to the Covid-19 pandemic, focusing our concerns into even sharper relief. Dr Gupta's letter states that we attribute the recent 47% rise in detentions primarily to the issues we have raised. Our article does not make this claim and we detail some other likely contributory factors. However, this very significant rise in detentions gives an additional reason to raise the standards of the accreditation process.

We agree with Dr Khwaja's statement that the approval courses can allow for debate around the intricacies of mental health law but assert that this should occur as well as, rather than instead of, ensuring basic competencies.

We of course accept Dr Ballantyne-Watts comment regarding the very low response rate to the questionnaire but want to highlight that the survey was conducted to try to ascertain what degree of standardisation there was between approval courses; we do not base our conclusions upon the questionnaire. We found the lack of engagement from course organisers frustrating and concerning, and this was a driver for writing the article. We plan to survey attendees of the approval courses to shed further light on this issue and perhaps the issue of smartphone usage and expect a much higher response rate.

We know of no other accreditation process in medicine that takes place with the lack of rigour described in this letter and in our article. We accept that the question of requisite knowledge and skills in Section 12-approved doctors is an

open one and would again welcome the opportunity to collaborate on performing a study to address the need for more up-to-date research in this field.

1.3.72 A day in the life of a psychiatrist in 2050: where will the algorithm take us?

George Gillett¹

Correspondence

George Gillett

(george_gillett@outlook.com)²

date

2020-06

Abstract

Digital phenotyping (such as using live data from personal digital devices on sleep, activity and social media interactions) to monitor and interpret people's current mental state is a newly emerging development in psychiatry. This article offers an imaginary insight into its future potential for both psychiatrist and patient.

Contents

- *A day in the life of a psychiatrist in 2050: where will the algorithm take us?*
– *A vision of the future*

The most exciting development in modern psychiatry is arguably the field of digital phenotyping. Encompassing data related to sleep, speech, activity, social media and keypad interactions, digital phenotyping promises to measure and interpret human behaviour at unprecedented scale. In psychosis, researchers strive to use such data to predict relapse, while others aim to predict suicide risk using machine-learning techniques.^{1,2} However, with the field in its infancy, the potential social effects of such technological advances are unclear. How successful will digital phenotyping be in clarifying psychiatry's uncertainties? Most importantly, where will the algorithm take us?

¹ Declaration of interest None.

A vision of the future

Arriving at work, Dr Singh rests her coffee on the desk and logs into her electronic record system. Ahead of her first appointment she browses the neuroimaging, bloodwork and behavioural data for her patients that day. Reminiscing on how quickly this new world had been sold to the profession, she remembers a lecture, 30 years ago, marking her first encounter with digital phenotyping. ‘Where will the algorithm take us?’, the conference programme asked, leaving Dr Singh shocked at the science fiction surrounding her. The algorithms, already claiming more accurate suicide risk assessment than clinicians, had begun to quantify mood, anxiety, sleep, physical activity, interpersonal interactions and geolocation as markers of social functioning.³ A former Director of the Institute of Mental Health had left to join Silicon Valley as early as 2015 and social media companies boasted about their own suicide risk screening tools only 3 years later.^{4,5} While psychiatrists of the past stole glimpses of psychopathology from snapshot mental state examinations and unreliable histories, the ‘big data’ revolution promised to chart patients’ entire behavioural phenotype for doctors to assess. Even the machines were learning, they claimed.

Steve’s alarm woke him. The day introduced him with a motivating message, psychoeducation they called it, as he hunched over a bowl of cereal, inputting its nutritional information to his diet-tracking app. The phone prompted him of his exercise schedule for later that day, a pending mood assessment and reflective diary entry, shortly followed by a reminder for his annual appointment with his psychiatrist.

Meanwhile, Dr Singh, like the rest of us, played catch-up. Medical students continued to read textbooks and revise mental state examinations. Mental health legislation remained reliant on risk, while algorithms predicted numbers but failed to rationalise their judgements in a way that humans could understand. Dr Singh watched the world reduce itself to binary, while her former colleagues – the radiologists and general surgeons she’d known since medical school – began fearing losing their jobs to automation and robotics. Governments, eager to improve ‘population well-being’ and keen to avoid culpability for suicide and violence, implemented their own machine-learning projects. Insurance companies demanded that their clients wear smartwatches, such that their every behaviour could be monitored.⁶ The rush towards big data, ‘the new oil’ as one economist put it, spared no profession, field or domain of daily life.⁷ As the future came to stay, the algorithms marked their next victim. Psychiatry?

Yes, Steve replied, as the receptionist beckoned him towards the sign marking the out-patient department. He took a seat in the waiting room, reflecting on what to do. How he might break the news. Remembering, tentatively, how he had stood on the bridge, looking across the city, contemplating ending it all. It was News Year’s Eve 2049, the new year coaxing him intolerably, daring him on. The fireworks exploding in the distance. A note waiting at his flat. A future without a place for him. He hadn’t seen his psychiatrist since then. Would she know what had happened?

Yet in this brave new world, technology wasn’t just an adjunct to clinical decision-making. It strove to compete, claiming a therapeutic relationship of its own with patients. As early as the 2010s, self-help phone applications advertised themselves with taglines such as ‘rule your mind or it will rule you’, while others offered individualised therapy through artificial intelligence techniques.⁸ The market flooded well beyond the traditional boundaries of academia, researchers were inundated with innovation but starved of time to regulate it. A 2018 analysis found that only 14 of approximately 100 studies using mental health apps had clinically validated evidence of their effectiveness.⁹ However, fears about the field’s lack of regulation could only chase the technology into the future.

His phone knew. The app which monitored his mood knew, as did the one which monitored his geolocation. Maybe the software which monitored his sleep had worked it out too. He was sure that some of his social media followers had guessed. His internet searches knew. His family didn’t. His phone had recognised something his friends had missed. Perhaps it was his phone which had stopped him. Or had it merely helped him stop himself?

In anticipation of Steve’s appointment, Dr Singh downloaded his data. She analysed the GPS data first, before turning to the sleep data, exercise records and daily mood assessments. She was sceptical of algorithms that claimed to close the loop between users and their care, seeking to displace the clinician. Even the most well-intentioned apps, the most effective, lacked something, she felt. But she didn’t resist the technology entirely. With data of its own, psychiatry demanded parity with physical health. Digital biomarkers offered patients objective evidence for years of lived experience and routine dismissal. The algorithms informed clinical decisions, streamlined cloudy diagnoses and personalised treatment choices. Yet alone they lacked something profoundly human, profoundly therapeutic.

Steve walks into the clinic and sees his doctor of 17 years. A tear drops from his cheek. The psychiatrist offers a tissue.

More come. They forget the numbers for a moment. A moment's pause in a world bustling of answers. A moment of silence in a world full of data. Steve looks up. 'It's good to see you' he says, wondering how to tell someone what they already know.

They talk, and they reflect. Dr Singh browses Steve's numbers in the way that doctors have glanced over blood tests and clinical observations for years. Steve adds meaning to the data, reflects on the read-outs, adds humanity to the algorithms. Together, they identify where the models shadow their subject like ill-fitting clothes. Algorithms worked in broad assumptions, clinical acumen dealt with individuals, Dr Singh explained, as she tailored the numbers to the man in front of her.

She was reasonable, Steve felt. He liked her. An ally with whom to navigate this increasingly impersonal world. As the appointment drew to a close, Dr Singh offered Steve an outreach service. We can have the data alert us if anything takes a turn for the worse, she explained, a run of poor sleep or abnormal text messaging could prompt your community team to check up on you, or even drop you a visit. It was something which had appeal, a safety net he wondered if he'd benefit from.

Dr Singh was hesitant to offer the remote-monitoring outreach service to all her patients. The qualitative studies had identified that some found it too intrusive, whereas others worried they would become fixated on their own mental health, causing an anxiety of its own.¹⁰ Historical concerns around the medicalisation of everyday experience persisted in new forms. Part of her was relieved when Steve declined.

New Year's Eve 2050. Another year had passed. As 2051 beckoned, Steve continued to struggle with his symptoms. He'd developed coping strategies, the data had helped him identify his triggers of relapse. Sometimes he wondered if the algorithms knew him better than he knew himself. And he wondered if that was OK. With their help, he'd learnt to predict and prepare for his relapses. At his most optimistic he wondered if he'd managed to prevent them.

After seeing her last patient for the day, Dr Singh turned back to her computer. Flicking through the screens, she glanced through a collection of records the remote-monitoring outreach programme had flagged for her attention. A man with schizophrenia exhibiting an unusual geolocation trail and a woman with bipolar disorder whose sleep had become increasingly erratic. She would call them in the morning, reassured that even technology could not evade the uncertainties of clinical practice. After shutting down her computer and returning her coffee mug to the kitchen, Dr Singh exited the clinic into the cold December evening.

Approaching midnight, Steve's phone notified him of another upcoming daily mood assessment. He glanced down, hesitated and turned it off. Placing his phone on the table next to him, he looked to the sky, stood up and walked towards the fireworks.

George Gillett, BA, BM BCh, is an Academic Foundation Doctor at the Oxford University Clinical Academic Graduate School, and at the Department of Psychiatry, University of Oxford, UK.

1.4 2019

1.4.1 The requirement for a general psychiatric assessment risks psychopathologising the experience of transgender people

Michael Shaw

date

2019-2

Contents

- *The requirement for a general psychiatric assessment risks psychopathologising the experience of transgender people*

This paper and the service from which the statistics are drawn appear concerning on a number of levels. It appears unlikely that the fundamental assertion which underpins the statistics in this paper is accurate, namely that ‘our case note review was able to capture all patients referred within a certain time period in this geographical area’.

The authors state that: ‘All individuals who request treatment for gender dysphoria in Oxfordshire are referred to a single clinician (C.B.) for psychiatric assessment and subsequent referral to a specialist centre’, and later, ‘there is a single point of access in Oxfordshire for onward referral to specialist gender clinics’.

This referral pathway is not consistent with mainstream practice in other areas of England and is not supported by current protocols and guidelines representing best practice. The 2013 College Report *Good Practice Guidelines for the Assessment and Treatment of Adults with Gender Dysphoria* emphasises referral by or via a general practitioner, with no other gatekeeping requirement.

The requirement for a general psychiatric assessment is at best unnecessary and at worst risks psychopathologising the experience of transgender people who are presenting with gender dysphoria, an experience of discomfort or distress which is not psychiatric in nature.

There is local awareness of the unusual nature of the arrangement in Oxfordshire. The Oxford University LGBTQ+ society advises on its website: ‘N.B. A lot of GPs will seek to refer trans customers to psychiatrists (in Oxford, this is usually Dr Chris Bass), but this is a completely unnecessary procedure. If you’re seeking referral to a Gender Identity Clinic to receive hormone treatment or surgery, this will only lengthen the process. Psychiatric assessments are not required by Gender Identity Clinics, and your GP is qualified to make the referral’.

Given the high proportion of students who will have families of origin outside Oxfordshire and the high level of awareness within Oxford University that a psychiatric assessment is unnecessary, it appears likely that a significant number are bypassing the service.

Another factor not considered by the authors is the almost exponential rise in people presenting to gender identity services who are under the age of 17. Provision is via a centralised national service for young people. At 17, their care is transferred to an appropriate gender identity clinic. Transfers of care now comprise an increasing proportion of referrals to the Northern Region Gender Dysphoria Service. As this is the case nationally, such patients will also bypass Dr Bass and will not feature in the statistics presented.

1.4.2 Night-time confinement and the practice of realistic medicine

Lindsay Thomson

Correspondence

Lindsay Thomson

(l.d.g.thomson@ed.ac.uk)

date

2019-2

Abstract

Summary

Night-time confinement is the practice of routinely locking patients in their rooms at night unless there is a contrary clinical indication. It is used in high-secure psychiatric hospitals. This article argues in favour of this practice on the basis of realistic medicine, an individual human rights based approach, the principles of mental health legislation in Scotland and England and cost effectiveness. This is not an academic debate. There is a real danger that those advocating against night-time confinement, if successful, will at best make little difference to the lives of our patients as they sleep, and at worst may hugely impoverish their lives because of reduced daytime activities.

Declaration of interest

L.T. is Medical Director at The State Hospital. Night-time confinement is used within this setting.

Contents

- *Night-time confinement and the practice of realistic medicine*

I am not in favour of night-time confinement (NTC), but I am in favour of maximising the benefit to patients, and of efficiency and equity, as set out in the principles of mental health legislation throughout the UK; and I am for optimising our patients' opportunities for care, treatment and rehabilitation, and for 'realistic medicine'.¹ Realistic medicine places the patient at the centre of decision-making, and aims to reduce harm and waste, tackle unwarranted variation in care, manage clinical risk and innovate to improve so as to ensure a well-functioning and sustainable National Health Service (NHS). I am therefore not against NTC, the practice of routinely locking patients in their rooms at night unless there is a contrary clinical indication. This approach to NTC is used within the high-secure hospital (The State Hospital, Carstairs, Scotland) where I work.

The State Hospital is the high-secure psychiatric hospital for Scotland and Northern Ireland. In one capacity or another, I have worked there intermittently since 1992. Throughout this period we have always utilised NTC, but it is important to note that whether then or now, all patients who have need of an open door at night will have this; for example, because of poor mental or physical health, distress over a recent or pending event or risk of self-harm.

The European Committee for the Prevention of Torture and Inhuman or Degrading Treatment or Punishment (CPT) visited the State Hospital in 2003. It highlighted the poor accommodation for patients but the issue of NTC was never raised, although it was raised at Rampton Hospital in 1994. In September 2011, we moved to a purpose-built new hospital within the same site. Our previous estate could accommodate up to 250 patients within ten wards. In our old hospital some patients had an open door. This literally meant an open door. There was no door-locking mechanism

for patients that could be overridden by staff. An unofficial quota operated within each ward. The wards contained between 24 and 26 patients and at any one time, approximately ten patients could have an open door. The admissions ward was excluded from this. Some patients did not want an open door because of their paranoia or legitimate concerns that other patients would enter their room. Others enjoyed the use of an open door, particularly as the majority of wards in the hospital at that time did not have en-suite facilities. This meant that patients could go to the toilet without having to ring a bell to attract the attention of staff.

The new hospital consists of four hubs, each with three wards for up to 12 patients. All rooms have en-suite facilities and televisions. The standard of these facilities is excellent, in fact, so good that a recent delegation from China asked to book in. The clinical model developed for the new hospital included the use of NTC for all patients. I emphasise again that any patient with a clinical need for an open door will have this. This allows us to use staff therapeutically during the day when patients are awake, rather than requiring an increased number of staff at night. Patients, named persons and carers were fully involved in developing the clinical model, during which time the views of these groups were considered, in addition to those of staff. Stakeholders reflected on the benefits of having staff available on shift during the day to support access to the grounds for escorted walks and to engage in structured activity.

NTC was also proposed because of the development of the en-suite facilities, the entertainment systems available in rooms and because the new hospital would be smoke free. No longer were the major motivating factors for an open door (the ability to go independently to the toilet and to get up to have a cigarette) relevant. NTC in its current form has been in place for almost 7 years. Never has this been the subject of complaint by a patient, named person or carer, nor raised by the Patient Partnership Group, the Carers' Group, the Independent Advocacy Service or the Mental Welfare Commission (MWC). The MWC is tasked under the Mental Health (Care and Treatment) (Scotland) Act 20032 with visiting people, monitoring the legislation, influencing and challenging all those involved in mental health and protecting the human rights of those under the care of mental health services.

The State Hospital is not alone in its use of NTC. It is used in all four high-secure hospitals in the UK. Rampton Hospital³ evaluated its use of NTC and found that there was minimal change to the experience of patients and staff following the introduction of NTC, and that NTC did not affect the patients' quality of life or produce adverse effects; indeed incidents of self-harm and aggression, and hours in seclusion reduced during the evaluation. In addition, patients appeared to go to bed earlier and sleep better, and were therefore better able to utilise the therapeutic programme during the day. Research with similar findings was also carried out at Ashworth Hospital.⁴

In practical terms, removal of NTC within The State Hospital would potentially have major resource implications in terms of nurse staffing and costs. Currently at night (21.00–07.40 h) within The State Hospital, there are 20 nurses for ten wards, with three additional staff members floating to give extra cover as required, plus the senior nurse in charge. This is a total of 24 staff members. There are two 'sides' to the shift, so a minimum of 48 staff are required to ensure daily cover.

The model of nursing that would allow the safe opening of all bedroom doors would require a minimum of 39 nursing staff plus the senior nurse in charge. This is based on three staff per ward plus eight incident responders and a duty resuscitation nurse. This a total of 40 nurses, or 16 per night in excess of the NTC model.

To realise the projected staffing model that could support the delivery of a non-NTC model, significant additional staffing would be required to be allocated for night duty. As 16 additional staff would be required for each side of the shift, this equates to 32 staff per week. Forty additional staff would actually be required when the percentage allowance is added on for training, leave and other absences.

There would be two options to realise this potential requirement to increase staffing. One would be to reallocate staffing resources from day duty to night duty, thus reducing staff availability during daytime hours by 16 staff per day (or 1.6 staff per ward). This would have an additional staffing cost for the night shift of £373 000. The other option would be to employ 40 new nursing staff to bridge the gap that this model would create.

It would be exceptionally challenging to recruit this number of staff in one cohort, and there would be a potentially destabilising effect of having a large influx of new clinical staff into a high-secure environment. In financial terms, employing 40 new nursing staff would cost £1.6 million, based on a projected average cost of £40 000 per post. Given that in 2017–2018 the State Hospitals Board for Scotland balanced its books with little to spare, and that it is most unlikely that further funding would be forthcoming for this from Scottish Government, this could only be paid for by reducing daytime staffing. This would likely have a direct and immediate detrimental effect on the care and treatment

of patients and is at odds with maximising the use of our staffing resource to best achieve safe, effective and person-centred care. As Scotland is moving to enshrine safe and effective staffing as part of our legislative framework, the current model of NTC could be argued to support achieving this legislative requirement in ensuring that our nursing staff are best deployed to meet the needs of our patients.

Undoubtedly some of the arguments above are utilitarian, but this in itself is an ethical theory. What then of other ethical and legal perspectives? The CPT report (2017)⁵ criticised the practice of NTC in English high-secure hospitals. It also criticised long-term segregation, but this is not a practice in use in Scotland. Specific powers to authorise NTC are set out in NHS England Security Directions (2013)⁶ and the 2015 revised Mental Health Act Code of Conduct.⁷ These state that NTC ‘should only be put in place where it is considered that this will maximise the therapeutic benefit for patients as a whole in the hospital’. CPT highlighted the importance of an individual perspective in the provision of psychiatric care and I would argue that each of our patients within The State Hospital is assessed for any negative effect that NTC may cause, and care is modified if this is identified. Indeed, The State Hospital adopted a human rights based approach over 10 years ago and this was independently evaluated by the Scottish Human Rights Commission⁸ and declared a good example for other public bodies. The UK Government⁹ in its response highlighted the public consultation on NTC, including patients in a high-secure setting, and the monitoring arrangements in place through the National Oversight Group for High Secure Services and announced its intention to review the use of NTC in light of the CPT’s comments.

It is the view of the Royal College of Psychiatrists’ Special Committee on Human Rights (SCHR) that NTC cannot be justified on ethical or human rights grounds (G. Szmukler, personal communication, 2017). The SCHR argue that NTC is incompatible with Article 5 (liberty and security) of the European Convention of Human Rights and probably Article 8 (private and family life), in that it is out of keeping with least restrictive measures found in the Mental Health Act Code of Practice 2015. SCHR considers the blanket imposition of NTC as an arbitrary restriction on liberty. They argue that NTC crosses a ‘red line’. Within The State Hospital, NTC was never introduced as a means to save money. It was brought in as part of a new clinical model that employed the same number of nursing staff for a reduced population, from 250 to 140 patients, but in smaller, more homely ward settings. Given that NTC within The State Hospital can be individually tailored regarding clinical needs and has never been the subject of any complaints or comments from patients, named persons, carers, advocacy, the Patient Partnership Group, staff or the MWC, it seems extreme to suggest it crosses a red line or that it constitutes inhuman or degrading treatment.

The SCHR suggests that NTC would be unlikely to meet criteria for a lawful restriction of persons’ residual liberty according to *Munjaz v UK* 2913/06 [2012] ECHR 1704. Residual liberty refers to a further deprivation of an individual’s liberty under Article 5 of the European Convention of Human Rights even if you are already detained. Further, they argue that Article 8 of the European Convention of Human Rights strengthens the importance of considering further restrictions in someone already detained, whose personal autonomy is limited.

