In an acute situation such as the above, the importance is in differentiating from an epileptic seizure. First, getting people to stand aside and leave the area is important to be able to assess the patient and manage the scenario. If your assessment is that this is a non-epileptic seizure, which from the description is likely, then some techniques can be used to arrest the seizure. For example, if a small mirror (or the front-facing camera on a smartphone) is brought to the patient's face, observe if the pupils converge on it (this is highly unlikely in an epileptic seizure). This mirror technique can in some cases stop the FNEA.¹³ However, if this is unsuccessful, it does not mean that this is *not* a functional seizure. If the patient's eyes are closed, it can be helpful to open their eyes to see if they resist eye opening, which would be very unusual in an epileptic seizure. If the patient can be spoken to and they respond emotionally to your voice (which, again, is common in FNEA), then you can talk to them and calm them. You could try asking them to tell you the day of the week, and to open their eyes and look at something in the room and describe it in detail. An example of such a grounding technique might be: 'tell me three things you can see, two things you can hear, one thing you can smell'. If the situation continues despite your best efforts, then be reassured the FNEA will stop eventually. It would be helpful to still see the patient despite the attack in the waiting room, if time allows. What is key is that the ambulance should not be called – unless the patient has seriously injured themselves – as a result of the FNEA and no acute pharmacological treatment is indicated.

Such acute treatment may not only reinforce a need for benzodiazepines or anticonvulsants, but has the potential to increase levels of dissociation by reducing alertness. Indeed it has been postulated that the variation in FNEA symptoms is due to the effect of anticonvulsants³⁰ and that other drugs inducing altered awareness states, such as anaesthetic agents, can induce FNEA.³¹

Patients may ask about driving. Current Driver and Vehicle Licensing Agency (DVLA) guidance in the UK dictates that people with FNEA should cease driving and inform the DVLA of their condition. To resume driving, people with FNEA should have episodes that are ‘sufficiently controlled’ for 3 months as long as there are ‘no mental health issues’. If there are ‘high-risk features’ then 6 months of control and a ‘specialist opinion’ is required before resumption of driving. This is the case for both group-1 and group-2 licences.³²

Conclusion

We have discussed the acute and chronic management of a patient with FNEA, highlighting the importance of individualised assessment and management based on biopsychosocial formulation. We would recommend that all patients with FNEA are referred to neuropsychiatric services, but also appreciate that due to service provision and funding gaps this is not always possible, and furthermore many patients have significant psychiatric comorbidity requiring the skills and resources of general psychiatry. Patients with FNEA can often seem as if they do not fall neatly within the responsibility of neurology or psychiatry; however a joint approach is likely to be the most productive given the degree of comorbidity. Their often-arduous journey towards diagnosis and treatment demonstrates why neurologists and psychiatrists should work, and train, in collaboration.

The extensive gaps in the literature that have been mentioned include the paucity of comparative studies between other episodic psychiatric syndromes such as panic attacks and FNEA (with these studies tending to compare FNEA patients with epileptic seizure patients), the lack of large-scale neuroimaging studies and genetic studies. The difficulty of establishing what abnormalities in studies are related to childhood trauma, comorbid psychiatric illness or the effect of chronic functional symptoms makes such studies difficult to perform. Studies assessing interventions focusing on purely social function are missing, as are large epidemiological studies, large personality disorder studies and studies examining the effect of being on or off a neurological caseload. Double-blind RCTs are extremely few in number, although this is not surprising as most studies are of psychological interventions which cannot provide a true placebo.

The earlier the diagnosis is made and biopsychosocial assessment and management put in place, the better the outcome, including a full resolution of symptoms. A neuropsychiatrist is ideally placed to do this, but a general psychiatrist, if following the basic principles discussed, can achieve good outcomes with these patients.

The authors thank Rowan Munson for his contribution to this article.

1.4.22 Queering the Mental Health Model

Andrew Camden

date

2019-8

Contents

- *Queering the Mental Health Model*

I have been involved in a project run by the artist La JohnJoseph (JJ) on ‘Queering the Mental Health Model’. JJ’s interest in the area was sparked by their experience visiting an ex-partner who was detained on a psychiatric ward, where ‘queerness’ often seemed to be conflated with illness by ward staff. JJ observed the difficulty of maintaining individuality in the confines of the ward environment; they noted that an attempt to do so was at times interpreted by staff as a sign of pathology.

JJ led 10 sessions over 12 months around the UK, to which people who self-identify as queer were invited to talk about their experience of psychiatric services. There was a general sense that people felt poorly understood outside specialist services, which are difficult to access; participants described a sense of having to fight their way through the system. There was, however, a multitude of positive feedback from people who had felt able to access a small number of appropriate specialist services.

‘Queer’ tends to be used now as an umbrella term to describe non-cis or non-heterosexual people. Historically derogatory, from the early 1990s, queer was reclaimed as a self-affirming term, originally by the gay rights movement. Queer challenges our tendency towards conventional categorisation into defined groups and helps remind us of individuality and the diversity of identity. As part of the LGBTQ community, it is known that people who self-identify as queer suffer higher rates of mental distress than the population at large.¹ JJ’s project will shed some light on the reasons for this.

There is a dearth of literature on this topic. A literature search by Reay House Library (based at Lambeth Hospital in London) on the ‘experience of psychiatric/mental health services of people who self-identify as queer’ found a total of 33 articles, of which four were by UK authors. None of these had a specific focus on people who identify as queer; they described experiences of the UK LGBTQ community in general. Two articles have an historical focus. Hughes *et al* have published two recent articles, one looking at the experiences of LGBTQ youth (ages 16–25) of suicidality and help-seeking² and one on the perceptions and practice of mental health staff of this group.¹ There is clearly scope to further examine the experience of psychiatric services of people who identify as queer, to help inform how these might better meet demand and reduce feelings of distress and marginalisation.

JJ’s performance piece based on their experiences on the psychiatric ward, *A Generous Lover*, will tour the UK in September. There is further information at www.lajohnjoseph.com.

1.4.23 Telepsychiatry in intellectual disability psychiatry: literature review

Giri Madhavan

Correspondence

Dr Giri Madhavan (girimadhavan@gmail.com)

date

2019-8

Abstract

Aims and Method

The aims of this review were to explore the effectiveness and patient and provider acceptability of telepsychiatry consultations in intellectual disability, contrasting this with direct face-to-face consultations and proposing avenues for further research and innovation. Computerised searches of databases including AMED and EMBASE were conducted.

Results

Four USA studies of intellectual disability telepsychiatry services have been reported. The majority (75%) focused on children with intellectual disability. Sample sizes ranged from 38 to 900 participants, with follow-up from 1 to 6 years. Outcome measures varied considerably and included cost savings to patients and healthcare providers, patient and carer satisfaction and new diagnoses.

Clinical implications

The innovations summarised suggest a requirement to further explore telepsychiatry models. Despite some promising outcomes, there is a relative dearth in the existing literature. Further studies in other healthcare systems are required before concluding that telepsychiatry in intellectual disability is the best approach for providing psychiatric services to this population.

Declaration of interest

None.

Background

In provision of psychiatric services to people with intellectual disability, several factors result in patients and carers experiencing difficulty in attending out-patient appointments.¹ As intellectual disability services often cater for large geographical areas, these factors include inconvenient travel.²

In the UK, there is an emphasis on finding efficiencies and providing cost reductions to address the political austerity agenda.³ The Transforming Care report⁴ for people with intellectual disability itself cited cost savings for patients returning to the community. Additionally, there is a growing movement towards a more environmentally conscious provision of service.⁵⁻⁷ Telepsychiatry⁸ consultations, on the surface, would appear to aid with these issues.⁹⁻¹¹

Telepsychiatry has been broadly defined as the use of information and communication technology to provide or support psychiatric services across distances.¹⁰ The General Medical Council¹² and the American Psychiatric Association¹³ have produced guidance on the fields of telemedicine and telepsychiatry, respectively. Notably, issues such as practicalities (including security, confidentiality, patient and provider identification, logistics, patient selection, prescribing responsibilities and reliability of equipment), as well as ethical issues including appropriate ability to escalate emergencies, are highlighted as important in such a modality.