SCHR argues that NTC is not compatible with the principles of the 2015 revised Mental Health Act Code of Conduct in England, chiefly the least restrictive option and maximising independence; respect and dignity; and purpose and effectiveness. The 2015 revised Mental Health Act Code of Conduct sets out five principles: least restrictive option and maximising independence; empowerment and involvement; respect and dignity; purpose and effectiveness; and efficiency and effectiveness. All principles are of equal importance, but their weighting may change depending on the context and nature of the decision being made. Surely here it is the principles of efficiency and equity, and purpose and effectiveness in promoting a system that supports recovery, that are of more importance than the least restrictive alternative. The Mental Health (Care and Treatment) (Scotland) Act 2003 has the underlying principle of least restrictive alternative enshrined within Section 1. It states that any function of mental health legislation should be discharged in a manner that appears to involve the minimum restriction on the freedom of the patient that is necessary in the circumstances. The person who is discharging the function shall have regards to the importance of the provision of appropriate services to the person who is subject to the certificate or the order concerned. It can be argued that minimum restriction should involve an open door at night-time, but this may be at the expense of providing appropriate services. Another principle contained within the Act is that of ‘the importance of providing the maximum benefit to the patient’. It is surely more important to have therapeutic opportunities open to the patients during their waking hours and to fulfil the principle of maximum benefit rather than argue that this is superseded by the principle of least restriction.

The debate about NTC is an example of the choices that the NHS, public, health professions and UK Government face. A legal case may result in a decision that removes NTC as an option, but this does not remove our responsibility for

such a decision if we promoted this to the CPT and we promote legal arguments in favour of removing NTC. Civil court decisions are seldom based on right or wrong. They reflect and may lead societal thinking. So have those who advocate for the abolition of NTC got this right and are thinking in advance of those of us mired in, or knowledgeable about, the practicalities of running high-secure services? Or are they advocating a view that, if successful, will at best make little difference to the lives of our patients as they sleep, given that we already open the doors of those in distress, and at worst may impoverish their lives because of reduced daytime activities if no new funding is forthcoming for the greatly increased costs? And even if new funding is made available, we have a responsibility to consider where it has come from in terms of NHS funding and what the opportunity costs will be. In considering the concept of value, increased daytime staffing is of high and personalised value to the patients, and increased night-time staffing is of low allocative (population) value. The CPT report highlights poor levels of activities for patients in high-secure care. At The State Hospital, this is our clinical priority. Patient activity levels will deteriorate if NTC is no longer permitted. I firmly believe that the principles of maximum benefit and efficiency and equity outweigh least restrictive alternative in the case of NTC. Indeed, removal of NTC may increase restrictions on patients during the daytime. NTC should remain in place. Improved opportunities for patient activity should be the campaign that unites us all.

Our paper aimed to highlight the marked increase in referrals seen locally within recent years. We accept that, as Dr Shaw notes, some people, particularly those from the student population who also have families of origin outside Oxfordshire, may have been referred directly to gender identity clinics and so were not captured by the data. This would mean that our findings likely represent an underestimate of the total increase in numbers of people seeking assistance from specialist clinics, which makes the increase we did find even more striking.

We also appreciate Dr Shaw's points regarding the referral pathway in Oxfordshire and the need to minimise the barriers transgender people experience to accessing services. The clinical pathway has indeed been reviewed and altered since the period described in the study, with service users now being referred directly by general practitioners, generally to the specialist clinic in Northamptonshire.

The clinic did not assess people under the age of 17, so we did not include data on this age group in our study, but it is certainly notable, as both Dr Shaw and Dr Clyde's letters highlight, that referrals to gender identity disorder services (GIDS) for children and adolescents have risen dramatically over the past five years. Dr Clyde in her letter draws attention to the high rates of referral to GIDS for children and adolescents since 2010, and in particular the increase in rates of referral of those assigned female at birth. This has also been our experience, although the increase was less marked in our adult population than in the child and adolescent population Dr Clyde describes, and it is interesting to consider possible reasons for this. In our data, we found a marked trend towards more natal females being referred over the six-year period from 2011 to 2016, with a ratio of approximately 1:2 compared with natal males requesting transition. In our previous audit published in 2011 and covering the period 2006–2011, this ratio was 1:3 (Saunders and Bass, 2011). However this apparent trend did not reach statistical significance in our data. We also identified 8.5% of people presenting with non-binary gender identities, which were not noted in our previous audit. The finding of increased rates of autism spectrum disorder is also of considerable interest, and our finding of 7.8% is almost certainly an underestimate. We agree that clinics are being overwhelmed, and that there is an urgent need for both more research and discussion in this rapidly changing field, in order to best meet the needs of transgender young people and adults.

1.4.5 Trials and tribulations of S49 orders

Ilyas Mirza Mukesh Kripalani

date

2019-2

Contents

- *Trials and tribulations of S49 orders*

The Mental Capacity Act 2005 (MCA 2005) is an Act of Parliament, applying to England and Wales, that provides a legal framework for acting and making decisions on behalf of adults who lack the capacity to make particular decisions for themselves.¹ Under section 49 (pilot order) of the MCA 2005, launched in 2016, the Court of Protection can order reports from National Health Service (NHS) health bodies and local authorities when it is considering any question relating to someone who may lack capacity, and the report must deal with 'such matters as the court may direct'.² This change has caused significant ethical challenges for psychiatrists.

With regard to professional implications, Section 49 reports require an opinion; according to British Medical Association (BMA) and General Medical Council (GMC) guidance, this falls under expert witness work. The recent Pool judgment is a reminder that the GMC is likely to consider that fitness to practice is impaired if a doctor acts outside what is considered their scope of work.³ The order is usually accompanied by an instruction letter containing legal precedents and a bundle sometimes containing conflicting assessments. Responding to such instructions require medico-legal training and experience in giving opinions to complex questions such as capacity to consent to sex, or consent to drink. We would argue that there is a blurring of boundaries between expert and professional witness. There is a need to clarify what legal safeguards are in place for the author of Section 49 reports, if their opinion is challenged, as it was in the Pool case.

In relation to patient care, the introduction of an automatic right to a medico-legal report, which was previously funded from elsewhere, has shifted the cost on to the NHS. Given that mental health services are still block funded; more work without additional funding leads to dilution of quality of care elsewhere in the system, affecting patient care. Lack of parity of esteem between physical and mental health funding makes this work an onerous burden. Increased workload without remuneration has an adverse effect on staff morale, influencing recruitment and retention within an already struggling NHS.

There is an urgent need to quantify the effects of these orders on services. The Royal College of Psychiatrists, working together with NHS England and the BMA, needs to define how medico-legal work can be safely done within existing resources. Moreover, the BMA, GMC, the College and NHS employers need to resolve the discrepancy that results from what is considered expert witness work by regulatory bodies being framed as normal NHS work by the Court of Protection.⁴ Legal safeguards need to be in place if NHS professionals become subject to legal challenge, e.g. from an aggrieved solicitor. Consideration needs to be given to a fresh legal challenge if it is evident that this pilot order is affecting patient care.

1.4.6 Tick, tock, lock: night-time confinement in high security – history, practice, ethics and practicalities

Ed Silva Andrew Shepherd

Correspondence

Dr Andrew Shepherd

(andrew.shepherd-2@manchester.ac.uk)

date

2019-2

Abstract

Summary

Night-time confinement, locking patients in their bedrooms overnight, is practiced within high-secure hospitals in the UK. This article provides context, sets out the history and reviews the ethical and pragmatic issues at stake. Thought is given to the future, where we appear to be moving toward a different approach.

Declaration of interest

E.S. is a consultant forensic psychiatrist at Ashworth Hospital. All his patients are confined at night. He represents the Royal College of Psychiatrists Forensic Faculty at the National Oversight Group, which is the strategic advisory body providing assurance to NHS England regarding the commissioning and provision of high-secure services.

 - *Research evidence*
 - *NTC and values-based practice*
 - *Moving forward*

History

Patients in UK hospitals are routinely locked up alone in their bedrooms from 21.15 h until 07.15 h for no clinical reason. This has recently been criticised by the Committee for the Prevention of Torture (CPT) in a report to the UK Government;¹ hence this series of articles relating to practices in high-secure hospitals (Ashworth, Broadmoor, Carstairs and Rampton). Until the 1980s Blom-Cooper Inquiry,² it was unremarkable that patients in the then special hospitals were locked in their rooms at night. The pendulum swung, and the 24 h opening introduced by one inquiry was questioned by the security review that followed another,^{3,4} which proposed night-time confinement (NTC) for ‘high-risk’ individuals – although this was rarely, if ever, used. As with almost all developments in forensic psychiatry, the reaction to a high-profile offence, followed by yet another inquiry introduced the Dangerous and Severe Personality Disorders services, which practiced NTC from their inception in 2003.

The current practice of NTC in the high-secure services has been permitted by the High Security Psychiatric Services (National Health Service Commissioning Board) Directions (current edition available through <https://www.gov>).

[uk/government/publications/high-security-psychiatric-services-directions](https://www.gov.uk/government/publications/high-security-psychiatric-services-directions)). In 2011, the then Minister for Health, Andrew Lansley, first allowed the provider organisations to lock a patient's room at night only on the conditions that the room had a toilet and nurse call bell, or if the patient was continuously observed. No individual clinical reason to lock the door was required. Instead guidance required the decision to be made on the utilitarian argument that therapeutic benefit should be maximised for patients as a whole; for example, by releasing staff during the day. At the time, the chairs of the Royal College of Psychiatrists' Forensic Faculty and Special Committee on Human Rights wrote to Mr Lansley to express the obvious concerns (*de facto* restriction of liberty through seclusion). The directions were considered by each of the provider trusts boards and NTC has been established in all the English high-secure hospitals as well as in Scotland (through different legal mechanisms), and has remained a subject for review within the existing governance arrangements. The recent Care Quality Commission (CQC) (<https://www.cqc.org.uk/>) reports remarked on the absence of available structured activity during the day for some patients in high-secure services, contrary to the original rationale. Significant further scrutiny has also followed the 2016 UK visit by the CPT who, among other things, said that '... the systematic locking-in of patients at night, which amounts to ten hours of *de facto* seclusion, is not acceptable in a care establishment provided there are sufficient staff.'¹ (p. 75 para. 139).

In practice this means that, apart from the unrenovated wards in Rampton and Broadmoor, patients, with very few clinical exceptions, are locked in their rooms for 10 h per night, regardless of route to high security, offending history, current risk to others or dependency needs. It is quite possible for a patient to be subject to NTC in high security while awaiting transfer to low security or even, quite exceptionally, to a community placement. Although the guidance accompanying the directions requires clinicians to note the absence of contraindications to NTC, few if any psychiatrists in this invidious position do so (as evidenced by frequent discussions in peer supervision and other meetings); those that do not, find themselves in the curious position of being criticised by the CQC. Many, if not almost all, patients in high security have significant histories of self-harm or attempted suicide, and some present with ongoing extreme self-mutilation. At the time of writing, every patient in Ashworth is confined at night. Nursing staff now dispense night-time medication at 20.00 h and then muster patients to go to their rooms as the night shift arrives. Night-time staffing in the hospitals has significantly reduced, on occasion to levels that have been themselves seen as worryingly low. Curiously, most patients do not complain, either informally or otherwise, and some report feeling safer.⁵ At Forensic Faculty Committee meetings, it has been suggested that the obvious remedy is judicial review by a patient. This has not occurred.

Research evidence

As for many coercive approaches in forensic practice,⁶ there is a significant absence of evidence in the literature. A search identified two mixed-methods studies.^{7,8} The first, based on the experience at Rampton, demonstrated no statistically significant change pre- or post-implementation in its chosen measures addressing ward atmosphere, working environment and patient quality of life. Semi-structured interviews suggested staff observed a less negative effect than had been anticipated, whereas patients expressed a certain ambivalence. The findings from the study are potentially influenced by the close affiliation between researchers and the site of study, as well as by the choice of wards (acute admission) for the pilot. In the second study, based on the experience at Ashworth, measures were collected relating to sleep hygiene, behaviour and findings from a bespoke questionnaire, seeking to understand patients' concerns regarding NTC. No statistically significant changes were observed. However, a parallel investigation considering the attitudes of nursing staff revealed a universally negative attitude to it. The potential to generalise findings from the study were limited by difficulties in recruitment and implementation, which may have resulted in skewed findings in relation to the experience within the hospital as a whole. More generally, as noted above, there is a general absence of evidence in relation to the implementation of practices such as seclusion. A qualitative study, addressing the process of seclusion in forensic practice,⁹ identified clear communication of the 'purpose' of seclusion as being a key ingredient in managing distress associated with the experience. Widespread application of NTC could be seen as partially mitigating this factor if it is assumed to be a normal practice by patients, staff and others.

NTC and values-based practice

Building on the concept of principled ethical clinical practice, the Francis report¹⁰ has reiterated the call for care providers to develop a culture that focuses first on the patient and providing, within resource limitations, compassionate care that does not inadvertently restrict basic rights or cause avoidable harm.

The CPT report notes that NTC had the potential to cause individual anxiety and that there was a lack of evidence of individual risk assessment to mitigate this potential distress. Although the limited research evidence base surveyed suggests an absence of harm, the CPT also noted the absence of evidence of benefit and the CQC reports are mixed, again highlighting concern at the restriction of liberty and remarking on a lack of increased daytime structured activity by way of mitigation.

Individual autonomy is clearly restricted through the act of confinement at any time. However, arguments in relation to autonomy are complicated with mentally disordered offenders¹¹ because acts of violence against individuals or society more generally lead to a socially sanctioned act of imprisonment. Although the situation of forensic in-patients will vary, the majority are not subject to court-ordered punishment. This may add weight to the position outlined in the Tilt report,⁴ which proposes that specific 'high-risk' individuals may perhaps be 'proportionately' subject to NTC. The blanket application of this restriction regardless of risk, or progress along the care pathway, is confusing to many.

The argument raised in support of NTC is that of a justice-based position, whereby resources consumed in the staffing of night shifts, to allow free movement of patients, can be more appropriately allocated in the day, to increase the availability of therapeutically oriented activity. However, as has been noted by both the CPT and the CQC, there has been an absence of increased structured activity during the day even with NTC, suggesting that no benefit has emerged in this area. However, interpretation of this situation is complex because, with the notable increase in constraint on resources in recent years, it is hard to determine how services would currently appear had funding remained on the projected trajectory from the time of NTC's inception.

Moving forward

The current position with regard to the practice of NTC is therefore difficult, particularly in its current blanket implementation. There is also a pragmatic reality: even if the decisions were reversed, neither the money nor the staff are available to fill the gaps.

To return to the analogy of the pendulum, swings between restrictive and more liberal practice can be seen as an institutional group response to anxiety and external scrutiny.¹²⁻¹³ Generally, these changes are seen as being a collective response from within the group; however, in this situation the swing of the pendulum has been affected by the massive gravitational change of austerity. Clinical decision-making is forced, in that it is being subjected to either political pressure or fiscal reality, depending on one's viewpoint. As in other political arenas, it seems apparent that it is some of the most vulnerable in society who are subjected to restriction. There is also an 'invisibility' to the phenomenon, occurring as it does behind the opacities of our walls, and it is perhaps also curious that it took an investigation from the CPT, rather than our own governance structures, to switch the night light on, and so we should thank our European friends. Movement to a more dynamic and rational response is necessary. The pendulum must swing again, but how can this best be achieved?

Ed Silva is a consultant forensic psychiatrist with Mersey Care NHS Foundation Trust, UK; **Andrew Shepherd** is a clinical lecturer in forensic psychiatry at the University of Manchester, UK and is a SpR in Forensic Psychiatry at Ashworth Hospital, Mersey Care NHS Trust, UK.

1.4.7 Lionel Hersov, MD, FRCPsych

Philip Graham

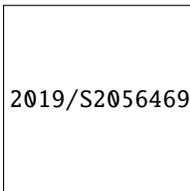

date

2019-2

Contents

- *Lionel Hersov, MD, FRCPsych*

Formerly Consultant Psychiatrist, Maudsley Hospital, UK; Professor, University of Massachusetts Medical School, USA

Shortly after South Africa joined the war against Germany, Lionel Hersov, who died recently at the age of 95, was 18 years old and just beginning his medical studies in Johannesburg. He volunteered for the South African Medical Corps Reserve and, from 1944 to 1945, he was attached as a medical orderly to the Royal Durban Light Infantry, 6th South African Armoured Division, and served first in the Middle East. He was then with the 5th Army Group as it fought its way up mainland Italy. His non-combatant status did not protect him against the threat of violence. On at least one occasion he was ordered to enter territory covered by enemy guns to check whether a fallen soldier had been killed or was lying wounded.

Nor was he protected from antisemitism. At another time, a German-speaking doctor pointed out to a severely wounded, captured German officer that the man treating his wounds was a Jew. The officer muttered 'Jude, schwein' as he spat at Lionel. He did not talk about his war experiences but, much later, visiting the battle sites in Italy with two of his children, he was deeply moved at the memory of friends who had not made it home.

At the end of the war, Lionel resumed his medical studies at the University of Witwatersrand, Johannesburg, qualifying as a doctor in 1948. Shortly after qualification, he decided to become a psychiatrist and worked in various junior posts in Johannesburg and Pretoria. However, training opportunities in psychiatry in South Africa were limited at that time. In 1952 he was accepted on the psychiatry training programme at the Maudsley Hospital, London. By 1955 he had decided to specialise in child psychiatry, and it was in this field that he made his mark. He only returned to South Africa subsequently for brief visits.

In the mid-1950s, child psychiatric practice in Britain and elsewhere was largely uninformed by scientific data. It was felt that the behaviour and emotional problems of childhood and adolescence were too complex to be studied in any systematic manner. Around that time, a small number of academically minded child psychiatrists, of whom Lionel Hersov was one of the first, decided that the time had come to apply scientific methods to the subject.

His chosen topic, which formed the basis of his MD thesis, was non-attendance at school. It was already known that children who failed to attend school fell into one of two groups. There were school refusers who were anxious about attending, either because of a fear of what might happen to them at school, such as being bullied by another student or a teacher, or because they were over-anxiously attached to their mothers.

Then there were truants who were usually rebelling against unsatisfactory home backgrounds and found little at school to interest them. Hersov was able to show that these two groups differed markedly in their relationships with their

parents, their personalities, their level of academic achievement and the presence of other behaviour disorders. His findings had major implications for clinical management.¹

After he left the Maudsley, he was appointed a consultant child psychiatrist, first at the Child Guidance Training Centre, London, and then at the Children's Hospital, Great Ormond Street, London. He returned to the Maudsley Hospital as a consultant in 1968, but also held a part-time appointment attached to the paediatric department at the Hammersmith Hospital.

While at the Maudsley, where he worked as a consultant child psychiatrist until 1994, he was an inspiring teacher and role model. Many of those who later made their mark in the field were led into it by his example. He was an astute clinician who formed excellent therapeutic relationships with the troubled children and families referred to him. While he had had experience of personal psychoanalysis, his approach was influenced not only by psychodynamic theory, but by a range of different perspectives. His colleagues found him to be a delightful man, tolerant and calm, with a talent for friendship. His warmth, humanity and wisdom were all deeply appreciated.

Shortly after the publication of papers arising from his research, he was invited to become Joint Editor of the recently founded *Journal of Child Psychology and Psychiatry and Allied Disciplines*. He acted as Senior Editor of this journal for 21 years, from 1963 to 1984. During his editorship, the journal gained so greatly in status and prestige, that, whereas in the beginning there were barely enough papers submitted to allow quarterly publication, at the time he stopped, it had an international reputation and began to appear six times a year, only accepting papers of very high quality. He retained his connection with the journal for a further 26 years, serving first as Corresponding Editor while in the United States, and then as Book Review Editor.

In 1977, he was invited by Michael Rutter to be Joint Editor of *Child Psychiatry: Modern Approaches*, the leading textbook in the field worldwide. He remained joint editor for the next two editions of this outstanding book. By now, Lionel's reputation as a leading academic had become international, and in 1978 he was elected President of the International Association of Child and Adolescent Psychiatry. The Congress held in Dublin in 1982, at the end of his presidency, was an event made memorable by the step-change in the quality of presentations.

In 1984, he moved to a position at the University of Massachusetts Medical School in Worcester, Massachusetts in the USA and remained there for over 6 years. There, he had a major influence on the teaching of child psychiatry and on clinical work. On hearing of his death, many of his former colleagues in Worcester referred to the contribution he had made there with extraordinary admiration. One wrote, 'Lionel was a wonderful man whose support to the emerging child division was phenomenal and long-lasting'. Another noted that 'While his expertise was child psychiatry, his knowledge went far beyond this...' Their recollections had a lighter side. Many recalled his predilection for frozen yogurt dessert.

After his return to London in 2000, Lionel was appointed Honorary Distinguished Visiting Scientist at the Tavistock and Portman NHS Trust and took a particular interest in mentoring psychiatrists in training. Earlier, he had held a number of other significant positions. From 1976 to 1984 he was Civilian Consultant in Child and Adolescent Psychiatry to the British Army, advising on matters arising with army families. In 2011 he was awarded an Honorary Doctorate jointly by the Tavistock Clinic and the University of Essex.

Although he did not practice his religion once he reached adulthood, Lionel's parents were both Jewish. They had migrated with their families from Russia in the later years of the 19th century. His father, Charles, was a shopkeeper, and his mother, May, née Goodman, looked after the family and helped in the shop. He was the oldest of three with a younger brother and sister. He was brought up in a small Transvaal town near Pretoria, winning a place at the University of Witwatersrand, Johannesburg, to study medicine in 1940. In 1952, shortly after he came to London for postgraduate training, he married Zoe Menell, a South African graduate of Vassar College, New York. She had just completed postgraduate studies at the Sorbonne, Paris. They had four children: John, an advocate for learning disabled adults; Gregory, a theatre director; Isabelle Mary, an art gallery curator; and Martin, a media company executive.