Several reviews have focused on telepsychiatry and autism.¹⁴⁻¹⁶ Many people with intellectual disability have comorbid autism; however, the reverse is not always the case.¹⁷ Therefore, extrapolation of studies in telepsychiatry with autism, unless intellectual disability is explicitly stated, may mask the underlying needs of those with intellectual disability. Although a brief review of intellectual disability in telepsychiatry exists in the literature,¹⁸ this was methodologically flawed, as searches were limited to PubMed, resulting in omission and limited synthesis with inclusion of student teaching rather than telepsychiatry (patient-directed care).

Several innovative telepsychiatry services have been developed for use in adult, forensic, and child and adolescent mainstream (i.e. non-intellectual disability) mental health services.¹⁹⁻²² These, however, do not focus on the key issues encountered by the intellectual disability patient group and the specialist psychiatric services that serve them.

Aims

The aims of this review were to explore the effectiveness and patient and provider acceptability of telepsychiatry consultations in intellectual disability, contrasting this with direct face-to-face consultations and proposing avenues for further research and innovation.

Methods

Search strategy

A computerised search was undertaken on 10 June 2018 using the following databases: Cochrane Library, AMED, BNI, CINAHL, EMBASE, Medline, PubMed and PsychINFO. The search was of English language, peer reviewed journals for all dates available published in the respective databases.

Search terms were kept broad, to include as many studies as possible and account for the different terminology used internationally and over time for intellectual disability. The grey literature (opengrey.eu) was also searched to avoid missing relevant publications. References from papers that were selected by the search were also included if suitable studies were encountered.

The search terms for title and abstract were: (telepsych*) AND (mental* OR intellect* OR development* OR learning*) AND (deficien* OR disabilit* OR disabl* OR retard* OR disorder* OR impair* OR handicap*).

Study selection

Papers considered eligible for inclusion in this review included those where: (a) the participants were mental healthcare patients (adults or children) who were classified as having an intellectual disability; and (b) the intervention described was telepsychiatry, i.e. live synchronous or asynchronous videoconference-based clinical psychiatry. English abstracts of non-English articles were reviewed where available.

Papers were excluded where participants did not have an intellectual disability, there was no telepsychiatric intervention, or they were general review papers on telemedicine.

The titles and abstracts of reviews were identified, screened and classified for extraction of full review for further analysis by the author.

Results

A record of the searches is provided in *Fig. 1*. A total of 472 records were identified by database searches. A further 12 were retrieved by hand-searching from references. Of the 472 studies, 185 were duplicates and the remaining 299 were screened with abstracts reviewed by the author. The majority of exclusions were on the basis of the article having no clear reference to people with intellectual disability. At this stage, 107 articles were selected, including several involving participants with autism where further information was required to determine whether an intellectual disability was also present. *Fig. 1* Results of literature review search strategy.

Upon reviewing the full text of these studies, a further 103 were excluded. In these cases, the articles were opinion, commentary or editorial pieces, primary research, or addressing autism but not concerning patient groups with intellectual disability. Four studies were included in the qualitative synthesis; a summary is provided in *Table 1*. *Table 1* Characteristics of included studies