In his younger days, Lionel was a stylish tennis player and later took up squash, which he played highly competitively. In his early 70s, however, he developed quite severe back pain which limited his mobility. He remained an enthusiastic lover of jazz. Sometime before he died, he developed Alzheimer's disease, which clouded his last years. He is survived by Zoe and his four children, as well as five grandchildren.

Lionel Hersov, child psychiatrist, was born on November 19, 1922. He died on March 11, 2018, aged 95 after a long

illness.

Note: This obituary is based on one published in *The Times* on 18 May 2018.

1.4.8 Contrast with referrals to Tavistock and Portman Gender Identity Disorder Service

Katherine Rae Clyde

date

2019-2

Contents

- *Contrast with referrals to Tavistock and Portman Gender Identity Disorder Service*

This article shows a modest increase in referrals year on year, approximately 18%, with a majority of referrals received being for those assigned male at birth (AMAB). This is an interesting contrast with data from the Tavistock and Portman Gender Identity Disorder Service (GIDS) for children and adolescents.

Referrals to GIDS have increased from 97 in 2009/10 to 2016 in 2016/17. From 2014/15 to 2015/16, referrals increased by over 100% and from 2015/16 to 2016/17 they increased by 41%. Ages at referral seen by the service ranged from a very few at 3 to 17 years old.

Also in contrast to this much larger increase in referral rates is a marked change in the proportion of those assigned female at birth (AFAB). Up until 2011 there were more referrals of those AMAB. Since then the number of those AFAB referred has grown steadily, and in 2016/17 more than twice as many referrals were made for those AFAB as those AMAB (data available on GIDS website).

We need to be looking as a profession at these striking differences, and more research is required to determine the reasons for them. It may be that reducing stigma has led to higher referral rates, particularly among teenage girls but it could also be that the characteristics of those being referred are changing. This links with the finding that there seems to be a higher prevalence of autism spectrum conditions (ASC) in clinically referred, gender dysphoric adolescents than in the general adolescent population. Holt, Skagerberg and Dunsford (2014) found that 13.3% of referrals to the GIDS service in 2012 mentioned comorbid ASC (although this is likely to be an underestimate).

In this context, it is alarming that referral rates are increasing at a rate that services and research cannot keep up with. Both the American Academy of Pediatrics and the Australian Standards of Care and Treatment for Transgender and Gender Diverse Children and Adolescents appear to support both medical and surgical transition in adolescents. And yet long-term outcomes in this group are not known. We know that adults who have gender dysphoria and who transition report the dysphoria beginning in early childhood. We do not know yet know that those experiencing dysphoria in childhood will go onto experience dysphoria in adulthood. Indeed, we know that 80% of individuals referred to GIDS do not proceed to transition.

In the UK, we are fortunate to have a national service for children that follows the best available evidence, but there is an urgent need for both research and discussion. This is not always easy in a highly emotionally charged atmosphere.

This passionate book gives insights into ways to understand and support people living with dementia. It holds out a challenge to all of us to remember the impact – for better or worse – that our words and actions have on those with dementia. It highlights the imperative of acting in ways that value people with dementia and enable them to continue to make the most of their strengths; it does so by giving the reader constructive, tangible, feasible ideas.

In making his arguments, Sabat uses the biopsychosocial framework, speaking of the importance of taking a person-centred, holistic perspective to appreciate each different person and his or her communications and reactions. He argues that prejudice, stigma and misunderstanding undermine morale and damage the lives of people with dementia, leading to inappropriate regimes in care settings and disrupted confidence and relationships.

It could be argued that none of this is new. Arguments for holistic understanding of the impact of illness have been put forward for several decades, including in relation to dementia, and the need for person-centred care is already enshrined in UK and in global policies. However, the continuing shortcomings in care and the prevailing myths about dementia indicate that there is a continuing need to improve the respect and care we offer people with this disorder. One part of this is to educate successive generations of health and social care professionals about the nature of dementia and of person-centred care, which is where this book can assist.

The book provides a path into the territory of truly understanding the nature of the sometimes-slippery concept of person-centred care. Its success lies in its readability and it is easy to pick up. The text is written in accessible language and is broken into bite-sized chunks by the use of headings written in the form of italicised questions. The arguments are based on research evidence and case studies, illustrated by personal examples from the lives of people with dementia. The superficial softness of the text provides a clever medium for some challenging messages, which Sabat gently but insistently brings home. They are challenges that are hard to refuse.

Dr Simon Vann Jones (s.vannjones@nhs.net)

date

2019-4

Abstract

Aims and method

Few studies have looked at subjective memory impairment from electroconvulsive therapy (ECT) after treatment completion. We aimed to systematically review all available evidence for subjective post-treatment effects.

Results

We included 16 studies in this review. There was considerable between-study heterogeneity in clinical population, ECT modality and assessment scales used. The most common assessment scale (eight studies) was the Squire Subjective Memory Questionnaire. The majority of studies reported an improvement in subjective memory after ECT, which correlated with improved depression scores. Subjective complaints were fewer in studies that used ultra-brief pulse ECT. Longer pulse widths were associated with more subjective complaints, as was female gender and younger age of treatment in the largest study.

Clinical implications

There is considerable heterogeneity between studies, limiting meaningful conclusions. Ultra-brief pulse ECT appears to result in fewer subjective complaints.

Declaration of interest

None.

Electroconvulsive therapy (ECT) is an effective treatment for major depression; however, there is debate around the specific long-term effects of the treatment on memory and the acceptability of this to patients.¹ There is wide variation in the post-treatment satisfaction rates after ECT, with previous studies showing that the percentage of patients who would consider having a second course of ECT varies between 36% and 98%.² Multiple studies have shown that dissatisfaction with ECT is related to feeling under-informed of potential side-effects.³⁻⁷

Pre-procedural fear and post-procedural assumptions that deleterious cognitive changes were a direct result of the treatment have been identified as the two areas most likely to lead to a negative view of ECT.⁸ Evidence suggests that clinicians tend to overestimate the effects of medical treatments and underestimate harm, so being able to accurately quantify the additional risk that ECT poses to subjective memory independent of the effects of depression would help both clinicians and patients alike and may improve outcomes.⁹⁻¹⁰ This review aims to summarise all studies that have assessed the post-treatment effects of ECT on meaningful memory loss.

Methods

This systematic review was completed in accordance with Preferred Reporting Items for Systematic Reviews and Meta-Analyses reporting guidelines (*Fig. 1*). *Fig. 1* Preferred reporting items for systematic reviews and meta-analyses flow diagram mapping search history. CINAHL, Cumulative Index of Nursing and Allied Health Literature database.

Inclusion criteria

Studies measuring subjective memory at baseline followed by at least one measurement after the completion of treatment, using a clearly described scale (such as the Squire Subjective Memory Questionnaire, SSMQ11), or questions that specifically assessed subjective memory were included.

A follow-up period of at least 24 h after the completion of therapy was considered sufficient to allow enough time for the acute effects of the final seizure to have passed and no limit was placed on the maximum length of follow-up. Both prospective and retrospective studies were included. Only published studies were included and studies in all languages were considered.

Studies measuring memory only during treatment were excluded. Squire's original studies from 1979 were excluded.

Information sources

The online databases PubMed, Google Scholar, Embase, PsychINFO and Cumulative Index of Nursing and Allied Health Literature (CINAHL) were searched for eligible studies. The following search terms and Boolean operators were used in PubMed as examples: 'subjective AND (ECT OR electroconvulsive)', 'memory AND (ECT OR electroconvulsive)'.

Study selection

Abstracts were screened for inclusion by two independent reviewers. Where any disagreement arose between reviewers, the full paper was requested. All full papers were read and scrutinised by both reviewers independently before deciding to whether to include them in the final review. Screened papers references were searched to identify any further papers.

Data collection process

Both reviewers used the same data extraction form and completed the data collection independently. Both reviewers screened all papers deemed eligible for inclusion and at the end of this process, data extraction forms were compared for agreement. Where data were missing from both forms and felt to be of significant value to the study question, the authors of the study were contacted directly.

Data items

The variables of interest from each study included the number and diagnoses of the patients involved in the study, the modality of ECT (e.g. unilateral versus bilateral or brief pulse versus ultra-brief pulse), the memory assessment method used, the results of this and the authors main conclusions.

Risk of bias within and across studies

Several sources of bias were considered including attrition bias, given the patient population in question, and also the risk of acquiescence and reporting or detection bias if memory assessments were carried out by the same team that performed the treatment. There was also a two-way risk of recall bias in this patient group with patients vulnerable to both underestimating and overestimating the extent of their memory impairment before ECT, because of the extent of their depression and the effect this is known to have on memory.

All studies described methods for dealing with missing data if applicable, with most studies reporting complete-case analysis or intention to treat.

Results

A total of 877 abstracts were identified for potential inclusion, of which 52 were felt to warrant full-paper requests. From these 52 and their reference lists, 16 papers were selected for inclusion in the final review (*Fig. 1*). The main reasons for rejecting papers were no baseline measure of subjective memory, paper measured objective memory only, no measurement of subjective memory beyond the final treatment and insufficient time between the final treatment and measurement of memory.

Synthesis of results

Because of significant clinical and methodological heterogeneity, it was not possible to perform a meta-analysis on the included studies. No two studies measured a comparable patient population, on the same scale, using the same ECT modality, at the same time points (*Table 1*). *Table 1* Summary of included papers

Study (first author, year)	Participants	Questionnaire used	Modality	Assessment	Results summary
Mohn 2016	23	<i>n</i> = 31	unipolar depression		
Everyday Memory Questionnaire					
Bifrontal	<i>n</i> = 1		unilateral	<i>n</i> = 22	
			mixed unilateral and bilateral	<i>n</i> = 8	
Baseline	6 weeks and 6 months				
Pre-ECT		104.0 (SD 37.9)			
6 weeks post-treatment		107.9 (SD 43.6)			
6 months post-treatment		98.6 (SD 42.6)			
					higher score indicates worse memory
Brus 2017	21	<i>n</i> = 1212	80% unipolar depression; 20% bipolar depression		
Seven-point variant of the 'failing memory' component of the Comprehensive Psychopathological Rating Score					86.9% had more than six treatments; 91.6% had unilateral electrode placement
Baseline and <1 week post-treatment					Subjective memory worsened in 28% of the sample (31% women <i>v.</i> 18% men; 32% young adults <i>v.</i> 22%

adults aged over 65 years); longer pulse widths correlated with more subjective complaints; no difference between bilateral and unilateral placement Bag 2016¹² $n = 140$, 24.3% unipolar depression; 59.3% bipolar mania; 16.4% bipolar depression SSMQBilateral, brief pulse; mean number of sessions was seven across all groups Baseline and immediately post-treatment Mean SSMQ score dropped 49.5 points between baseline and end of therapy; patients with bipolar disorder reported less complaints than patients with unipolar depression Kumar 2016¹⁴ $n = 75$, 77% unipolar depression; 10.7% bipolar type 1 disorder; 2.7% bipolar type 2 disorder; schizophrenia 2.7%; schizoaffective disorders 5.3% Subjective Assessment of Memory Impairment 96% received right unilateral; the majority received brief pulse Baseline and 1 day post-treatment No change in subjective memory score during therapy despite objective evidence of impairment-Mayur 2013¹⁵ $n = 40$, unipolar depression SSMQ Right unilateral; 50% ultra-brief pulse; 50% brief pulse Baseline, after 8 sessions and 3 months post-treatment Brief pulse: 21.6 at baseline ($n = 19$), 16.2 at 3 months ($n = 10$), within-patient change of +12.7; ultra-brief pulse: 23.2 at baseline ($n = 16$), 0.8 at 3 months ($n = 14$); within-patient change of 14.86 Fernie 2014¹⁶ $n = 126$, unipolar depression SSMQ and PRMQ Not described Baseline, 1 month, 3 months and 6 months post-treatment SSMQ improved from 14.1 at baseline to 4.58 at 6 months, with the greatest improvement seen 1 month after therapy: 1.59 (SD 2.73); PRMQ score improved by approximately 10% from baseline Fazzino 2013¹⁷ $n = 26$, unipolar depression Selected SSMQ questions 17/26 received right unilateral; 17/26 received ultra-brief pulse width 3–7 questions daily for 60 days (including treatment) No change in subjective memory scores despite objective memory improvement Ng 2000²² $n = 34$, unipolar depression Self-Rating Scale of Memory Function Right unilateral Baseline, after six treatments and 1 month post-treatment Improved subjective memory score at end of treatment; negative correlated with HRSD score Schulze-Rauschenbach 2005¹⁸ $n = 14$, unipolar depression SSMQ Right unilateral and brief pulse width Baseline and within 1 week of completing 5.5-point improvement in SSMQ score, although not statistically or clinically significant Frith 1983²⁴ $n = 70$, unipolar depression Single binary question: ‘do you experience memory problems?’ Bifrontal ECT, median course of eight sessions Baseline, after treatment and at 6 months Sham ECT responders, ECT responders and sham ECT non-responders all reported improvement in memory; ECT non-responders memory remained stably poor Smith 2010¹⁹ $n = 85$, unipolar depression SSMQBilateral ECT; half had ten sessions of continuation ECT Half had continuation pharmacotherapy Baseline (post- ECT), 12 weeks and 24 weeks Both groups’ SSMQ scores significantly improved from baseline; study looked at continuation treatment only Sienaert 2010² $n = 48$, unipolar and bipolar depression; 23% had psychotic symptoms SSMQ Ultra-brief bifrontal $n = 24$ and unilateral $n = 24$ Baseline and 6 weeks 73% patients were glad they had ECT; SSMQ performance strongly correlated with satisfaction on multiple regression analysis but also correlated with depression score, so may not be independent Berman 2008²⁶ $n = 333$, unipolar depression CFQ memory subscale 40% bilateral, 34.7% unilateral, 24.3% combination; 14% sine-wave, 86% brief pulse Baseline, 1 week and 24 weeks Baseline 14.97 (SD 6.75), 1 week 13.01 (SD 6.39), 24 weeks 14.05 (SD 6.85) (higher scores indicate greater impairment) Arts 2006²⁵ $n = 12$, bipolar and unipolar depression CFQBilateral Baseline, 5 days and 30 days CFQ score improved from coefficient of 0.2 at baseline to 0.17 at 30 days Coleman 1996²⁰ $n = 70$, unipolar depression SSMQMixture of bifrontal, RUL and bilateral Baseline and 2 months 31.5 at baseline, 5.4 at 2 months Ikeji 1999¹³ $n = 70$ ECT, $n = 70$ control; 30% unipolar depression; 37.1% schizophrenia; 28.6% mania; 4.3% schizoaffective disorders Two binary questions: ‘Is your memory poor?’ ‘Do you worry about your memory?’ Bilateral Baseline and seven intervals up to 6 months post-treatment Subjective memory complaints at 6 months: 37.1% of ECT group, 22.6% of control group¹

Participants

We found that 15 out of 16 studies reported that major depressive disorder in unipolar or bipolar depression was the indication for treatment in the majority of patients. One study reported 59.3% of their sample being treated for mania.¹² Two studies reported use in patients with schizophrenia and schizoaffective disorders, although it was unclear whether these patients were treated for their depressive or primary psychotic symptoms.^{13,14}

Assessment tool used and time points

The most commonly used tool for measuring subjective memory change was the SSMQ, with eight studies using all or part of this scale.^{6,12,15–20} This is an 18-item questionnaire assesses various aspects of subjective memory on a Likert scale from 4 (much worse) to +4 (much improved), providing a total score comparing current memory with a previous time point. For the purposes of these studies, it was assumed that memory was being compared to premorbid memory, although this was not explicitly stated in any study. Five of the six studies that provided group-averaged SSMQ scores showed sustained improvements from baseline after ECT treatment (*Fig. 2*). *Fig. 2* Subjective memory change over time. A comparison of studies using the Squire Subjective Memory Questionnaire (SSMQ). Studies used brief pulse unless stated otherwise.^{12,15,16,18,20} ECT, Electroconvulsive Therapy.

Modality

Pulse width

Four studies included patients who had received ultra-brief pulse width.^{2,15,17,21} Two of these compared brief with ultra-brief and both found longer pulse widths were associated with more subjective complaints.^{15,21} One of these studies demonstrated that this difference was not accounted for by use of bilateral versus unilateral.²¹

Laterality

Eight studies favoured or exclusively used right unilateral electrode placements, three studies favoured bilateral, one used bifrontal, three used a combination of bilateral, bifrontal and unilateral, and one study compared bifrontal with unilateral.

Discussion

Studies showed wide variation in the length of follow-up period used to assess post-treatment memory. Although this does not allow a truly longitudinal picture, it does allow the possibility of assessing whether patterns may exist at different times points post-treatment.

Short-term follow-up

A retrospective analysis of 1212 medical records from the Swedish ECT treatment registry found, compared with a pre-treatment baseline, 26% reported worse subjective memory post-treatment, defined by a two-point deficit on the subjective memory component of the Comprehensive Psychopathological Rating Scale questionnaire.²¹ In an attempt to stratify risk, the study found that more women suffered with subjective memory loss than men (31 v. 18%) and more younger adults than adults aged over 65 years (32 v. 22%). The large sample size adds validity to this finding. Patients were assessed within 1 week of treatment ending compared with the start of therapy, limiting the extrapolation of this data to long-term outcomes, and the majority of patients (91.6%) received unilateral treatment. Short pulse wave and remission of depressive symptoms were associated with reduced subjective memory complaints and no dose effect was found.

A more recent study of 140 in-patients, 75% with bipolar depression, undergoing ECT found a significant negative correlation between number of treatments and deterioration in subjective memory score across diagnostic groups tested within days of treatment by the SSMQ.¹²

Contrary to these findings, the only study to use the Subjective Assessment of Memory Impairment found no change in scores amongst participants between pre-treatment and immediately after completing the course of ECT.¹⁴ Two smaller studies, using different measures, found similar findings.¹⁸⁻²²

In a pragmatic study, an automated telephone system was used to intensively monitor day-to-day fluctuations in mood and memory in a small sample ($n = 26$) of patients undergoing out-patient ECT.¹⁷ Patients were asked daily questions related to subjective memory. Objective memory scores improved with time and were correlated with mood, whereas subjective memory scores remained stable. The authors suggested that objective scores could be used to counter subjective beliefs that may cause premature termination of ECT because of concerns over side-effects.

Medium-term follow-up: up to 3 months

Using the SSMQ, a 2013 study found that patients ($n = 35$) experienced a clinically meaningful and statistically significant improvement in subjective memory across most domains with no significant deterioration in any one domain, correlating with an improvement in depressive symptoms.¹⁵ This improvement was sustained after 3 months. A study of 48 patients in Belgium reported similar findings with improvements in SSMQ scores in both groups at 6 weeks post-treatment.²

In a case-control design involving 70 patients and 18 controls without depression, those in the ECT group reported worse subjective memory at baseline and a significant improvement immediately post-treatment. Interestingly, at 2 months, their SSMQ scores were no different from the control group who had not received ECT.²⁰ Improvements were closely correlated with mood scores and there was a possible relationship between greater autobiographical memory deficits and subjective memory problem complaints.

Medium-term follow-up: up to 6 months

A study of 31 patients in Norway measured cognitive function and subjective memory with the Everyday Memory Questionnaire before starting ECT, and at 6 weeks and 6 months post-treatment.²³⁻²⁷ There was no statistically significant change in subjective memory found between all three time points, suggesting subjective memory complaints were not simply correlated with mood.

A 2014 retrospective case-notes study of 126 patients in the UK found that subjective memory improved at 1 month, 3 month and 6 months after ECT.¹⁶ This improvement was closely correlated with an improvement in Montgomery-Åsberg Depression Rating Scale score, suggesting a causal link between depression and memory impairment that was reversible by ECT; however, complete information was only available for 56 patients. Further evidence of longer-term positive outcomes were found in a 2010 study of 85 patients that found significant improvements in subjective memory at both 12 and 24 weeks after the end of the acute treatment course.¹⁹

Comparing sham and real treatment, a study of 70 patients assessed subjective memory with a single yes/no question. The percentage of patients complaining of subjective memory problems had significantly improved at 6 months in three of the four groups (sham versus real; responders versus non-responders) and was no worse in the fourth (real ECT, non-responders).²⁴

Using a simple binary question, a Nigerian study ($n = 70$) found that 37.1% of the ECT group reported subjective memory problems at 6 months compared with 22.6% of disease-matched controls.¹³ All participants in this study recovered within six treatments, an unusually high response rate that may, when combined with the average age of 29.4 years, limit the generalisability of the findings.