Study ID	Subjects	Study location	Intervention	Outcome	Funding	Gentile <i>et al</i> (2017)
22	900 patients,	Ohio (64 out of the 88 counties), USA	Synchronous telepsychiatry appointments with upper level residents and faculty physician partners. Various locations including homes, schools	Follow up: 4 years Data compared with year preceding intervention	Improved access to care, reduced emergency visits/hospital admissions. Cost savings, reduced travel and medical expenses	Reduced long-term services and support costs Grants from Ohio Department of Developmental Disabilities and Ohio Department of Mental Health and Addiction Services
23	Four groups of children, including one group of children with developmental disorders and severe behavioural disorders within the total of 100 participants.	Iowa, USA	Synchronous cable system connected to two public school sites and a small regional hospital from the hospital-based Center for Disabilities and Development	Two of the sub-projects included: (a) Telepsychiatry consultation – a real-time, two-way video conferencing psychiatry service for rural clients; and (b) specialised interdisciplinary consultations – a real-time, two-way video conferencing service for children with special health and behavioural needs in rural Iowa communities	Follow up: 1.5 years Phone-based interview for families and professionals	Outcomes specific to children with ID and severe behavioural disorders were not described separately.
24	Approximately 200 children with developmental disorders	Four case studies described, one involving clear behavioural or mental difficulties with an ID	Two rural counties in North Ohio, USA	Asynchronous telemedical care	School-based telemedicine program	Primarily uses store-and-forward technology to connect children with ID to their own primary care physician
				Follow up: 1 year	Post-visit survey and parent-reported outcomes	

High level of parent satisfaction, with 100% opting to continue to use service; 84% of children remained in school Grant from the Office for the Advancement of Telemedicine/HRSA (H2ATH07764) and a grant from Akron Children's Hospital Foundation Szeftel *et al* (2012) 25126 patients; 45 of these evaluated, of which 84% had an ID and 69% were children California, USA Synchronous care Collaborative-care model: primary care provider provides long-term care at the local clinic; child psychiatrist provides evaluation and recommendations at a distant clinic through videoconferencing Follow up: 3 years Retrospective chart review Prior to initial assessment, no patients were diagnosed with anxiety or mood disorders Approximately one-third of patients received one of these diagnoses in the telepsychiatry clinic Patients seen six times on average in first year and three times in the second and third years Telepsychiatrist recommended a change in patient's medication for 82% of patients at initial assessment, 41% at year 1 and 46% at year 3 Unclear¹

Study location

All studies took place in North America. Two of the studies took place in Ohio but were run by separate teams in different locations. The telepsychiatry care was provided in schools, hospitals and homes. All studies appeared to be funded by non-commercial sources.

Study designs

There were no randomised controlled trials identified. The Harper study used control groups that were evaluated on site rather than through a telepsychiatry modality and were matched using age, gender, socioeconomic status and problem type. The Langkamp study provided access to a primary care physician; while this was not a study of a psychiatric service, it was included as the cases described illustrated patient types likely to be seen in a UK intellectual disability service.

Study populations

Most studies (three) focused on children with intellectual disability, while the remaining study (Gentile23) included both children and adults with intellectual disability.

¹

ID, intellectual disability.

Sample size

Sample sizes of people with intellectual disability were unclear in two studies (Harper²⁴ and Langkamp²⁵); however the sample sizes of the others ranged from 38 to 900 participants.

Interventions

Broadly categorised, the interventions in this review included psychiatric assessment and psychiatric follow-up, provided using a telepsychiatry service. Prior to the development of the telepsychiatry service, consultations were provided in a standard face-to-face model. Studies included in this paper used both asynchronous and synchronous connections, with the latter being more common (three studies). Synchronous services provide live, two-way interactive transmission at geographically separate locations,¹⁰ thereby simulating face-to-face interviewing. Asynchronous services, by contrast, do not require the presence of both parties at the same time, and have the advantages of being relatively inexpensive and not requiring any special hardware support. The information can be transferred in the form of data, audio, video clips or recordings, and can be done by email or web applications for review by a specialist at a later date.

Length of follow-up

Follow-up length varied from 1 to 6 years.

Outcome measures

Outcome measures varied considerably across the research studies and included cost savings to both patients and healthcare providers, patient and carer satisfaction, new diagnoses and medication changes.