Pulse width

All four studies that used ultra-brief pulse width reported a low incidence of subjective memory complaints and where a direct comparison was made, ultra-brief pulse width showed fewer side-effects than brief pulse, with no difference in treatment effect.^{2,15,17,21}

Six weeks after the end of treatment, 73% of the 48 patients who received ultra-brief therapy in a 2010 study were glad that they had received ECT and satisfaction was correlated with both subjective memory and depression scores.² A 2013 study comparing brief and ultra-brief therapy in 40 patients found improvements in memory at the end of treatment from both brief and ultra-brief pulse widths; however, ultra-brief therapy was superior, resulting in a resolution of memory problems that was sustained at 3-month follow-up, with no difference in treatment efficacy.¹⁵ A study of 26 patients undergoing ultra-brief ECT who were followed up on daily for 60 days found ultra-brief therapy to have no effect on subjective memory, as assessed by a selection of SSMQ questions.¹⁷ The majority of patients in this small sample were out-patients, reducing generalisability, and almost 40% were receiving maintenance ECT.

Limitations

Heterogeneity of studies

There were considerable differences in patient characteristics across all studies, including average age, diagnosis, gender and modality of ECT, and all combinations of electrode placement positions were used across studies. Within studies, only five delivered ECT with the same electrode placement and pulse width to all patients. This heterogeneity makes it very difficult to determine if any relationship exists between mode of delivery or demographic factors and risk of side-effects. Data on which patients are most vulnerable to ECT side-effects is still lacking.²⁸

Ratings scales

Seven different measures of subjective memory were used across the 16 included studies, making comparison between studies challenging. The SSMQ was the most widely used assessment tool, but doubt remains about how well subjective tools capture actual experience. A study reporting treatment satisfaction rates did not find the SSMQ to be an independent predictor variable in their multiple regression model.²

A further criticism of rating scales is that they produce a single summary or average score that may mask domain-specific complaints within the questionnaire. Studies using qualitative assessments of memory impairment have found subjective deficits at 24 weeks that were not picked up by scales designed to capture subjective experience.²⁶

A key limitation of all studies on ECT is the acceptability of the treatment versus the alternatives, which could include additional or alternative drug therapy or a longer period of illness. Also, with ECT usually being reserved for the most unwell patients, there are issues of impaired insight and recall bias that may undermine the construct validity of any subjective memory questionnaire in this patient population.

Conclusions

The few studies that assessed subjective memory several months beyond the end of ECT suggest that, on average, subjective memory scores tend to recover over time, with ultra-brief pulse showing fewer side-effects than brief pulse therapy. However, there is considerable heterogeneity both between and within studies, limiting meaningful conclusions. Past and future studies are vulnerable to high drop-out rates, observer bias and concerns over the face validity of standardised instruments designed to measure subjective memory. However, these tools and studies should not be dismissed as being unreflective of patient experience. Contemporaneous quantitative data provides a longitudinal picture, reduces hindsight bias and may be most useful in identifying common risk factors for significant memory loss rather than as a tool for identifying specific deficits. Future subjective memory studies should use the same outcome measure,

such as the SSMQ, and measuring subjective memory should become a routine part of ECT treatment and follow-up, ideally allowing an international registry to be created to help us identify those at low and high risk of memory impairment. Comparable outcome measures should ideally be collected for patients receiving alternative treatments.

More qualitative studies are needed to identify common experiences, effects and meaning of any subjective memory loss after treatment, and ultimately, whether this is an acceptable risk from this treatment for major depression. Both of quantitative and qualitative approaches may then be used to develop more sensitive memory assessment tools, providing more informative to both patient and clinician during joint discussions around whether to proceed with a treatment that remains one of the most effective and controversial in medicine.

Dr Simon Vann Jones is an ST5 in old age psychiatry at Cornwall Partnership Foundation Trust, Bodmin, UK. **Dr Rick McCollum** is a consultant in old age psychiatry at Devon Partnership Trust, Exeter, UK.

Emily's Voices is an autobiographical narrative of the experience of living with voices, and forms part of a growing movement to normalise and de-stigmatise voice-hearing. It can also be read as an astute critique of the effects of psychiatric knowledge on selfhood and identity. Knoll's story raises questions about what is at stake when we label psychological phenomena as symptoms of specific illnesses. Voice-hearing is often linked to schizophrenia, a diagnosis that can be a source of fear and stigma.

The relationship between voice-hearing and schizophrenia in modern medicine, and the perception of the schizo-disorders as 'madness proper', are largely a product of the diagnostic separation of affective and cognitive disorders, with hallucinations and 'bizarre' delusions chiefly assigned to the latter. This division does not, however, reflect the lived experience of many people who hear voices, as Knoll's story illustrates. Her voices emerge in response to escalating anxiety; that is, they appear to have a mood-congruent basis. Recent studies have suggested that it is not unusual for auditory verbal hallucinations to be induced by anxiety or depression, and this has also been the case historically. Throughout much of the 19th century, it was widely recognised that 'hallucinations of hearing' (as it was then referred to) manifested in a range of different mental states, and were often triggered by anxious or depressed mood. Following on from this, *Emily's Voices* contributes a crucial embodied perspective to existing challenges to dominant psychiatric nosology.

Emily's Voices can also be read as a manifesto for change. Knoll's narrative shows that a more flexible, person-centred approach to voice-hearing is urgently needed. Moreover, there is little evidence from Knoll's experience that receiving a psychiatric diagnosis (or several) is central, or even helpful, to her recovery; on the contrary, it reinforces her existing fears that she is 'crazy'. The various tools that enable Knoll to rebuild a life that is meaningful to her are not contingent upon a specific diagnosis. Making peace with her voices (however fraught that peace might be at times) becomes possible through interpersonal support, talking therapy and, perhaps most importantly, turning a difficult and traumatic experience into a resource, a form of expertise, through her work as a researcher into voice-hearing. This chimes with Callard and Bracken's suggestion that 'psychiatric diagnosis is not fundamental to the enablement of people with mental illness', but rather that the strategies that have held the most benefit for patients 'have not been diagnosis specific'.

In sum, *Emily's Voices* is a timely and important contribution to recent approaches to voice-hearing that seek to normalise this phenomenon and understand it at the level of lived experience, as well as to current debates about diagnosis in psychiatry and its relationships with therapeutic interventions, selfhood, stigma and shame. It is a moving story, and above all a courageous one, and I would recommend it to anyone with an interest in voice-hearing, whether that interest is professional or personal, or both.

1.4.10 Psychological aspects of wound management following self-harm on psychiatric wards

Alla Rubitel

date

2019-4

Contents

- *Psychological aspects of wound management following self-harm on psychiatric wards*

I note with interest the initiative by Buick *et al* to evaluate a peer-led workshop on suturing skills for doctors working in psychiatric hospitals.¹

The authors describe improved confidence of doctors with regards to suturing, associated with a reduction in transfers to accident and emergency (A&E) departments and a significant potential cost saving (calculated at £183.76 for each transfer that is avoided). It would be interesting to learn whether the intervention was associated with any change in the frequency of self-harm on the psychiatric wards.

Albert *et al* make important comments on the benefits for doctors in continuing to apply their basic medical skills in this context, and point to a cognitive–analytic model to describe role reciprocity in the case of self-harming patients having interventions for their wounds. It would be interesting to investigate further how in-house physical treatment may differ from A&E treatment concerning rescuer-to-rescued roles and reinforcement.

I would like to suggest that the decision to provide physical treatments (including suturing) – or the decision not to do so – will have an effect on the overall treating relationship and treatment frame.

What does it mean for a patient who expresses distress or hostility through cutting, when the doctor tasked with treating their psychological difficulties also becomes involved in the physically intimate act of suturing their body? How are the doctor's own emotional responses towards the patient's self-harm and the subsequent restorative procedure registered and managed when the doctor either performs the procedure directly, or sends the patient to A&E?

Perhaps these complex emotional factors could also be worked out in peer groups – in particular through Balint or other psychological case-based discussion groups.

1.4.11 Cairns Aitken, CBE, MD, FRCPE, FRCPsych

Bruce Ritson

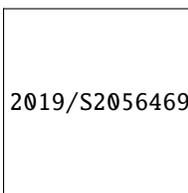

date

2019-4

Contents

- *Cairns Aitken, CBE, MD, FRCPE, FRCPsych*

Emeritus Professor of Rehabilitation Studies, Edinburgh University Medical School, UK

Cairns Aitken, who died of pulmonary fibrosis on 12 March 2018 at age 84, had a distinguished career as a Scottish psychiatrist and had many prominent roles in management within Scottish universities and the health service. Perhaps his major achievement was when, as Chair of the Royal Infirmity Trust, he masterminded the move of the Royal Infirmity of Edinburgh from its historic site in the city centre to its new building, on the periphery of the city, in Little France. This involved negotiating the rebuilding contract via the private finance initiative. He recognised the importance of clinicians' involvement in management at a time when many were wary of its inevitable conflicts and disputes. When Cairns encountered a challenge, he would always face it head-on and not shrink from difficult or unpopular decisions; he would identify a goal and then form a project team of skilled experts around him who would all work together to overcome obstacles and succeed.

Cairns held a number of other major positions. From 1984 to 1987 he was Chairman of the British Broadcasting Corporation Scottish Medical Advisory Board, and from 1991 to 1996 he was a member of the General Medical Council. He was appointed to the Human Genetics Advisory Commission in 1996. This public body was created to report on new developments in human genetics, and the consequences thereof, in relation to public health, insurance, patents and employment, and to advise on ways to build public confidence in – and understanding of – these developments.

In addition to all of Cairns' clinical and academic work, he became Chairman of the Council of Napier College and helped steer it from being a local college to becoming a national polytechnic and finally the renowned university it is today. This transition was an enormous achievement involving hours of painstaking negotiations. In 1990 he was made a Fellow of Napier University.

Many would have felt such an achievement was sufficient but Cairns then threw himself into a series of challenging projects, first as Vice Dean and then as Dean of the Faculty of Medicine from 1988 to 1991. Finally, he was appointed Vice Principal of Edinburgh University and was responsible for planning and budgeting at what was an exceptionally challenging time. He thus played a major part in forming the foundations of the University as it is today. He was a director of the Lothian Health Board from 1991 to 1993, which led to his role in the re-siting of the Royal Infirmity.

Cairns was born on 20 December 1933, an only child. His father was a qualified accountant, but his parents ran a hotel in Dunoon. Cairns attended Dunoon Grammar School before going to board, first at Cargilfield in Edinburgh and then at Sedbergh School in Yorkshire. He went on to study medicine at Glasgow University. While he was a medical student his mother died of severe asthma. He vividly recalled the stress and worry caused when she had severe breathless attacks. This had a profound effect on him and he felt the experience influenced his career choice and clinical outlook throughout his life.

Early exposure to psychiatry came from a chance meeting with a fellow medical student who told Cairns about free lodgings if you helped as a student at the Gartnavel Royal Mental Hospital. He described how, for 2 years, he enjoyed free accommodation, meals and an introduction to the fascinating challenges of a traditional psychiatric hospital.

Qualifying as a doctor in 1957, he went as an exchange Fellow to McGill University in Montreal. He obtained a short-service commission in the Royal Air Force (1959–1962) and joined the Institute of Aviation Medicine in Farnborough. This enabled him to travel widely and develop his clinical and research interest in treating phobias of flying. During this time, he had the fascinating experience of visiting NASA in its very early days. He was part of a delegation to Washington to hear the first American astronaut, John Glenn, give his report on his return from space to President Kennedy and the nation.

Cairns completed his specialist training in psychiatry at the Maudsley Hospital in London. In 1966 he was headhunted by Professor Carstairs to return to Scotland, first as a lecturer and then senior lecturer in the department of psychiatry, and then as a consultant psychiatrist at the Royal Edinburgh Hospital. Here he continued his research into asthma and psychosomatic medicine. In 1974 he was appointed professor of rehabilitation studies in Edinburgh. This new position was designed for someone who combined an interest in disability with an understanding of the interplay of biological, psychological and social factors in motivating or frustrating recovery. To meet these objectives, Cairns recognised the importance of a team including not only nurses and medical staff but also psychologists, physiotherapists, occupational therapists, the patients themselves and their families. This biopsychosocial approach to healthcare, for which he had advocated for so long, became a practical reality.

He edited the *Journal of Psychosomatic Research* from 1979 to 1986, was President of the Society for Research in Rehabilitation from 1981 to 1983 and was President of the International College of Psychosomatic Medicine from 1989 to 1994. He was a member of the Council for Professions Supplementary to Medicine from 1983 to 1990.

After so many years of public service, Cairns was awarded a CBE in 1998. Among his other honours, he received the Order of Merit of the Polish Republic in recognition of the important and continuing links between the Edinburgh and Polish medical schools.

In retirement he pursued many interests, for example, visiting and documenting all the inhabited islands of Scotland, tracing the journeys of Bonnie Prince Charlie and visiting all the Scottish hydroelectric schemes. Each of these projects was approached with energy and scientific rigour. They involved the preparation of meticulous reports and photographs. He was a skilled photographer and many of his photographs are in the Scran collection, available to the public. In his approach to these projects one detected the passionate and meticulous way in which he set himself objectives and approached challenges throughout his career.

Cairns was very fortunate in having a family who provided love, support and infinite tolerance. He was devoted to his wife Audrey and their three children, Robin, Gail and Shona. Tragically, Shona died of a bone tumour while a student at St Andrew's University. Cairns was also very proud of his two grandsons whom he was thrilled to see gain places at Cambridge and at his own, much-loved University of Edinburgh.

1.4.13 David James, FRCPsych, FRCPS (Glasgow, Hon), DCH, DipEd, DPM

Michael Morton

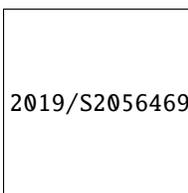

date

2019-4

Contents

- *David James, FRCPsych, FRCPS (Glasgow, Hon), DCH, DipEd, DPM*

Formerly Consultant Child Psychiatrist, Royal Hospital for Sick Children and Knightswood Clinic, Glasgow, Scotland, UK

David James, who died on 5 May 2018 at the age of 79, was one of three pioneer consultant child psychiatrists appointed in 1971 to develop a Department of Child and Family Psychiatry in the newly rebuilt Royal Hospital for Sick Children, Yorkhill, Glasgow. During higher training in psychiatry in the West Midlands, he studied the interplay of physical and mental disorder at Birmingham Children's Hospital. This expertise, together with his perspective on deprived families, was in demand in Glasgow at a time of rapid advances in paediatrics. He worked closely with the Yorkhill Renal Team to address psychosocial challenges arising in the new paediatric dialysis and transplantation service.

His work at Yorkhill laid the foundation for an award-winning paediatric liaison service, and, in 1989, his contribution to paediatrics was recognised with an honorary Fellowship of the Royal College of Physicians and Surgeons of Glasgow.

Facing pressures to base child and adolescent mental health services (CAMHS) entirely in the community, David fought hard for the continuation of a hospital psychiatric service. He became a consultant in Knightswood community CAMHS but also remained one of a small number of paediatric hospital-based psychiatrists in the UK, sustaining the Yorkhill service until a policy shift allowed the appointment of colleagues to develop a modern paediatric liaison service.

David enjoyed multidisciplinary working but was conscious of the particular responsibilities of doctors. He cherished the close relationships between paediatric specialists that grew up in the Children's Hospital. At a time when many child psychiatric teams were reluctant to use medical diagnoses, and some would not prescribe, David advocated for medical expertise, while awareness of the family and the social context of medical transactions informed his practice and prescribing. He was an early practitioner of family therapy. When faced with lack of progress, David always retained hope and when other professionals had decided that no more could be done he would continue his work with patients and their families, with some remarkable results. An enthusiastic teacher, he shared his wide experience through carefully co-authored textbook chapters.

Born in Harrogate and proud of his Yorkshire heritage, David studied medicine at Sheffield University, with house jobs at Sheffield Children's Hospital. In a year out of medicine, with teaching practice in an Approved School, he obtained a Diploma in Education and started to consider training as a child psychiatrist. After a spell in paediatrics at the Sheffield Children's Hospital, he moved back to psychiatry at Mapperley Hospital. Early in his career, as one of a Sheffield University team studying 'problem families', he co-authored a Royal College of Psychiatrists book, 'Families without Hope' (1975), which has been labelled a 'medical classic'.¹

David met Hilary, his future wife, in Nottingham. Respect for her career as an educational psychologist broadened David's expertise; he was highly knowledgeable about the effects of developmental and psychiatric disorders in the classroom. He leaves his wife, their two surviving children and four grandchildren, of whom he was very proud. His older daughter, also a doctor, pre-deceased him by three years.

'I do not consider precision in diagnosis, or even assessment, to be the main goal. I want us to remember that helping a child forward is the main goal.' Andrew West's learned lament for what has been forgotten about the primary task of child and adolescent psychiatry is required reading for anyone engaged in child mental health. Often ironic, his text puts us in the position of a child visiting a Child and Adolescent Mental Health Services (CAMHS) clinic: 'the child will be looking for some genuineness ... children are as acutely aware of bullshit as they are of condescension and they are not fooled'. Here is a doctor who sees it as his duty to identify with his patient: 'I know what it feels like to be misunderstood,' says Andrew, taking the further step to see 'that it may not be in [the child's] greater interests to be free of this particular symptom'. That symptoms have functions is a sophisticated perspective, encouraging the clinician not to hurry too quickly to remove them.

Andrew cites the great paediatrician-turned-psychoanalyst Donald Winnicott's view that it is necessary to 'contain the conflicts ... rather than anxiously looking around for a cure' (p. 2).¹ In that spirit – though it may only be for a short time – the psychiatrist offers himself as a 'powerful therapeutic companion' who is 'able to slow time down and actually enable treatment to take place'. This creative encounter is not likely when the clinical service has a very limited number of answers. 'A parent says, "I want my child to behave better," and the clinician says, "this is ADHD; I suggest that you attend a parenting group and I can prescribe medication for your child"'. It is reminiscent of a conversation between two deaf people along the lines of, "are you thirsty? No, it's Friday".

Since diagnostic psychiatry became the dominant mode around three decades ago, too little attention has been paid

to consultative skills in the profession. Andrew West proposes an ethical practice for modern child and adolescent psychiatrists, placing particular emphasis on the initial assessment and on the ‘saying goodbye’, both of which can be powerfully therapeutic in themselves, whatever other clinical intervention may be provided. Dr West obliges us to see the experience from the patient’s and family’s point of view, where ‘treatment’ is not just what is ordered after an assessment but something that ‘begins at the point that the service accepts the referral’. A beautifully written, highly intelligent and inspiring book.

1.4.14 Naomi Richman, BM, FRCPsych

Philip Graham

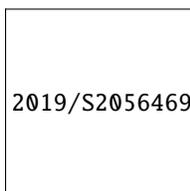

date

2019-4

Contents

- *Naomi Richman, BM, FRCPsych*

Formerly Reader, Institute of Child Health, and Honorary Consultant Child Psychiatrist, Hospital for Sick Children, Great Ormond Street, UK.

Naomi Richman, who died recently at the age of 84, carried out pioneering studies on the prevalence of emotional and behaviour disorders in pre-school children in the 1970s and 1980s. She was the first author of a monograph published in 1982 *Preschool to School: A Behavioural Study*¹. A review of this book began by quoting John Ruskin: ‘All books are divisible into two classes: books of the hour and books of all time’. There was no doubt into which category this monograph belonged, nor would her two co-authors – Jim Stevenson and I – have been in any doubt that she was the inspiration behind the study.

The study was carried out while Naomi was based at the Hospital for Sick Children, Great Ormond Street, and then at the Institute of Child Health, London. It involved more than 700 3-year-old children living in Waltham Forest. First, it demonstrated that it was feasible to produce criteria for a ‘case’ in pre-school children. This was achieved by the development of the Behaviour Screening Questionnaire, the first specifically designed for pre-school children. It allowed the calculation of the high prevalence of behaviour disorders in this age group: around 7% for moderate and severe problems. Further, by following children up to 8 years old, she and Jim Stevenson were able to show that, contrary to the then-current popular belief, behaviour problems in pre-school children and the language delay often associated with them were not transient and part of normal development, but often persisted at least well into the primary school years.

This study was the first (although many were later carried out by other researchers) that examined the stresses leading to behaviour problems in very young children. A particular set of problems related to bringing up young children in tower blocks, and much of the concern for family life in such buildings first arose from studies in which Naomi played a leading part. With Jo Douglas, she went on to develop behavioural methods of dealing with sleep problems in early childhood. These were evaluated using controlled designs and found to stand up to rigorous testing. Naomi and Jo published a best-selling Penguin book *My Child Won't Sleep*, which described their techniques, and then ran training workshops for health visitors, enabling them to apply this management approach.

In 1989, Naomi went to work for the Mozambique Ministry of Education, first on sabbatical leave and then full time, on a Swedish Save the Children Fund programme aimed at helping children traumatised by the civil war that was then raging in that country. She developed training programmes for teachers working in areas where large numbers of children had been in direct contact with war and violence. From her experiences in Mozambique, she developed her ideas regarding principles to help children involved in organised violence.