Notably, there was a 96% decrease in emergency room visits (Gentile²³) in the 12 months following treatment via the telepsychiatry model compared with the preceding 12 months. The authors of that study suggest that teams have access to nursing and medical staff between appointments to assist in problem-solving in real time when issues occur between appointments. They also discuss how staff provide education on de-escalation techniques and options when patients exhibit behavioural change. Although a remarkable 96% decrease was noted, one would question the practice that existed prior to the telepsychiatry model. It is likely that, as there was limited access to local professionals before, the patients and carers may have been able to access professionals remotely. Further information on this would have been useful to balance the use of high-cost medical services with multiple accesses to lower-cost services.

Gentile described hospital admissions decreasing by 85%. The authors also noted that of their first 120 subjects, none had been admitted or readmitted to state-operated institutions. They estimated the state of Ohio saving approximately US\$80 000 per person per year in support costs. As above, more information on the frequency of contacts would have been useful. Although the study highlights several patients historically having had to use state-operated institutions, it cannot necessarily be concluded that the telepsychiatry intervention was the only reason there were no admissions or readmissions.

Harper²⁴ noted a positive attitude to their telemedicine group, with 98% stating that the experience was the same or more positive. Some parents (12%) reported technical problems such as poor audio and camera movement. Professionals rated the consultations as comparable to face-to-face consultations. There were no significant differences in consultation time. Over the time period, the authors evaluated costs including time, travel and mileage. They concluded that the average saving to the local district (professional and patterns) was US\$971 per telemedicine session. Additionally, the average saving for parents was estimated to be US\$125 per session, and fewer parents missed work.

Although there was no breakdown of cases in the Langkamp²⁵ study, the case studies included one illustrating a 10-year-old girl with intellectual disability and agitation. The authors comment that her parents were absent from work for healthcare visits less often as a result of using the telemedical link. The parents also reported appreciating their child receiving quality medical care without becoming excessively distressed.

Szeftel²⁶ and colleagues reported their patients as being seen six times on average in the first year, and three times per year in the second and third years. Severity and number of symptoms were noted to have decreased over the three years, with fewer visits as treatment progressed and fewer medication changes. The authors noted that changes in medication, either in dosage or type, tended to take place in the first rather than in later appointments, with 82% of patients having a recommended medication change at the initial assessment; this may suggest an emphasis on a biological rather than a holistic approach.

Discussion

This study is the first review to undertake a comprehensive synthesis of telepsychiatry in intellectual disability. There were two major findings: (a) very few reports of such studies exist; (b) all studies took place in North America. Unfortunately, it is therefore difficult to draw firm conclusions about the benefits and constraints of such a modality in this population group. The majority of the studies had relatively low sample sizes and focused on a single nation's health infrastructure (USA); hence, extrapolation to other populations and to other countries is potentially erroneous.

Unsurprisingly, most studies focused on children, given the relative ease of implementing such systems in children's services (as children attend schools and are more likely to have parents as guardians). It is therefore difficult to extrapolate satisfaction levels of parents to those of adult patients receiving such services. Information on exact numbers of patients with intellectual disability and mental illness or challenging behaviour was missing in half the studies. None of the studies discussed any legal implications of using remote services and storage of video data, nor how to escalate difficulties if and when they arose.

The absence of randomised controlled trials, the gold standard in research study design, was a major flaw in these studies – and, in fact, in telepsychiatry research as a whole.²⁷ Furthermore, it is possible that there are commercial intellectual disability telepsychiatry services who have not published their data for economically sensitive reasons and have therefore been missed by the searches.

However, despite these limitations, it would be irresponsible to dismiss this body of evidence when taken in the context of the telepsychiatry and general telemedical literature. Most notably, several reviews of telepsychiatry in autism^{14–16} have been conducted; these offer some overlapping features that could benefit those considering setting up telepsychiatry services in intellectual disability in other countries. There are potential legal and technological issues that could restrict the development of this field, and contextualising other non-intellectual disability studies could benefit such service innovators. Greenhalgh²⁸ and colleagues recently conducted a mixed-method study on video out-patient consultations, in which it was concluded that despite such consultations appearing convenient, safe and effective, this was only in patients judged clinically appropriate and was a fraction of the overall clinic workload. The paper also highlights that the National Health Service appears to be a difficult setting in which to introduce technologies that imply major changes in service models.