Naomi also worked in Angola (with Pam Zinkin and Nazeen Kanji), Central America, the occupied territories and South East Asia, organising training programmes for children similarly exposed to violence. She was strongly critical of medical approaches to so-called post-traumatic stress disorder. She saw this as an often inappropriately applied diagnosis that implied a psychiatric condition needing specialist therapy, without regard to the frequently ongoing nature of traumas and the ways culture influenced community attitudes towards them. Instead, in her influential articles and manuals, she emphasised the need for traumatised children to be reintegrated into their families and given appropriate education.

In 1996 after returning to the UK, Naomi carried out a comprehensive study of the psychosocial needs of Kurdish, Somali and Vietnamese refugee children and families in Hackney, London. Out of this work, she wrote a guide for professional workers entitled *In the Midst of the Whirlwind: Manual for Helping Refugee Children*.

Naomi was born and brought up in Leeds. Her father, Louis (a shopkeeper), and her mother, Gertrude (Gerti), were second-generation Jewish immigrants from Eastern Europe. She won a place at the local grammar school, Roundhay High School, and from there she went on to read medicine at St. Hilda's College, Oxford. After clinical training at the Middlesex Hospital Medical School, she did house jobs, one of them with the paediatrician Dermod McCarthy who insisted that parents of children in hospital should, contrary to the then-current practice, be allowed to visit at all times of the day.

Her psychiatric training was undertaken at the Maudsley Hospital between 1961 and 1964. After leaving the Maudsley, she spent some years in the USA, some of the time as a research fellow on a course in the epidemiology of mental handicap, which was run by Zena Stein at Columbia University Medical School, New York.

Naomi was active politically throughout her life, both as a left-winger and as a feminist. In 1980 she was one of a small group of women doctors who founded the organisation 'Women in Medicine' to combat patriarchal attitudes in the profession and to assist medical women in their careers. She remained highly active in this group until it disbanded in 2002.

She was a woman of wide interests with strong political views, feisty in her support for the underprivileged. A talented artist, she was also a keen and knowledgeable birdwatcher, gardener, theatregoer, swimmer in the Highgate Women's Pond and loyal friend to many. She did not have a family of her own, but developed very close, supportive relationships with her niece, Rachel, and nephew, David. In her later years she suffered from Alzheimer's disease. Not always an easy person, in her last years she became an altogether sunnier, more relaxed personality. Naomi died on 16 June 2018 and is survived by her niece, two nephews and three great-nephews.

1.4.15 Sutures benefit not only wounds

Ann Maria Albert Karel Wildschut Marinos Chatzopoulos Johanna Selway

date

2019-4

Contents

- *Sutures benefit not only wounds*
 - *Reputation*
 - *Self-esteem*
 - *Costs to other patients*
 - *Stigma*
 - *Perpetuation of self-harm behaviour*
 - *Mental health trusts' view*
 - *The way forward*

We compliment Buick and colleagues¹ for their innovative venture. We want to stress that the benefits of in-house management of minor wounds are far more than financial.

Reputation

Many foundation year, general practitioner and psychiatry core trainees go to psychiatry after doing their surgery and Accident & Emergency (A&E) posts, where they would have managed many wounds with glue, staples and sutures. However, while in psychiatry, they are 'duty-bound' to refer patients with self-inflicted superficial wounds to the A&E. This arrangement would make the A&E staff and others wonder why junior doctors relinquish this role when moving to psychiatry, especially if a few months earlier this had been part of their day-to-day role.

Self-esteem

When junior doctors who are skilled in the management of superficial wounds are forced by mental health trusts to refer patients with superficial wounds to the A&E department, many junior doctors will wonder why they are no longer being seen as suitable and competent enough to carry out this procedure.

Costs to other patients

Most psychiatric in-patient wards are understaffed. Buick and colleagues estimated the nursing costs under the presumption that only one nurse would go to A&E with the patient. Often, two or more nurses would have to accompany the patient to manage risks, including that of absconding. Nurses taking patients to the A&E for management of superficial wounds would result in less staff on the ward and less nursing care for those patients who do not self-harm.

Stigma

Taking every patient with superficial wounds to A&E would perpetuate the stigma about mental illness, mental health patients, services and staff.

Perpetuation of self-harm behaviour

At least for some patients who self-harm, being the centre of attention, and being taken to the A&E by ambulance and accompanied by one or more nurses is likely to perpetuate their self-harm behaviour.

The psychological dimensions of self-harm behaviour can be complicated. The cognitive analytic model offers an understanding of how relationship roles might play out in self-harm, whether self-to-self or self-to-other.

For some patients, self-harm can elicit unhelpful, reinforcing reciprocal roles and procedures, which may seem obvious if judged at face value only. Continuing to enact these roles may delay the adoption of more sustainable and healthy ways of dealing with distress. Being accompanied to A&E by caring professionals and receiving restorative care and attention there – while appropriate and wholesomely good – might feel rewarding. It has the potential to evoke a rescuer-to-rescued reciprocal role, or perhaps a caring-to-cared for role, but at substantial personal cost.²⁻⁴

For many patients, the same situation can indeed feel disempowering and punishing when they are not given a choice in how we care for them in the aftermath of self-harm. The National Institute for Health and Care Excellence emphasises the need for people to be fully involved with decision-making about their treatment and care.⁵

In the same context, it is possible for the patient to experience a more direct reward. If the social reinforcement of self-harm is rewarding enough, the individual may inflict more severe pain in order to continue receiving that positive reinforcement from their environment.⁶

Mental health trusts' view

Often, mental health trusts object to junior doctors managing superficial wounds based on unsubstantiated arguments, e.g.: •how do we prove that the junior doctor is competent?•what will happen if patients complain about scars?•how do we ensure that the equipment is of the required standard?•If they do so, both the trainee and the consultant need to be very clear that they are doing this outside any Trust governance structures and under their own assessment of the risks and consequences. There are no supporting Trust policies or guidance for this. It is a minefield for litigation.

The way forward

It would be helpful for the College to take a stand and advise the mental health trusts about the minimum services that need to be provided, to ensure that junior doctors have the necessary skills and enable them to provide the services that they are competent to deliver.

1.4.16 Effects of suicide on psychiatry trainees

Marilia Calcia Alice Debelle

date

2019-8

Contents

- *Effects of suicide on psychiatry trainees*

We read with interest the survey by Gibbons *et al*¹ and welcomed the idea of examining what kind of support may help clinicians deal with this difficult aspect of mental health practice.

It is interesting to note how some responses to the survey indicated that having experienced a patient suicide as a trainee had a significant influence on the responder's choice of subspecialty. This finding highlights how junior doctors, whether in a formal training programme or not, are particularly vulnerable to the adverse effects of a patient suicide, with potential effects on recruitment and retention in psychiatry.

In our mental health trust in South East London, trainee-led initiatives in collaboration with the postgraduate training department have been making changes to the learning and support offered to junior doctors who are involved in a serious incident investigation in the past 5 years.² The projects involve annual events to promote knowledge and discussion about quality and safety; discussions about the process of serious incident investigations and the support available at each junior doctor induction; and the development of a written resource on formal and informal sources of support for junior doctors involved in a serious incident investigation. These projects are under constant review in order to respond to trainee feedback.

We thank the authors for the valuable work exploring how suicide can affect doctors of any grade. We hope that mental health trusts and postgraduate training departments continue working to develop formal and informal support structures for doctors experiencing this difficult event.

Lynne Jones has spent much of the last two decades setting up and running mental health programmes in places devastated by natural disasters and wars. Jones is a child psychiatrist, who began her career in the Allinton Psychiatric Hospital, the former Allinton Asylum. From the off, she cared more about pragmatic pacifism and 'doing the right thing', which included a commitment to living by her values of public service and altruism. She has a CV 'full of gaps': when she was at Greenham Common, Bosnia, on the Somali border in Ethiopia, in Kosovo, Ethiopia, Haiti, Tacloban, and many other places where bombs have fallen or tsunami have washed away communities. Jones says her mother thinks she is on 'an extended gap year'.

Her memoir has been compared to the writing of Oliver Sacks, which I think does them both a disservice. Jones' style and approach are different to Sack's pen portraits of neurological conundrum, although she does interlace clinical stories through her accounts. Her reminiscences of being with asylum patients on the dance floor evoke the recent work of Dr Charlie Howard, whose Music and Change project engages with teenage gangs at street level, co-producing models of care delivery.

Professionally, there is much to admire here, not least Jones' commitment to academic rigor despite being far from university departments. For instance, she describes staying on in Bosnia for an additional year after her contract had

ended to study the effects of war on children. Her contributions to the intellectual, cultural and academic life in the countries she is sent to are similarly admirably. These exchanges are two-way: by spending time with communities and by listening to young people, Jones provides solutions that work for them and their families. She wears diverse theoretical cloaks lightly, using combinations of systemic family therapy, medication, group therapy and supportive counselling. Her stance is pragmatic, for example commencing a young man on medication earlier than she would like so that she can monitor the effects before her likely evacuation from the country.

Jones writes without bitterness or naïvety, recognising that, as a humanitarian worker, she is sometimes a pawn in political game, for example when she is part of a wider evacuation of international aid workers and has to say hurried farewells to unwell patients and local colleagues. There must surely have been times when Jones was fatigued, professionally isolated, personally lonely. We don't hear about it. But though she is stoic, she is also angry, especially about the pseudoscience that underpins the trauma industry and the resultant thoughtless 'quick-fixes' from many who ought to know better.

The atrocities she describes are apocalyptic in both scale and terror. In them, she endures personal hardships: living without running water, without electricity, yet aware of her privileged status, her passport, her choice to be there, her safe home in the UK. Jones is repeatedly drawn back to disaster scenes, not because of their horrors, but because, 'I hope,' she says, 'that some [of their courage] will rub off on me'. In retelling these stories from her long humanitarian career, she passes some of that courage to her readers. Her beautifully weft stories of a lone psychiatrist bearing children's unbearable burdens are beacons of hope to their bomb-shattered childhoods and to our broken world.

In 2014, Jones and I were coincidentally participants on a memoir writing course run by the Guardian Newspaper. We have not remained in contact and she does not know I have read her book.

1.4.17 The Islamic faith and best interests

Jessica Two Martin Curtice

Correspondence

Dr Martin Curtice

(mjrc68@doctors.org.uk)

date

2019-8

Abstract

This article reviews a 2017 Court of Protection case which assessed and decided issues relating to the Islamic faith and the Mental Capacity Act 2005. The case involved a 39-year-old Muslim man with learning difficulties. It centred on his ability to make decisions about two specific aspects of his faith – capacity for fasting and for the removal of pubic and axillary hair. The judgment describes how s.4 of the Act was applied in deciding these decisions under the doctrine of best interests. In doing so, it elucidates key principles which can be applied to similar cases of this and other faiths.

Declaration of interest

None.

 - *Was it in IH's best interests for his pubic and axillary hair to be trimmed?*
 - *Conclusions of the court*
 - *Discussion*

This article reviews the Court of Protection judgment *IH (Observance of Muslim Practice)* [2017].¹ The case involved a 39-year-old man, IH. It was an influential case as it considered the observance of Muslim custom and practice in patients who lack capacity under the Mental Capacity Act 2005² (MCA) and Islamic law. In reviewing the case, this article aims to bring out salient principles that may be of assistance to clinicians and services that have a responsibility for Muslim adults who lack capacity.

Background to the case

IH suffered from a profound learning disability, with the intellectual developmental level of a 1–3-year-old, and had a diagnosis of atypical autism. For the first 35 years of his life he resided in his family home, where he was principally cared for by his father, TH. IH was born in Pakistan but had lived in West Yorkshire all his life. His family, devout Sunni Muslims, engaged in all daily activities associated with the Five Pillars of Islam – faith, prayer, charity, fasting, and pilgrimage – as well as fasting during Ramadan and celebrating Eid (the Five Pillars being the foundation of Muslim life and regarded as obligatory for Muslims). While at home, IH would participate in some of these religious practices as he was able. This included daily prayers and, earlier in his life, attending Mosque, although he eventually stopped attending as his behaviour was occasionally disruptive to others. TH, being a devout Muslim, was motivated to ensure his son was supported, as was practical, to adhere as closely as possible to the Five Pillars of Islam.

Despite increased levels of support for the family, IH eventually moved into supported housing provided by the Local Authority. He required 2:1 support 24 hours a day, and was dependent on carers for all aspects of his care. His family visited regularly and he returned to the family home three times per week. IH experienced regular periods of agitation, which could occur ‘dramatically and without warning’. During these periods of agitation, which could be prolonged, IH had a tendency to kick, bite, punch, and/or spit at his carers, who had sustained injuries as a result.

The court was asked to consider two questions: 1) whether it was in IH's best interests to fast during the daylight hours of Ramadan; and 2) whether it was in his best interests for his axillary and pubic hair to be trimmed.

The position of the parties involved in the application

TH contended that the removal of IH's pubic and axillary hair was a compulsory activity stipulated under Islamic law, and hence there was a 'religious duty' to observe this (albeit he modified this stance following expert evidence as below). His father used to shave his son when he was at home and in the first year when he moved into accommodation. TH held the view that having his son's pubic hair shaved was IH's 'right' and something he would have chosen to do himself had he the requisite capacity to do so. IH was provided with Halal food to eat and celebrated Eid with his family, but he had never been expected to fast during Ramadan as it was recognised that he would not understand the purpose of food and drink being withheld during daylight hours and that this might have caused him distress.

The local authority's position was that it recognised the importance of facilitating the religious observances of an individual, even those who lacked capacity. It was agreed that staff members would carry out the hair removal process every two weeks, although in actuality this did not happen, and IH had not had his pubic or axillary hair shaved for three years and never by his carers.

IH's social worker, herself a Muslim, expressed the view that Islam was a significant part of IH's identity and 'something of which he should be proud', and that 'the observance of religious practices should be supported where possible to allow a person to continue to associate with their identity, background, culture and beliefs'. IH's main carer did not believe trimming of IH's pubic and axillary hair to be in his best interests, but the Team Manager of the Community Team for Learning Disabilities considered that, 'on a fine balance', it was.

While the court accepted that it was important to support the religious practices of IH, it concluded that the social worker 'had significantly misunderstood IH's capacity to understand and reflect the concepts associated with the religion' and that IH 'has *no* understanding of the concept of Islam ... he has *no* capacity to feel 'proud' of his religious heritage; nor is he able to actively 'associate with' an identity or culture ...'.

Capacity for fasting

There was no dispute among the parties that, according to the MCA, IH lacked capacity to make decisions regarding fasting during Ramadan. In relation to fasting, the judgment laid out six specific criteria that a person would be expected to understand in order to have capacity in this regard (*Box 1*). It was agreed that IH was not able to understand any of the six points listed, and that in view of the nature of his disability he would never acquire capacity to make these decisions and hence lacked capacity to make this decision. *Box 1* Specifies a person should be able to understand when making decisions regarding fasting. 1. What fasting is; the lack of food and liquid, eating and drinking. 2. The length of the fast. 3. If for religion, for custom (family or otherwise), for health-associated reasons or for other reasons. 4. If for religion reasons, which religion and why. 5. The effect of fasting on the body. 6. What the consequences would be of making a choice to fast and the risks of choosing to not fast or of postponing the decision.

Capacity for removal of pubic and axillary hair

The specific aspects that a person would be expected to understand in order to have capacity to make decisions in regards to the trimming or removal of hair for religious or cultural reasons were elucidated by the court (*Box 2*). It was again agreed by all parties that IH did not have, and would never acquire, capacity in this regard. *Box 2* Specifies a person should be able to understand when making decisions regarding removal of hair for religious or cultural reasons. 1. Which parts of the hair are being removed – pubic, axillary, perianal, trunk, beard, leg, torso or head. 2. Whether the reason for the hair trimming/removal is religious, for the maintenance of good hygiene, custom or some other. 3. If for a religious reason, which religion and why. 4. What the consequences would be of making a choice to have hair trimmed/removed, and of not trimming/removing the hair.

Requirements of the Islamic faith for those lacking capacity

When considering the degree to which those lacking capacity are expected to adhere to the Five Pillars of Islam, the court consulted Dr Ali, lecturer in Arabic and Islamic Studies at Cardiff University. Dr Ali advised that while certain actions under Islamic law are obligatory, allowances are made for those that are deemed to lack ‘legal competence’. This term was defined as ‘a capacity or a potential for mental functioning, required in a decision-specific manner, to understand and carry out decision-making.’ As with capacity under the MCA, capacity under Islamic law is always initially presumed to be present. A person can only be declared to be ‘legally incompetent’ by a court, following evidence from medical practitioners or experts in legal competence, whose opinions under Islamic law would be deemed ‘legitimate and authoritative’. A legally incompetent person (as well as terminally ill people, disabled people and minors) is deemed to be in a heightened state of spirituality and as such is exempt from adhering to many of the major rituals of Islam. All parties agreed that IH could be declared legally incompetent under Islamic law.

While fasting during the daylight hours of Ramadan is an obligatory custom for all legally competent Muslims, certain groups are exempt from fasting. These include minors, pregnant women, those who are travelling, the ill, and the incapacitous. Given that IH had been declared ‘legally incompetent’ under Islamic law, it was agreed that he met these exemption criteria and as such would not be expected to fast.

The holy book of Islam, the Qur’an, advises Muslims to uphold high standards of personal hygiene and to be ritually clean. As well as Quranic verses, there are teachings from Hadiths (traditions or sayings of the Prophet Muhammad revered as a major source of religious law and moral guidance second only to the authority of the Qur’an) advising Muslims as to the rulings of personal grooming. Under Islamic law, the cleaning of pubic or axillary hair is a religiously sanctioned practice deemed to be a normal human right (‘fitrah’) related to a pursuit for ritual purity and cleanliness. The removal of pubic and axillary hair is a recommended practice (‘mustahab’) but is not obligatory. While it would not be acceptable for a Muslim to expose his genitals, it is permissible for a Muslim who requires assistance with his care to have carers clean or shave his genitals. However, the removal of pubic and axillary hair is not a recommended practice for those that lack ‘legal competence’ and there is no suggestion that Islamic law requires IH’s carers to carry out hair removal on his behalf or that his religious rights are being violated by their not doing so.

Best interests decision-making

In determining what was in IH’s best interests in relation to fasting during Ramadan and removal of his axillary and pubic hair, the court analysed Section 4 MCA – Best interests. This stipulates that, as far as is ‘reasonably ascertainable’, IH’s past and present wishes and feelings (s.4(6)(a)), the beliefs that are likely to have influenced his decision had he had capacity (s.4(6)(b)), and the wishes of his family (s.4(7)(b)) should be taken into account. Explicit reference was made to the seminal Supreme Court judgment in *Aintree University Hospitals NHS Trust v James* [2013]3, which opined that any best interests test ‘should also contain a strong element of “substituted judgement”’, meaning that the person making the decision should place great emphasis on what the person is likely to have done had they had capacity to make the decision for themselves. However, while an important component, substituted judgement is not the entirety of a best interests decision. The Supreme Court further stated ‘The purpose of the best interests test is to consider matters from the patient’s point of view. That is not to say his wishes must prevail, any more than those of a fully capable patient must prevail. We cannot always have what we want. Nor will it always be possible to ascertain what an incapable patient’s wishes are’.

Was it in IH's best interests to fast during Ramadan?

All parties agreed that IH would not be able to understand the purpose of withholding food or fluids from him during the daylight hours of Ramadan, and that to do so may cause him significant distress. There were also concerns that fasting might lead to mild dehydration, which could amplify side-effects of medication. The court concluded that it was not in IH's best interests to fast during Ramadan and granted a declaration that he should be relieved of this obligation.

Was it in IH's best interests for his pubic and axillary hair to be trimmed?

The court noted that the local authority caring for IH had an obligation to 'create a care environment and routine which is supportive of the religion' of any person under their care and 'to facilitate the person's access to, or observance of religious custom and ritual'. The court cited the provision of IH with a Halal diet, despite him having no understanding of the fact that the food he was provided with was Halal and no understanding of the significance of a Halal diet, as an example of the local authority recognising the need to respect IH's religion. However, in regards to the custom of shaving of IH's pubic and axillary hair, the court concluded that there was no obligation on the local authority to ensure that this religious custom was observed. The court's best interests reasoning on this is described in *Box 3*. *Box 3*Text from the judgment in reaching the conclusion that it was not in IH's best interests for his pubic and axillary hair to be trimmed 'In short . . . there is simply no religious duty, or obligation on a person who lacks capacity ('legal competence' in Islam) to trim or shave his or her pubic and axillary hair, or on his carer to do so for them. IH does not need to acquire this state of ritual cleanliness in order to derive spiritual benefit as he already occupies an elevated status by virtue of his incapacity. Moreover, I am satisfied that IH himself derives no religious 'benefit' by having the procedure undertaken, as he would not understand its religious significance. It is of no consequence to me, in the consideration of these facts, that the carers may be blessed in the eyes of Islam in undertaking a 'praiseworthy' activity by trimming the hair; their interests are not my concern.' 'I agree with TH . . . that if IH had capacity he probably would have observed this custom. . . . It would have been entirely consistent with the religious and cultural norm within his home and community. . . . However, this factor carries little weight in my overall reckoning given that in progressive Islamic religious teaching, as an incapacitous person IH is exempt from observing the Islam rituals because he is already on a heightened state of spirituality.'

This assessment also considered in depth the practical intricacies of staff attempting such a procedure under the best interests doctrine. The court was concerned that even if IH was cooperative, the procedure was likely to be anxiety-inducing and distressing for him, which could heighten his propensity to agitation and aggression. The court acknowledged that, while IH did not 'have any sense of personal modesty', the nature of such a procedure incurred 'compromises to the preservation of dignity'.

Conclusions of the court

The court concluded that it was not in IH's best interests to (1) fast during Ramadan, or (2) to have his pubic and axillary hair shaved in accordance with Islamic custom. The balancing act contained within the best interests assessment was eloquently described by the presiding judge as: "I have faithfully endeavoured to consider these issues from IH's point of view, while ultimately applying a best interests evaluation. IH has a life-long developmental condition and has never had the capacity to understand the tenets of Islam; the benefits of adherence to such rituals do not obtain for him, but for others. The fact is that by reason of his disability IH is absolved of the expectation of performing this recommended procedure, and there is no other clear benefit to him. The trimming of the pubic and axillary hair would serve no other purpose. I am anxious that IH should be spared additional stresses in his life, and wish to protect him and the staff from the risk of harm – an approach which itself has the endorsement of Islamic teaching'."

Discussion

The judgment included consideration of Islamic bioethics in its decision-making and specifically that ‘No hurt no harm’ was a cardinal principle of this approach. The judgment opined that it would be wrong to create a situation whereby observance of Islamic custom could or would cause harm to the person or their carers. Islamic bioethics is an extension of Shariah (Islamic Law) and is intimately linked to the broad ethical teachings of the Qur’an.⁴ It teaches that the patient must be treated with respect and compassion, and that the physical, mental and spiritual dimensions of the illness experience should be taken into account. The principlist approach to biomedical ethics⁵ as a culturally sensitive approach is broadly accepted and has been discussed among Muslim scholars.⁶ The four general principles of this are: (1) respect for autonomy, (2) beneficence, (3) non-maleficence, and (4) justice. Justice is often regarded as being synonymous with fairness – it can be seen as the moral obligation to act on the basis of fair adjudication between competing claims.⁴ Gillon⁷ subdivided the obligations of justice into: (1) fair distribution of scarce resources (distributive justice); (2) respect for people’s rights (rights based justice); and (3) respect for morally acceptable laws (legal justice). In this way, it can be seen that the MCA and the doctrine of best interests can readily be applied to individuals of the Islamic faith, and that Islamic bioethics underpins such an approach. Other legal cases involving various aspects of the Islamic faith include adoption,⁸ child care orders and immunisations,⁹ capacity to marry,¹⁰ capacity to marry and to have sexual relations^{11,12} and circumcision of a child.¹³

While this case centred on the Islamic faith, a similar approach can be taken in best interests cases for people of all faiths. Where needed, obtaining clarity from experts within a particular faith will be vital. Also, systematically applying the whole MCA rubric for s.4 Best interests decisions is of course paramount – the best interests checklist as advised by the MCA Code of Practice¹⁴ (Para 5.32) being vital for this. Within this assessment, it is important to establish a person’s reasonably ascertainable past and present wishes and feelings, and the beliefs and values that would be likely to influence their decision if they had capacity (s.4(6)). Similarly, where practicable and appropriate, it is important to gain the views of significant others as to the decisions at hand (s.4(7)). While such collateral history can be invaluable, the intricacies of balancing and weighing such information can be complex, as was seen in a case involving the potential cessation of clinically assisted nutrition and hydration from an elderly Christian man with end-stage dementia.¹⁵ In needing to obtain history from the family for this best interests decision, the court noted that it was ‘important that the strength and conviction of their views is not allowed to detract from a steady appreciation of the welfare of the individual concerned’.

There has been a rapidly developing body of best interests case law in recent years emanating from the Court of Protection. This has included cases involving best interests decisions containing a significant religious or faith-based element (*Box 4*). The case of *Re BM*¹⁷ suggested an approach to the weighing up or balancing of elements within best interests decision-making. This approach, which could be applied as part of a balance sheet approach or used as free-standing, involved identifying ‘the factor of magnetic importance’ – this factor being the one that tips the balance and determines the eventual outcome. Although not finally accepted by the judge, counsel had proposed that it was BM’s ‘very deep faith’ that was the magnetic factor in his case. *Box 4* Examples of best interests cases involving a religious or faith-based element 1. *Sandwell Metropolitan Borough Council v RG & Ors* [2013]¹⁶ – annulment of a marriage for a Sikh man with a learning disability. 2. *BM, Re* [2014]¹⁷ – the appointment of a deputy for property and financial affairs in a man of Christian faith who suffered an extensive cerebrovascular accident. 3. *The London Borough of Tower Hamlets v TB & Anor* [2014]¹⁸ – the assessment of where to live and capacity to consent to relations for a married Bangladeshi woman with moderate learning disabilities. 4. *P, Re (capacity to tithe inheritance)* [2014]¹⁹ – the capacity of a man with a chronic schizoaffective disorder to make a ‘tithe’ donation of 10% of an inheritance to a church. 5. *Wye Valley NHS Trust v B* [2015]²⁰ – the potential amputation of a foot in a man with chronic schizophrenia in whom religious delusions and auditory hallucinations had become so entrenched as to become an ‘intrinsic part of who he is’. This case has arguably been at the forefront of a sea change in how courts apportion weight to a person’s views and beliefs as part of any best interests assessment. 6. *N, Re* [2015]²¹ – the determination of whether it was in the best interests for a Jewish woman with multiple sclerosis and in a minimally conscious state to continue to receive life-sustaining treatment by means of clinically assisted nutrition and hydration (CANH). *The above judgments, and all within this article, can be found via www.bailii.org

The Law Commission review of Mental Capacity and Deprivation of Liberty law²² has recommended a legislative addition to s.4(6) MCA such that decision makers should ‘give particular weight to any wishes or feelings ascertained’. The Government response²³ has accepted that this recommendation ‘should be enshrined in law’, noting that as part of

a person-centred approach the principle of taking past and present wishes and feelings into account already represents good care practice.

1.4.18 Using Twitter to assess attitudes to schizophrenia and psychosis

Giorgianna L. Passerello James E. Hazelwood Stephen Lawrie

Correspondence

Stephen Lawrie (s.lawrie@ed.ac.uk)

date

2019-8

Abstract**Aims and method**

Schizophrenia is a psychotic disorder that is stereotypically stigmatised as untreatable and associated with violence. Several authorities have suggested that changing the name, for example to psychosis, would reduce such stigmatisation. We aimed to compare attitudes to schizophrenia and psychosis on Twitter to see if psychosis was associated with less negative attitudes. Tweets containing the terms 'schizophrenia', 'schizophrenic', 'psychosis' or 'psychotic' were collected on www.twitter.com and were captured with NCapture. On NVivo, tweets were coded into categories based on user type, tweet content, attitude and stigma type by two independent raters. We compared the content and attitudes of tweets referring to schizophrenia/schizophrenic and psychosis/psychotic.

Results

A total of 1120 tweets referring to schizophrenia/schizophrenic and 1080 referring to psychosis/psychotic were identified over two 7-day periods; 424 original tweets for schizophrenia and 416 original tweets for psychosis were included in the analysis. Psychosis was significantly more commonly included in tweets expressing negative attitudes ($n=131$, 31.5%) than schizophrenia ($n=41$, 9.7%) ($\chi^2 = 237.03$, $P < 0.0001$). Of the personal opinions or dyadic interactions, 125 (53.4%) in the psychosis data set were stigmatising, compared with 33 (24.6%) of those in the schizophrenia set ($\chi^2 = 44.65$, $P < 0.0001$).

Clinical implications

The terms psychosis/psychotic are associated with a significantly higher number of tweets with negative content than schizophrenia/schizophrenic. Together with other evidence, this suggests that changing the name of schizophrenia to psychosis will not reduce negative attitudes toward the condition.

Schizophrenia and stigma

Schizophrenia is the prototypical psychotic disorder and is characterised by the psychotic symptoms of hallucinations, delusions, disorganised speech, grossly disorganised or catatonic behaviour, and negative symptoms.¹ Typically, people with schizophrenia suffer from social or occupational dysfunction, such that only a minority will be able to live independently and obtain paid employment.² Nevertheless, around half of those with schizophrenia can be regarded as having a relatively good outcome³ and most will derive some benefit from antipsychotic medication.⁴

People with schizophrenia face a great deal of stigma, which is defined as a ‘negative attitude (based on prejudice and misinformation) that is triggered by a marker of illness’.⁵ This affects their social life, occupation, self-esteem, confidence and ability to seek help and succeed with treatment⁵. Stigma may even be ‘the main obstacle to the success of programmes to improve mental health’.⁵ For example, young people with schizophrenia are likely to delay seeking treatment because of perceived stigma and the concerns that it would harm their chances of getting jobs, they would not be taken seriously and would be seen as weak.⁶ Indeed, the way that members of healthcare teams treat patients with schizophrenia is affected by stigma; for example, in reducing the willingness and confidence of pharmacists to

provide medication counselling to people with schizophrenia.⁷ Further, people with the diagnosis of schizophrenia often stigmatise themselves in that they regard themselves negatively, and such ‘self-stigma’ is associated with poor neurocognitive function.⁸

Changing the name of schizophrenia

There has been debate as to whether renaming schizophrenia would reduce the negative attitudes expressed about people with the condition. A narrative literature review concluded that the advantages of a name change would outweigh the disadvantages and suggested that an eponym be used,⁹ although this conclusion was based largely on expert opinion. A recent systematic review found that in countries that have adopted a name change, the results have been inconclusive.¹⁰ The names changed from and to are likely to be important. For example, in Japan, what was called mind-split disease (a literal translation of the Greek origins of the word schizophrenia) was renamed integration disorder.¹⁰ Koike *et al*¹¹ found that this name change ‘had a limited effect’, whereas Aoki *et al*¹² found some improvement in reducing the frequency of reporting an association with violence.

In the English-speaking world, many authorities are beginning to abandon the use of the term schizophrenia both in clinical practice and in the academic literature, and increasingly refer to the condition as psychosis (e.g. Sami *et al*¹³). For example, the former *Schizophrenia Bulletin* recently changed title to *Schizophrenia Bulletin: The Journal of Psychoses and Related Disorders* in a bid to acknowledge the changing ideas about the diagnosis of schizophrenia.¹⁴ In 2016, van Os suggested a name changed to psychosis susceptibility syndrome and that the ICD-11 should remove schizophrenia as a term.¹⁵ The authors of the British Psychological Society’s report *Understanding Psychosis and Schizophrenia* debated whether even to use the word schizophrenia in the title of their report.¹⁶⁻¹⁷ They argued that symptoms of schizophrenia and psychosis are not necessarily mental illness, and labelling all patients who fulfil diagnostic criteria for schizophrenia as having a mental illness can be detrimental and cause more harm than good because of stereotypes and stigmatising views from patients themselves and society. They argue ‘schizophrenia is essentially an idea’ and does not explain the aetiology or likely outcome for a patient.¹⁶ The move to psychosis appears to be based on the assumption that this term will carry less of the negative connotations with severity, chronicity, untreatability and violence associated with schizophrenia. For example, it has been shown that the chances of recovery for a patient diagnosed with schizophrenia (13.5%) may be less than for those who have experienced only first-episode psychosis (38%).¹⁸⁻¹⁹ To our knowledge, this assumption of a reduction in stigma has not been tested. Therefore, we wished to examine if and how the word psychosis and the related term psychotic are used. If it was found that people talk less negatively about psychosis than schizophrenia, it would provide some support for the view that making such a change in official documents, scientific papers and clinical services would reduce stigma.

The role of social media

One way of assessing how different conditions are referred to and discussed is to examine the usage of various terms on social media. Many people use social media as an outlet for opinions and as a resource for information about mental illness.²⁰ Social media brings people from different parts of the world together for debate and discussion and the dissemination of information, and influence attitudes and health behaviour.²⁰ Twitter is a micro-blogging platform allowing users to write tweets up to 140 characters in length. On Twitter, one can access a vast amount of data in a limited amount of time, compared with other social media outlets such as Facebook and YouTube, and people’s tweets are easily accessible without a reader having an account. Previous studies have investigated how schizophrenia is discussed on Twitter, finding a significant association with negative attitudes and opinions compared with depression and diabetes.²¹⁻²² However, as far as we are aware, no study has compared how schizophrenia and psychosis are discussed.

Aims

Therefore, the primary aim of this study was to investigate the use of schizophrenia and psychosis on Twitter and compare the relative proportions of negative use of the two terms. We tested the null hypothesis that there is no difference in the stigmatisation of psychosis compared with schizophrenia on Twitter.

Method

To identify tweets for the study, Twitter's advanced search tool was used on www.twitter.com to find tweets that contained the words 'schizophrenia' or 'schizophrenic', and 'psychosis' or 'psychotic' (we henceforth refer to these as schizophrenia/c and psychosis/tic) and were captured with NCapture (NCapture for Chrome, QSR International, Victoria Australia, available for download at <https://www.qsrinternational.com/nvivo/support-overview/downloads#Download-NCapture-and-other-NVivo-add-ons>). On NVivo (NVivo 12 for Mac, QSR International, Victoria Australia, available for download at <https://www.qsrinternational.com/nvivo/support-overview/downloads#Download-NCapture-and-other-NVivo-add-ons>), using an inductive coding method suggested by Reavley and Pilkington,²¹ tweets were coded based on the degree and nature of stigma toward schizophrenia/c and psychosis/tic as well as coding for user type and tweet content. Exclusion criteria were as follows: (a) Lack of context: where the tweet was unable to be understood by the reader or the tweet was a spam tweet with no meaning behind it. (b) Non-English: where all or the majority of the tweet was not in English. (c) Repetition: where the tweet was exactly the same as another tweet in the data-set. (d) Retweet: a reposted or forwarded tweet that was originally posted by another user.

If included, each tweet was coded into three or four categories, as follows: (a) User type: individual, consumer, health professional, organisation and advocate. (b) Tweet content: personal experience of mental illness, awareness promotion, research findings, resources for consumers, advertisement, news media and personal opinion/dyadic interaction. (c) Attitude: stigmatising, personal experience of stigma, supportive, neutral and anti-stigma. (d) (If category (c) indicated stigma) Stigma type: social distancing, dangerousness, snap out of it, personal weakness, inaccurate beliefs, mocking or trivialising and self-stigma. G.L.P. and J.E.H. initially coded 100 tweets, using the categories and definitions from Reavley and Pilkington.²¹ Any tweets that were hard to categorise were discussed and resolved before J.E.H. and G.L.P. both coded 10% of the identified tweets to confirm the interrater agreement. The overall agreement was 87.6%, illustrating that the coding method had high reliability. G.L.P. then coded all tweets from two 7-day periods: 16–22 April 2017 and 21–28 September 2017. Fig. 1 Proportion of all tweets coming from each type of Twitter user.

To analyse the data, χ^2 -tests were manually calculated to compare the proportions of the different types of tweets about schizophrenia/c versus psychosis/tic. These were compared with a χ^2 table to determine the *P*-value, with a value of *P* < 0.05 deemed significant.

We did not seek ethical approval for this study as it concerns the use of previously published material in the public domain. Fig. 2 The proportion of all tweets in each 'tweet content' category. Fig. 3 The proportion of all tweets in each 'attitude' category.

Results

Examples of tweets in each category are shown in *Appendix 1*.

Inclusion and exclusion

The total number of schizophrenia/c tweets over the two 7-day periods was 1120 and the total number of psychosis/tic tweets was 1080 over the two 7-day periods. We excluded 696 (62.1%) schizophrenia tweets and 664 (61.5%) psychosis tweets from the data-set based on the criteria above, leaving 424 (37.9%) schizophrenia tweets and 416 (38.5%) psychosis tweets in the analysis.

For schizophrenia/c, 490 (70.4%) of the excluded tweets were retweets, 157 (22.6%) were repetitions, 27 (3.9%) were excluded because of lack of context and 22 (3.2%) were not in English. For psychosis/tic, 560 (84.3%) were retweets, 78 (11.7%) were repetitions, 15 (2.3%) were excluded because of lack of context and 11 (1.7%) were not in English. Fig. 4The percentage of tweets that were stigmatising within each 'tweet content' category.

User type

For schizophrenia/c, individuals ($n=188$, 44.3%) and organisations ($n=186$, 43.9%) tweeted the most. This was followed by consumers ($n=22$, 5.2%), health professionals ($n=18$, 4.2%) and mental health advocates ($n=10$, 2.4%).

For psychosis/tic, individuals tweeted the most ($n=275$, 65.9%), followed by organisations ($n=108$, 25.9%), health professionals ($n=28$, 6.7%), mental health advocates ($n=5$, 1.2%) and consumers ($n=1$, 0.2%).

Tweet content

For schizophrenia/c, the tweets were most commonly personal opinions/dyadic interactions ($n=134$, 31.5%). This was followed by research findings ($n=105$, 24.6%), experience of mental illness ($n=76$, 17.8%), awareness promotion ($n=37$, 8.7%), advertisement ($n=35$, 8.2%), news media ($n=29$, 6.8%) and resources for consumers ($n=10$, 2.3%).

For psychosis/tic, the majority of tweets were also personal opinion/dyadic interaction ($n=234$, 56.1%). This was followed by experience of mental illness ($n=59$, 14.1%), research findings ($n=49$, 11.8%), advertisement ($n=38$, 9.1%), awareness promotion ($n=20$, 4.8%), resources for consumers ($n=10$, 2.4%) and news media ($n=7$, 1.7%).

Attitude

For both schizophrenia/c and psychosis/tic most of the tweets were neutral ($n=334$, 78.6% and $n=266$, 63.9%, respectively). However, there was a significant difference in the number of stigmatising tweets: 41 (9.6%) of the schizophrenia/c tweets were stigmatising, whereas 131 (31.5%) of psychosis/tic tweets were. ²-testing revealed a significant difference with a ² value of 237.03 (1 d.f., $P < 0.0001$).

For schizophrenia/c, 35 (8.2%) were anti-stigma, 10 (2.4%) were supportive and 5 (1.2%) were recounting a personal experience of stigma. For psychosis/tic, 15 (3.6%) were anti-stigma, 2 (0.5%) were supportive and 2 (0.5%) recounted a personal experience of stigma.

When analysing the stigmatising tweets, it was found that for schizophrenia/c, 35 (85.4%) came from individuals, 5 (12.2%) came from organisations and 1 (2.4%) came from a consumer. The vast majority of the stigmatising schizophrenia/c tweets were personal opinions/dyadic interactions ($n=33$, 80.5%). Six (14.6%) were from news media and two (4.9%) were about experience of mental illness.

In the stigmatised psychosis/tic tweets, 123 (94.6%) came from individuals and 5 (3.8%) came from organisations. Mental health advocates and consumers made up the other users, each tweeting one (0.8%) of the stigmatising psychosis/tic tweets. Finally, 125 (95.4%) of the stigmatised psychosis/tic tweets were personal opinion/dyadic interaction, 3 (2.3%) were about experience of mental illness, 2 (1.5%) were advertisements and 1 (0.8%) was news media.

For schizophrenia/c, 33 (24.6%) of personal opinions/dyadic interactions were stigmatising and 6 (20.7%) of the news media tweets were stigmatising. Two (2.6%) of the schizophrenia/c tweets about experience of mental illness were stigmatising. For the other categories of tweet content, none of the tweets were stigmatising.

For psychosis/tic, 125 (53.4%) of personal opinions/dyadic interactions were stigmatising. One (14.3%) of news media tweets was stigmatising, two (5.3%) of the advertisement tweets were stigmatising and three (5.1%) of tweets about experience of mental illness were stigmatising. The other categories did not contain any stigmatising tweets. Comparing the percentage of personal opinions/dyadic interactions that were stigmatising demonstrates a statistically significant difference, with a χ^2 value of 44.65 (1 d.f., $P < 0.0001$).

Stigma type

Of the stigmatising schizophrenia/c tweets, 22 (53.7%) were mocking or trivialising schizophrenia/c, 10 (24.4%) were categorised as dangerousness, 4 (9.8%) as social distancing, 3 (7.3%) as inaccurate beliefs and 2 (4.9%) as self-stigma.

For psychosis/tic, 93 (69.4%) were categorised as mocking or trivialising, 36 (26.9%) as dangerousness, 3 (2.2%) as inaccurate beliefs and 2 (1.5%) as self-stigma.

Discussion

The aim of this study was to assess any difference in views expressed about schizophrenia compared with psychosis on Twitter to assess the potential effect of a name change of schizophrenia. We found that the terms psychosis/tic were more commonly included in tweets expressing negative attitudes to these conditions than tweets referring to schizophrenia/c. Most of the stigmatising tweets were tweeted by individuals in the format of personal opinion/dyadic interactions. The most common forms of such stigmatisation were mocking, trivialisation or making associations with dangerousness. For both schizophrenia/c and psychosis/tic, however, the majority of tweets were non-stigmatising and provided potentially useful information, often about new research, normally broadcast by organisations. Fig. 5 Proportion of 'stigma type' in all stigmatising tweets.

Comparisons with previous studies

As far as we are aware, this is the first study to assess attitudes to schizophrenia compared with psychosis on Twitter or any other social medium. However, there are some previous studies that have compared attitudes to schizophrenia and other conditions on Twitter and on other social media. Reavley and Pilkington²¹ compared schizophrenia with depression on Twitter and found that there was a significantly greater stigmatisation toward schizophrenia: 5% of the schizophrenia tweets they identified ($n = 451$) were stigmatising. Joseph *et al*²² examined the use and misuse of schizophrenia on Twitter compared with diabetes and found a significantly greater proportion of schizophrenia tweets contained negative attitudes. Approximately one-third of their schizophrenia tweets had negative connotations ($n = 685$). Our figure of 9.35% ($n = 424$) falls in between what these two studies found. The difference in the percentage of schizophrenia tweets rated as stigmatising at different times could reflect coding differences but may be because of the effect of short-term changes in discussions about schizophrenia on Twitter.

There is some literature on the stigmatisation of schizophrenia and psychosis in entertainment media. A content analysis of Finnish and Greek videos on YouTube found that 83% of 52 videos portrayed schizophrenia in a negative way.²³ Similarly, Nour *et al*²⁴ found that most videos presenting schizophrenia on YouTube inaccurately portray the condition. Goodwin²⁵ examined the stereotyping of characters experiencing psychosis in 33 psychosis-related horror films released before the study was conducted. He concluded that 78.8% portrayed a homicidal maniac and 72.7% portrayed a pathetic or sad character. This is in keeping with our finding that psychosis is heavily stigmatised.

News media are also a focal point for the stigmatisation of mental health conditions. Vilhauer²⁶ analysed 181 USA newspaper articles mentioning the auditory verbal hallucinations that are diagnostic features of schizophrenia and other psychotic disorders. They found that about 50% of the articles associated auditory verbal hallucinations with criminal behaviour and violence. These findings are broadly in keeping with a more recent study that concluded that over half of all UK newspaper articles about mental health ($n = 200$) are negative and 18.5% indicate an association with violence.²⁷

Strengths and limitations

The main strength of this study is its ability to assess peoples' uncensored views about schizophrenia and psychosis without the need of a survey, the results from which could be affected by social desirability bias. The nature of Twitter means that, once published, a tweet is accessible to anyone without further permission from the tweet's author. Relevant tweets were easy to access on www.twitter.com with the advanced search tool and the process of coding was relatively time-efficient and simple using NVivo.

There are, however, a few limitations of this study. First, capturing data for two arbitrarily chosen 7-day periods means that external events and news cycles may have affected the way people discuss schizophrenia and psychosis, perhaps reducing the generalisability of the data. Of note, there were news stories about USA's response to North Korean nuclear missile testing in the April 2017 observation period,²⁸ and September 2017's period was soon after a bomb injured 30 people in London, England.²⁹ A further study could look in detail about how news media and current affairs influence people's expression of mental illness on social media. A longer period of study could examine detail how current affairs influence people's discussion of mental illness on social media, and potentially highlight trends in how people discuss schizophrenia and psychosis.

Another limitation is that spelling mistakes, abbreviations and colloquial terms for the searched terms may be used in tweets. By searching for only 'schizophrenia', 'schizophrenic', 'psychosis' and 'psychotic', tweets containing mistakes, abbreviations and colloquial terms will not have been captured in the search. We decided not to include abbreviations and colloquial terms in the search because it may not be clear whether tweets would actually have been about schizophrenia and psychosis. An example would be the abbreviation 'psycho', which could refer to psychopath, rather than psychosis. However, if anything, it is more likely that spelling mistakes, abbreviations and colloquial terms may have higher rates of stigmatisation. In a similar vein, future studies could map the different definitions of schizophrenia/c and psychosis/tic used by lay individuals and professionals as this may influence the degree of stigmatising attitudes.

Both the 7-day window convenience sampling and the ability of users to privatise their Twitter accounts could have contributed to selection bias within the study. Content from private accounts would not be visible to our searches, and it would be an interesting but technically challenging study to assess whether private and public accounts have different levels of stigma. Selection bias is an often-encountered issue when conducting research on internet-based communications, and although an attempt to mitigate this was made by analysing all tweets from within the time frame, this may reduce the external validity of the conclusions.³⁰

Finally, this study only looked on www.twitter.com and there are other social media platforms that could be assessed. Facebook data may be hard to access as the average person is likely to have their profile on a private setting, but it would be interesting to see if psychosis content on YouTube is as negative and inaccurate as it is for schizophrenia. Future work could also compare the stigmatisation of different psychoses on Twitter and other social media.

In conclusion, on Twitter, psychosis is more stigmatised than schizophrenia. This suggests that the term psychosis should not be used if schizophrenia is to be renamed with the aim of reducing stigma. Further, given that different psychotic disorders have particular treatments and varying prognoses,³¹⁻³² such a move to a more generic term may do more harm than good.

1.4.19 Against the stream: intermittent nurse observations of in-patients at night serve no purpose and cause sleep deprivation

David Veale

Correspondence

date

2019-8

Abstract

This paper argues that intermittent nursing observations of in-patients at night do not reduce the risk of suicide or severe self-harm. Suicides between 23.00 h and 07.00 h are rare, and these overwhelmingly occur under intermittent observations. Such observation is purely a defensive intervention to document that a patient is safe at a particular time, as there is no engagement. For the large majority of in-patients, it has the unintended consequence of causing sleep deprivation. The intervention may cause harm to in-patients by making their disorder worse and increase their risk during the day. If patients are judged to be at immediate risk, then they should be placed on constant observation. If they are not, then optimising sleep is important for treating a psychiatric disorder and they should be placed on general observations.

- *Against the stream: intermittent nurse observations of in-patients at night serve no purpose and cause sleep deprivation*

Nursing observation is defined as ‘... regarding the patient attentively, minimizing the extent to which they feel they are under surveillance, encouraging communication, listening, and conveying to the patient that they are valued and cared for ...’.¹ National Institute for Health and Care Excellence guidelines² define various levels of observation determined by a risk assessment, especially for severe self-harm, suicide, violence and absconding. These include *continuous* observation by one or more staff; low-level *intermittent* observation (usually a frequency of once or twice an hour); and

high-level *intermittent* observation (usually two to four times an hour). The term *general* observations usually refers to a frequency of once or twice in a staff shift. The importance of ‘engagement’ (that is, emotional and psychological containment of distress and giving of hope) is emphasised as a genuine (not just linguistic alternative) to observation.³ National guidance and local policies assume that nursing observation operates over 24 h. As I shall explain, this is where the problem lies: ‘engagement’ is not required at night when a patient needs to sleep and to be kept safe.

It is up to the nursing staff to determine what fulfils ‘reasonable’ observation when patients are sleeping at night. A variety of practices and frequency of observations are used at night to document that a patient is safe at a certain time. Policies usually require the staff member to clearly see the patient is breathing. At night this typically involves either opening the window hatch in the door or entering the bedroom and shining a torch on the patient’s face or switching on a light or waking the patient by shaking them to see that they are still breathing. There are many complaints by patients on the practice as it disturbs their sleep and they are frequently unable to get back to sleep. However, the documentation of a patient’s safety has become the only metric of importance to regulators and managers. No research or discussion has ever been published into the effectiveness for risk management of nursing observations at night. However, I will argue that the process of documentation by intermittent observations at night has many unintended consequences.

Surveys of psychiatric in-patients find that the large majority experience insomnia because of the noise and light on the ward and from nursing observations.^{4,5} There is a bidirectional relationship so that insomnia is not just a symptom of psychiatric disorder – intermittent sleep deprivation makes most psychiatric disorders worse.⁶ Importantly, sleep duration is negatively correlated with subsequent length of time in hospital⁷ and is associated with a range of physical and mental health problems.⁸ Specifically, sleep deprivation leads to negative changes in the neuroendocrine, immune and inflammatory systems, as well as hypertension. Furthermore, evidence from correlational and experimental studies have demonstrated that reduced sleep has a severe effect on emotional regulation.⁹ Paradoxically, it would be better to have one night of continuous sleep deprivation, followed by advancing the time of sleep over 3 days combined with bright light in the mornings (called ‘triple chronotherapy’). This resets the circadian rhythm and can lead to a rapid improvement in risk of suicide and improvement in mood.^{10,11}

Sleep deprivation and worsening of symptoms for the many might be justified if it significantly reduced the frequency of suicide or severe self-harm. However, the effectiveness of intermittent observations at night in preventing suicide is highly questionable. The most recent National Confidential Enquiry into Suicide and Homicide¹² reported that there were 114 suicides by in-patients in the previous year (compared with 1600 suicides *per annum* by people known to psychiatric services and about 6200 people *per annum* in the community who are not known). About one-third of the in-patient deaths occurred during busy periods on the ward (e.g. 07.00–09.00 h, 13.00–15.00 h and 19.00–21.00 h), hours during handover or when staff had multiple duties to attend to.¹² I requested a further search from the National Confidential Inquiry on the numbers of in-patients who died between 23.00 h and 07.00 h. Between 2011–2016, there were 464 in-patient suicides. Of these, 54 out of 338 (16%, excluding unknowns) died at night (about half on the ward, about half off the ward). There are no statistics collected on the frequency of severe self-harm. However, it would be surprising if the pattern of self-harm were very different to the reduced risk of suicide between 23.00 h and 07.00 h.

What is also known is that 91% of in-patient deaths by suicide occur under *intermittent* rather than constant observation.¹³ This is not really surprising. If you were determined to end your life or self-harm while being observed intermittently, you would choose a time just after you have been observed and then act. The rate of suicide is 13.7 per 10 000 admissions (0.14%).¹⁴ Therefore, about two out of 10 000 admissions die at night between 23.00 h and 07.00 h, and these are overwhelmingly under *intermittent* observation. It is true that because there are no randomised controlled trials (RCTs) we do not know how many deaths were prevented (or delayed) by intermittent observations. Owing to of the very low rate of suicide at night (two per 10 000 admissions), there will never be a RCT of, say, intermittent *v.* general observations at night with mortality as the primary outcome, because the numbers required would be about 250 000 to demonstrate non-inferiority between two groups.

My conclusion is that intermittent observations at night currently cause sleep deprivation for the majority of in-patients. They appear to do little to prevent suicide and are just as likely to be increasing risk during the day and prolonging in-patient stays. The best way of managing risk is to treat the disorder, and this includes insomnia. When I discuss this with colleagues, I find a widespread view that the practice stems from institutions’ fear that something may go wrong, and that the staff or hospital may be criticised by a coroner or regulator. When a serious event occurs, the monetary as well as the human costs can be large, and thus the best defence against possible negligence claims is for staff to follow local policies or national guidelines. However, guidelines that assume the same frequency of intermittent observations

during the day or night do not make sense because (a) staff are not expected to engage a patient at night; (b) suicide is much less common at night; and (c) when suicide does occur, it is generally under intermittent observations. Night-time observations thus cannot be justified on the grounds of keeping patients safe and may increase risk over the following days by causing sleep deprivation.¹⁵

If a patient is assessed as an immediate risk to themselves or others, then they should of course be put under *constant* observation at night – I do not have a problem with this, with the caveat that deciding who is at ‘immediate risk’ is unreliable at predicting suicide. There is no evidence for differentiating between low, medium and high risk in psychiatric in-patients.¹⁶ In brief, there is an overwhelming number of false positives from those rated as having a high risk and just as many suicides from those rated as a low or medium risk. This is important because such ratings determine the level of observations during the day *and* at night. Balancing reasonableness and proportionality are crucial issues in observations at night. Thus, a policy of placing a patient under intermittent observations at night because they are rated as low or medium risk allows an institution to feel they are doing something to manage risk and protect themselves from criticism from regulators or negligence claims.

I would like to see several areas of change. First, observations should be routinely called ‘engagement’ during the day and ‘observations’ by night. Second, national guidelines on engagement and observation should take into account that only a minority of suicides occur at night. Then it should be possible to have a personalised care plan so that the frequency of engagement during the day and observations at night can be varied if the risk is assessed as differing according to context. Thus, patients who are on intermittent once-an-hour engagement during the day may be put on general observations at night. This should not stop staff being inquisitive and vigilant when they believe something is ‘not right’.¹⁷ Last, I would like sleep on an in-patient ward to be taken seriously, and the principles of sleep hygiene and cognitive-behavioural therapy for insomnia, adapted for a psychiatric ward, to be implemented.¹⁷ This means focusing the culture and environment of a ward on optimising sleep at night and therefore managing risk by treating the disorder through improving sleep. We need to listen to patients and develop innovative solutions to improve care at night. Finally, duration of stay, global severity of psychiatric disorder and quality of sleep should be important indicators for RCTs, single case experimental designs and quality improvement projects on observations.

How can we understand psychosis without experiencing it ourselves? How can we convey such a complex, bizarre and (as Jaspers would have it) *un-understandable* experience to others, particularly those new to psychiatry? It is a difficult task.

Karin Fossum, the respected Norwegian crime writer, does not shy away from confronting the more unpalatable aspects of the human mind. Her portfolio has included an exploration of the psychological motivation of paedophiles, elder abusers, and vulnerable people who are drawn into crime. Her focus is not on what, but why.

The Whisperer centres on the unremarkable, quiet, middle-aged Ragna Reigel, who, after surgery, was left with a disability that means she cannot talk above a hoarse whisper. Isolated and ignored, no-one notices (or particularly cares) when her thoughts and behaviour start to change, until it is rather too late.

Fossum has used her talent for drawing us into the minds of the misunderstood to powerful effect. Through the format of a sensitively conducted police interview, we are carried alongside Reigel as she develops psychosis. It is an unsettling and disorienting experience.

The book captures the sense of unease and apprehension that come with delusional mood. This progresses into more defined delusions and paranoia that permeate every aspect of Reigel's life. The loss of her sense of agency and experience of perplexity and distorted perceptions is well described. "...her overview was slipping...her body had been knocked out of its natural measured rhythm...life was no longer safe...external powers were taking over." "The night was no longer silent, she could hear the seven billion people who lived on this earth. They were breathing like an enormous beast, cackling and screaming and wailing."

The language changes subtly as Reigel deteriorates, reflecting her increasingly disordered thoughts as she struggles to make sense of what is happening to her.

Through Reigel's isolation and loneliness, the book raises broader questions about how we as a society care for the vulnerable and marginalised. The effect of disability and impaired communication on mental health is considered, as is the humane treatment of offenders with mental disorders.

The book's great strength is its accessibility. It can be enjoyed on its own merits as a work of fiction; yet it also communicates an experience of psychosis in a way no textbook can. I would recommend it to medical students and trainee psychiatrists, but even seasoned psychiatrists could gain a great deal from it. Empathy starts with understanding the experience of those we care for, and *The Whisperer* – quietly, unassumingly and unnervingly – helps us to do just that.

1.4.20 How long is (too) long?

Birgit Völlm

Correspondence

Prof Birgit Völlm

(birgit.voellm@med.uni-rostock.de)

date

2019-8

Abstract

Forensic psychiatric services care for patients who present with a mental disorder as well as a risk to themselves or others, and have usually been convicted of an offence. Their needs are complex and the length of stay (LoS) in forensic settings is long. LoS is affected by patient factors as well as legal and policy issues. Owing to the considerable economic and ethical issues surrounding lengthy stays in highly restrictive settings, it is crucial that a strategy is developed for how to deal with this patient group.

Earnshaw *et al*, in this issue, describe a study looking at the length of admissions in a medium secure unit in England over a period of nearly 30 years. They show a significant increase in length of stay (LoS) in the most recent cohort, as well as far more discharges to other psychiatric settings and fewer to independent living, with the diagnostic composition of the cohorts remaining largely unchanged. The paper is a welcome addition to the literature on LoS in forensic settings. Evidence on LoS is scarce, despite its obvious ethical and economic relevance. This editorial summarises the research on LoS to date and considers ideas to improve service organisation for this group of patients.

Methodological issues

There are a number of ways to investigate LoS:¹ (a) admission samples (i.e. considering all patients admitted during a particular period with LoS calculated from admission to discharge); (b) cross-sectional samples (the sample consisting of all patients resident in the particular unit of interest on a particular date with LoS calculated from date of admission to this time point); and (c) discharge samples (all patients discharged during a particular period with LoS calculated from date of admission to this date). Which method is the best depends on the questions to be answered. Earnshaw *et al* use admission samples, which has the advantage that the political and service provision context is likely to be the same for all patients in the sample at point of admission. What this method cannot capture is those patients who have not been discharged at the time of data collection, as their length of admission cannot be known at this point, thereby underestimating LoS. Another, and more significant, limitation of most research to date, regardless of which of the three approaches is used, is that it only considers a relatively short period in the patient's care trajectory, the admission to a single unit. In reality, patients' pathways are complex and an individual may be admitted to a number of secure units consecutively, adding to their overall LoS in secure care.

What we know about LoS in forensic settings

Concerns that some patients stay for too long in too high a level of security were first raised following studies in high secure settings in the 1990s involving assessments by the patients' own teams as well as independent multi-disciplinary reviews. These suggested that between one-third and two-thirds of patients did not require that level of security.²⁻⁵ Inadequate provision of beds in less secure settings and inefficiencies in the system of transfer and discharge were thought to be significant factors in the delayed transfer to a more appropriate level of security. These findings led to the 'accelerated discharge programme',⁶ aimed at reducing patient numbers in high secure care while bed numbers in medium and low secure settings increased. At the beginning of the 1990s, there were 1700 high and 600 medium secure beds,⁷ while in 2015 there were just under 800 high and about 3200 medium secure beds.⁸ Although the reduction of high secure beds is a welcome development, the increase in the overall number of patients detained in secure settings is worrying. In addition, while I am not aware of any published research in this area, anecdotally, restrictions have increased in medium secure settings, e.g. with regards to leave and handcuffing during leave.

Maybe somewhat surprisingly, there is no agreement or guidance as to how long patients should stay in high secure settings in the UK. For medium secure care, the original guidance from government, based on the recommendations in the Glancy and Butler reports,⁹ suggested an upper limit of 2 years; however, a number of studies have demonstrated that this LoS is far exceeded in a large proportion of cases.¹⁰ In a multicentre study in the UK, including all three high secure hospitals and 23 medium secure services, both within the National Health Service and the independent sector,¹¹ we found that 23.5% of high secure and 18.1% of medium secure patients fulfilled our criteria for ‘long-stay’. We defined ‘long-stay’ as having been in a high secure setting for more than 10 years, in a medium secure setting for more than 5 years or in a combination of both for more than 15 years. These figures were based on pilot work showing that these thresholds would identify a population large enough in size to provide meaningful conclusions for service developments, but not so large that a substantial proportion of the total patient population would be captured. Whether there has been an actual increase in LoS, however, remains unclear – the paper in this issue of the *Bulletin* is the first to investigate this question.

Research identifying factors associated with long stay is limited. In the UK, one early study at one of the three high secure hospitals¹² identified severity of index offence as the most important factor for personality disordered patients, while for those with mental illness psychopathology was a more relevant predictor of LoS. Studies in medium secure settings have identified severity of psychopathology, psychiatric history, seriousness of offending, patients being on ‘restriction orders’ (requiring Ministry of Justice permission for transfer), non-engagement in interventions, dependency needs and lack of step-down facilities as factors associated with long stay. A review of the international literature¹ similarly found that the factors most frequently associated with longer stay were seriousness of index offence, longer previous prison sentence, psychotic illness, symptom severity and having no close relationship.

Patient perspective has thus far been largely neglected in research on long stay in forensic settings. A qualitative study which formed part of the multicentre study described above¹² and included 40 patient interviews investigated patients’ perspective on reasons for long stay, their current situation and the prospect of moving on. Based on the emerging themes – attribution, outlook, approach and readiness for change – four overall ‘stances’ could be identified. Patients in the ‘dynamic acceptance’ group attributed their long-stay to themselves; they felt overall positive about therapy and being in secure care but felt they were ready to move on. Patients in the group we labelled ‘static acceptance’ attributed the reason for long stay internally and externally, were somewhat less positive about therapies and did not believe they were ready to move on. Those in the ‘dynamic resistance’ and ‘static resistance’ categories attributed their long-stay to external factors and were largely negative about their placement and interventions. Whereas the former group still believed they would move on eventually, the latter had largely given up on the prospect of moving on, despite their belief that they did not need to be in secure care.

Service provision

Service provision in secure care is complex, entailing different levels of security with vague entry and even vaguer exit criteria. For example, those admitted to high secure care should present a ‘grave and immediate’ danger, obviously words that leave a lot of room for interpretation. Maybe somewhat surprisingly there is no agreement that those having entered high secure care presenting such a danger should then move on or be discharged if they no longer do so. In addition, how does one measure progress, e.g. of a patient having committed sexual offences against children? Such a patient might be very well adapted in any setting not giving access to children, but what should be the criteria to decide which level of security is the right one and when to move on after years of settled behaviour? The debate around the poor to moderate accuracy of risk assessment instruments for long-term predictions is also pertinent here.¹³ Unfortunately, in the UK there seems to be little appetite to tackle these complex questions nationally. Instead, each responsible clinician makes their own judgement, and in many cases has to fight individual battles with the next unit, trying to ‘sell’ their patient.

Little is known about the complex pathways forensic patients take. In theory, they move from higher to lower levels of security in accordance with the lowering of their risk and progress in therapy. In practice, such ideal pathways are rarely achieved. For instance, we showed in our study¹¹ that less than one-third of the sample of long-stayers had stayed in their current secure unit only, while about 40% had stayed in three or more settings. More than 50% of long-stay medium secure patients had been admitted from another medium secure unit. This may be good practice in order to try a different approach in individuals with limited treatment gains. Nevertheless, it is clear that rather than moving *on*, a

large number of patients seem to be moving *around*. It is difficult to see how this unfortunate state of affairs could be changed without taking a longitudinal view and without the development of national policy for this patient group.

Considering their pathways, the group of long-stay patients probably consists of three subgroups: (a) those who are still on a trajectory of positive, albeit slow, progress; (b) those who are 'stuck' currently but might move to less secure conditions under certain circumstances; and (c) those who require secure care for life. The first group is of least concern. The second might benefit from improvements in service organisation and advancements in psychotherapeutic and pharmacological therapies. The third group is most controversial. In our own study, consultants predicted that more than 40% of long-stay patients currently resident in high secure care would still be there in 5 years' time. Even for long-stay patients in medium secure care at the time of the study, only a minority of patients were expected to achieve independent living in the next 5 years.

Nevertheless, interviews with professionals in the UK demonstrated that staff working in secure units still conceptualise the process of care along the lines of 'admission, treatment, rehabilitation, cure', in denial of the actual situation of most patients.¹⁴ Staff felt uncomfortable with the idea of dedicated 'long-stay units', which they saw as warehousing. Many did not consider long periods of detention to be problematic as long as treatment was still offered, despite the fact that such treatment did not seem to make a difference to the patient's chances of moving on. Although these sentiments are understandable, not openly recognising long stay as a problem is likely to act as a barrier to considering service improvements for this patient group.

International perspective

A number of countries have started to recognise the problem of long stay in forensic psychiatric hospitals, resulting in a range of legal and service provision developments.¹⁵ Croatia, Italy and Portugal now have legal provisions such that detention in hospital can no longer exceed the length of a prison sentence the individual would have been given had they been convicted as a non-mentally disordered offender. While not going that far, in Germany the constitutional court ruled that the length of detention has to be proportionate to the index offence and that the longer detention lasts, the more the individual's right to freedom weighs in relation to the protection of the public. While this principle has long been established in the case law of the German constitutional court, the new Criminal Code additionally specifies that after 6 years of detention in a forensic psychiatric hospital, detention has to be terminated unless there is a risk that further offences will be committed that will cause 'serious' physical or psychological harm to a victim; after 10 years such risk has to be 'grave'.¹⁶

Other countries have developed policies and services specifically for long-stay forensic populations. One example of particular interest is service provision in The Netherlands. There patients can be given 'long-stay status' by a court on the application of their treating team. Criteria for this status are: •having been an in-patient in a forensic institution for at least 6 years;•having been a patient in two separate forensic hospitals;•having completed relevant treatment programmes but with little discernible progress (or consistently refusing to participate in such programmes);•no reduction in risk in the foreseeable future expected.

Individuals with long-stay status are diverted to specific long-stay units, where the emphasis is on quality of life rather than risk-reducing interventions. Crucially, an open discussion is held with the patient about this process and they are fully aware of their new status. Importantly, from a human rights point of view, this status is not a dead end; rather, patients can move back into mainstream provision if it is clinically indicated.

Recommendations

Given the significant ethical and economic consequences of long stay in forensic care, it is essential that a national strategy is developed to deal with this complex patient group. Issues to consider in such a strategy are: •taking a whole pathway approach;•clear entry and exit criteria for services;•cut-off points for the definition of ‘long stay’ in the different levels of security;•independent reviews of long-stay patients;•exploration of interventions designed to reduce LoS;•improvement of the efficiency of pathways for this group;•incentives to move patients on (e.g. through the Commissioning for Quality and Innovation framework, as is already happening in some trusts);•flexibility in moving between services with prolonged transition periods;•introduction and evaluation of pilot services for long-stay patients.

To develop such a strategy, wide consultation including patients and carers is required to capture relevant perspectives and concerns.

Birgit Völlm is Professor of Forensic Psychiatry at the University of Rostock and Medical Director at the Hospital for Forensic Psychiatry, Rostock, Mecklenburg-Vorpommern, Germany.

This is an insightful and extremely valuable book depicting a man’s journey through depression and anxiety. It is based on Brent Williams’ experiences and is a deeply personal account, but is also based on sound medical science. Williams’ personal experiences and the unusual graphic novel format make the book very accessible, allowing the reader to understand the experience of depression and anxiety. It is beautifully illustrated by Korkut Öztekin, with pictures which often ‘say’ so much more than words in terms of evoking the atmosphere and man’s mood.

We journey with the man from a period of deep depression to recovery, passing through multiple steps on the way—including trying to recover alone, resisting help and later becoming open to help. The book offers an explanation as to how and why one might be feeling depressed and anxious, as well as enabling the reader to learn about the symptoms of depression and anxiety.

Importantly, the story shows the reader how to take the steps towards recovery. The man is told, ‘[y]ou need to break the downward spiral . . . by doing lots of small and manageable things’. The reader is exposed to breathing techniques, mindfulness and the importance of nature, learning, human contact and exercise amongst other practical steps which help promote recovery.

The book also demonstrates a realistic recovery path with the ups and downs which are so typical. Most significantly, by charting the man’s recovery it offers hope and demonstrates a way forward which will be helpful and comforting to those with similar problems. There are elements of the narrative which are perhaps a little alien to the National Health Service culture. Nevertheless, this is a much-needed book which will be very useful to patients and their families/friends as well as a great help to general practitioners by supporting the messages we give.

date

2019-8

Abstract

Functional non-epileptic attacks (FNEA) are seizure-like events occurring in the absence of epilepsy. Having had many different names over the years including dissociative convulsions and pseudo-seizures, they now fall in the borderland between neurology and psychiatry, often not accepted by either specialty. However, there is evidence that there is a high rate of psychiatric comorbidity in these patients and therefore it is likely that psychiatrists will come across patients with FNEA and they should know the broad principles of assessment and management.

We have provided a clinically based overview of the evidence regarding epidemiology, risk factors, clinical features, differentiation from epilepsy, prognosis, assessment and treatment.

By the end of this article, readers should be able to understand the difference between epileptic seizures and FNEA, know how to manage acute FNEA, and understand the principles of neuropsychiatric assessment and management of these patients, based on knowledge of the evidence base.

Clinical scenario

You are a core trainee in a community mental health team, working in an out-patient clinic. You come out to call your next patient when you see a 40-year-old woman lying on her back on the ground with her eyes closed in the waiting room, with people crowding around her. The receptionist informs you that she arrived a few minutes late in a distressed state and was asked to take a seat. Within a minute she was seen slumping in her chair and then sliding down to the ground, jerking all four limbs while crying. When you approach her and try to talk, she responds to your questions and soon opens her eyes and her shaking stops, but she then slips back into jerking all four limbs again. You see on her wrist that she has a medical alert bracelet, which reads ‘medical alert: non-epileptic attacks’.

- What would be your immediate management of the situation?
- What are the principles of assessment and management in functional non-epileptic attacks (FNEA)?
- What are the differences between epileptic seizures and non-epileptic attacks?

Evidence base in FNEA

FNEA are when people present with what looks like epileptic seizures but they do not have epilepsy or associated electroencephalogram (EEG) changes or a physiological condition that may mimic seizures such as syncope. This condition is also known as psychogenic non-epileptic seizures (PNES), non-epileptic attack disorder (NEAD), psychogenic seizures, hysterical seizures and so on. In ICD-10 (1992) they are classified as ‘dissociative convulsions’, in ICD-11 (2018) as ‘dissociative neurological symptom disorder’ and in DSM-5 (2013) as ‘functional neurological symptom disorder – with attacks or seizures’. The change in terminology over the years reflects the changes in theoretical underpinning and clinical understanding. FNEA have been described in multiple cultures without a specific diagnostic label for 4000 years, the term hysteria was then used for the next 2500 years,¹ followed by conversion, dissociation and now FNEA, which is theoretically neutral from a psychological standpoint and considered to be acceptable to patients.²

FNEA are commonly seen in neurological and accident and emergency (A&E) settings. Up to one in five patients in epilepsy clinics present with FNEA and 20–40% of patients in epilepsy-monitoring in-patient units have FNEA.³ These patients or their carers will often initially call an ambulance and present to A&E departments. Indeed, nearly a quarter of FNEA patients report an episode of FNEA status,⁴ which may in some cases even lead to intubation in the intensive treatment unit. The estimated prevalence of FNEA is 2–30/100 000 in the general population⁵ and population incidence has been estimated to be 1.4–4.9/100 000/year.³ By contrast, the median estimated population incidence of multiple sclerosis is 4.2/100 000/year and that of epilepsy is 48/100 000/year.⁶ FNEA most commonly present in young adulthood and in women, but can occur in children, older adults and men.³

The aetiology of FNEA, as with functional neurological disorders in general, is thought to be multifactorial. Risk factors include female gender, childhood abuse and neglect, avoidant coping styles, previous functional disorders and somatisation, and recent stressful event which may itself be ‘organic’ – such as a head injury or syncope.⁷ In addition, FNEA are associated with neuropsychological deficits and alexithymia.⁷ Often overlooked is a family history of functional disorders, although there have been no positive genetic findings to date.⁸ There is an association with personality disorder, especially cluster B and cluster C personality disorders,⁹ and a number of patients have other psychological comorbidities such as affective disorders and anxiety disorders,¹⁰ which may act as predisposing, precipitating or perpetuating factors. Symptoms of panic and dissociation are common leading up to an attack, and patients may even ‘bring on’ an attack to rid themselves of these symptoms.¹¹

Distinguishing epileptic from non-epileptic attacks can be difficult, and it is important to remember that there are no clinical signs that *never* occur in epilepsy, and the only certain diagnostic feature of epileptic versus non-epileptic attacks is video EEG (vEEG) confirming epileptic or non-epileptic seizures.¹⁰ If this shows the *absence* of epileptiform activity in the *presence* of the patient’s typical attacks, it confirms the diagnosis of FNEA. vEEG is of course only diagnostic if the attack occurs during monitoring and can be falsely negative on scalp EEG if there is an ictal focus deep in the frontal lobe. However, vEEG is expensive and is carried out in only some cases. Diagnosis is largely clinical, based on good history and clinical observation of an attack, ideally supplemented by clinician-viewed video of the attack. *Table 1* helps distinguish clinical features of epileptic versus non-epileptic attacks, but should not be used in isolation to make a diagnosis either way. *Table 1* Distinguishing clinical features in FNEA and epilepsy.

Feature	FNEA	Epilepsy
Onset in certain situations	Sometimes	Rarely
Gradual onset	Commonly	Rarely
Over 2 minutes duration	Commonly	Rarely
Asynchronous limb movements	Commonly	Rarely
Purposeful	Rarely	Purposeful

movements Sometimes Very rarely Thrashing, violent movements Commonly Rarely Side-to-side head movements Commonly Rarely Tongue biting of tip Sometimes Rarely Tongue biting of side Rarely Commonly Eyes closed Very commonly Rarely Resistance to eye opening Commonly Very rarely Pupillary light reflexes Commonly retained Commonly absent-tictal crying or vocalisations Sometimes Very rarely Incontinence Sometimes Commonly Post-ictal rapid reorientation-Commonly Uncommonly Absence of cyanosis Commonly Rarely¹

Confusingly, some patients with epileptic seizures may also have non-epileptic attacks. What is important in this case is the semiology (clinical features of the seizure) and whether it is different from the patient's normal epileptic seizures. Epileptic seizures tend to be short, stereotyped and highly consistent, although of course they can take different forms in the same patient, e.g. simple and complex. However, in the case of the emergence of a new seizure type in a patient with stable epilepsy, FNEA should be considered.

In terms of prognosis and outcomes, data suggest that 4 years after diagnosis around a third of patients will be attack free.¹⁴ However, being attack free alone does not result in greatly improved levels of psychopathology or recovery of social function, as nearly half of patients who are attack free are still in receipt of state benefits.¹⁴ These data suggest that social interventions aimed at recovery of social function, e.g. going back to work, may be efficacious in improving quality of life more than aiming for patients to be attack free; however there are no studies examining social interventions alone and this is a gap in the literature. Furthermore, there is a general lack of long-term follow-up studies of patients with FNEA. Features associated with a favourable prognosis include lack of past psychiatric history, identifiable recent stressor, short duration of FNEA, higher socioeconomic class, normal IQ, lower age, less vigorous seizures, absence of comorbid epilepsy and no ongoing use of anticonvulsant medication.^{7,12}

Multiple treatments have been trialled including cognitive-behavioural therapy (CBT) (both individual and group based), paradoxical treatment, psychodynamic therapy, group therapy, family therapy, case management, eye movement desensitisation and reprocessing, acceptance and commitment therapy and multimodal approaches.^{7,12,15-18} However, the evidence base is hampered by lack of control groups, small numbers of patients in trials and also the highly variable population and presentation of FNEA. We would suggest that the individualised treatment approach as described in 2014 by Agrawal *et al*¹⁸ helps address this problem of the high variability in FNEA patients.

The problem of small numbers in treatment trials is also being addressed: The largest randomised controlled trial (RCT) to date is in CBT. Goldstein *et al*¹⁹ conducted an RCT of CBT versus standard medical care (SMC), with 33 patients in both arms, and seizure frequency reduced significantly in the CBT arm. However, the statistical power reduced significantly ($P = 0.086$) due to patients being lost to follow-up. This CBT trial was extended and repeated and is currently evaluating data as the 'COgnitive behavioural therapy versus standardised medical care for adults with Dissociative non-Epileptic Seizures' (CODES) trial.²⁰ It aimed to allocate around 150 patients to each arm – SMC and SMC with CBT – and is due to report.

Only one double-blind placebo RCT of treatment has been published in FNEA, and this was of sertraline versus placebo.²¹ A total of 33 patients were assessed and a non-significant reduction in seizure frequency was found in the sertraline versus placebo group. This was a feasibility study for a larger RCT which, to date, has not been undertaken.

Assessment of FNEA

There are some key elements to the assessment of FNEA that should never be forgotten. (1) A clear history from both patient and an informant, ideally supplemented by video of the attack itself, is invaluable. Patients with non-epileptic attacks tend to talk about attacks in a different way to those with epilepsy (for example, talking about seizures by total negation and without context, i.e. 'I feel nothing', 'I don't know anything has happened'), whereas those with epilepsy try to give detailed explanations of what they did experience before or after.²² It is important to get a clear understanding of how the family react when a non-epileptic attack occurs as, in some cases, they may inadvertently be reinforcing or maintaining the attacks. (2) A good history is essential, especially for any recent stressful events. Some patients' attacks are clearly temporally related to a stressful event, although this is no longer required for diagnosis. (3) A full psychiatric history is required, assessing both past and current mental illness. Both patients with epilepsy, and with FNEA are more likely than the general population to have higher rates of depression and anxiety.¹⁰ Treatment of any comorbidities is an important part of treatment for FNEA as – although the data are limited by small numbers – comorbid prevalence rates of 63% with affective disorders, 46% with personality disorders, 32.5% with somatoform disorders, and 19% with both anxiety disorders and post-traumatic stress disorder (PTSD) have been reported.²³ (4) A thorough general medical history must be taken. Patients with non-epileptic attacks have been found to be more likely than patients with epilepsy to have functional or medically unexplained symptoms in different organ systems, such as fibromyalgia, chronic pain and irritable bowel syndrome.²⁴ The most common symptom combination distinguishing FNEA from epileptic seizures in one tertiary centre study was chronic pain, migraines and asthma in FNEA compared with diabetes and non-metastatic neoplasm in epilepsy.²⁵ (5) Determine the personal and social history of the patient. Patients with non-epileptic attacks are much more likely to report a history of abuse or neglect in childhood, and this should be sensitively asked about along with usual information such as birth trauma, developmental milestones, head injuries and details of schooling and relationships. Importantly however, some will not have this history of abuse or neglect. In some cases this may need to be asked about after developing rapport with the patient. They should also be asked whether they are still driving. (6) The premorbid personality should be ascertained. Patients with non-epileptic attacks are more likely to have a personality disorder than the general population, especially cluster B and cluster C personality disorders, although there are methodological problems with much research in this area.^{9,23} (7) The patient's illness beliefs, concerns, wishes and expectations should be ascertained. Research has shown that patients who are confident in the diagnosis of FNEA have a better outcome.²⁶ Lasting doubts about epilepsy should be dispelled and it must be emphasised that this condition is treatable and many patients fully recover. (8) Finally, a biopsychosocial formulation encompassing the above factors should be composed, using predisposing, perpetuating, precipitating and protective format. This will guide management.

Box 1 Patient experience of functional non-epileptic attacks

My dissociative seizures (NEAD) were precipitated by an episode of moderate depression and its treatment with Sertraline on transition to university. I also was experiencing panic disorder, GAD and depersonalisation–derealisation disorder. Everyone was very panicked by my first seizures. I visited several A&E departments, had numerous ambulance visits and was bounced between psychiatric liaison, the A&E staff and the CMHT, even having an overnight stay in AMU. No one could give me a concrete diagnosis, or know where to refer me. I was dosed up on benzodiazepines, which did not stop the seizures, and just made the experience harder to cope with. I experienced PTSD following the traumatic nature of these interventions; and they were completely needless. Psychiatrists at CMHT seemed very worried, even more so than I was, and this compounded the stress that was prolonging my condition. They were, however, helpful in sourcing CBT to treat my anxiety and depression. Six months after my first seizure, I was officially diagnosed with dissociative seizures. The reassurance of a diagnosis itself, along with further research into the condition, was enough alone to cause a noticeable decrease in the severity of my seizures. I then saw Dr Sheldon & Dr Agrawal at St George's. Dr Agrawal drew a diagram explaining how stress can build to cause my seizures, and I used a CBT diary to identify triggers over two months. I surprised myself with the diversity and number of my triggers on reviewing my diary, which I now manage. A greater understanding of my condition gained through psychoeducation, and the use of grounding, distancing and distracting techniques, have all been instrumental in my recovery. I am now discharged, and almost seizure-free. I wonder how much better my experience could have been if doctors had known how to treat my acute presentation?

A&E, accident and emergency; AMU, acute medical unit; CBT, cognitive–behavioural therapy; CMHT, community mental health team; GAD, generalised anxiety disorder; NEAD, non-epileptic attack disorder; PTSD, post-traumatic stress disorder.

Management

The management for all patients will naturally be different due to the different nature of their attacks and their individual triggers, but there are important overarching principles. These include making the diagnosis clearly and early (and ideally soon coming off anticonvulsants); biopsychosocial formulation including the role others play in reaction to attacks; psychoeducation about non-epileptic seizures; the management of comorbidities; the development of personal insight and understanding triggers to attacks (which can be achieved by things such as attack diaries); offering trauma-focused therapy if appropriate; and the personal testing and utilisation of different techniques such as grounding, relaxation and mindfulness. The use of benzodiazepines and anticonvulsants can be harmful both in the short and longer term. An overview of one such pragmatic, individualised treatment pathway is provided in Agrawal *et al.*¹⁸

The diagnosis should in most cases be made by a neurologist. However, many patients will benefit from neuropsychiatry-led sensitive and detailed exploration of illness beliefs, further explanation of the diagnosis and psychoeducation about triggers and management strategies. In some cases, patients will have been on anticonvulsants and will have lived with negative side-effects for years, not to mention the stigma of epilepsy and practical handicaps from the condition, such as being unable to drive. Some patients may only require a clear, sensitive diagnosis for the FNEA to stop; however, these patients are thought to be in the minority. In any case, the way a diagnosis is made is important (*Box 1*).

Four models about conveying a diagnosis have been published.^{13,27–29} However, what is common between models are the principles of reassurance; discontinuation of anticonvulsants; providing a type of model for how FNEA come about – including the relationship with emotions; and that although symptoms are not consciously controlled, patients can learn to identify triggers for seizures and learn to intervene.

People with FNEA will ideally be seen by a psychiatrist with experience of the assessment of FNEA and epilepsy, i.e. a neuropsychiatrist. The multidisciplinary team is often helpful, for example in discussing difficult formulations, and the team can offer individual therapy tailored towards the FNEA or underlying factors as appropriate. Enough time should be set aside in clinic to explore symptoms and history as well as management. The clinic letter can itself be a useful tool to explore illness beliefs at the next consultation.

Whether or not patients should remain on the neurological caseload is an interesting topic and how helpful this is has not been explored prospectively. Given some of the similarities in interpersonal interactions with borderline personality disorder and patients with FNEA, some believe that consistency is key and patients should be kept in follow-up and that discharge should be slow and gradual.⁹ Indeed, patients with FNEA often struggle to fit in within both neurology and psychiatry services and they bounce between teams with clinicians reluctant to take responsibility, similar to those with personality disorders in psychiatric services.