The studies overall suggested positive effects of the telepsychiatry model for intellectual disability patients. Notably, an often-considered concern from professionals regarding remote consultations is the loss of subtleties and direct relationships that are built with face-to-face appointments. These studies and the literature as a whole²⁹ do not support this. In fact, there is even evidence that children with severe anxiety and autism can be more engaged during a telepsychiatry consultation.³⁰

In addition, there are notable savings to services, both directly and in prevention of future hospital admissions, which are likely to appeal to service providers. When this is taken in the context of the positive patient and carer satisfaction results noted in the studies, it is surprising there has not been a larger uptake of telepsychiatry services in intellectual disability. If they develop sufficiently, such services may eventually be classified as a reasonable adjustment as per the UK Disability Discrimination Act. In fact, the most recent National Institute for Health and Care Excellence guideline³¹ for care and support of people growing older with learning disabilities includes specific advice to 'consider the use of technologies such as telehealth and telecare to complement but not replace the support provided by people face to face'.

All studies identified were conducted in North America; no published UK or European studies were found. This is surprising, as the UK has a faculty of intellectual disability at the Royal College of Psychiatry (<https://www.rcpsych.ac.uk/workinpsychiatry/faculties/intellectualdisability1.aspx>) and a well-established training scheme for psychiatrists

to specialise in intellectual disability psychiatry,³² as well as highly active patient advocate groups such as Mencap³³ and the Challenging Behaviour Foundation.³⁴ However, psychiatric services are generally be closer to patient populations when compared with the USA. Of the locations mentioned in the studies identified, Iowa is significantly low in population density (21/km²) when compared with California and Ohio (93 and 109/km², respectively),³⁵ although it is recorded as having more urban than rural population. In the UK, the population is more dense (271/km²)³⁶ overall, with an estimate of 83% of the population living in an urban setting.³⁷ However, it is notable in the UK that many on-call rotas are non-residential, covering large geographical regions; thus, the application of telepsychiatry could benefit both patients and a significant proportion of psychiatrists who work with intellectual disability patients.

Nevertheless, despite the identified studies focusing on intellectual disability services for children, the transition period from child and adolescent mental health services to adult services could be a positive avenue of research. Collaborative multi-professional appointments may in fact ease the transition, and research involving telepsychiatry could help to determine whether this is the case.³⁸⁻³⁹ This is often a difficult period for patients, carers and professionals, particularly for those with intellectual disability.

More research in this field would be welcomed for less-developed and more geographically spaced-out healthcare systems. Implementing both synchronous and asynchronous remote consultations using some of the more accessible, encrypted and mainstream video streaming services with intellectual disability population groups is likely to become more feasible, given that broadband services (and reductions in costs) have permeated much of the globe, including geographically isolated areas. Further research in less-developed countries as well as in other healthcare systems would help to build a more robust literature and facilitate innovation in this field. The rolling out of broadband services across other nations, including the UK, has been relatively slow in comparison with the USA; this may partly explain the lack of telepsychiatry services, which require reasonable connection speeds.

Additionally, as costs of technology such as secure smartphone devices and cheap encrypted applications decrease and data connection speeds increase, it is likely that more healthcare providers internationally may consider both implementing telepsychiatry services and sharing their outcome data in the peer-reviewed literature. Integrating the findings would therefore enable best practice guidelines to be developed, for example.

None of the studies in this review mentioned the use of interpreters; their incorporation into telepsychiatry, whether for Makaton, other forms of signing or in fact more mainstream language translation, is another potential avenue of research.⁴⁰⁻⁴¹

It is feasible that access to expertise via international collaborations using asynchronous methods or taking advantage of time zone differences for synchronous methods could enable, for example, vulnerable intellectual disability populations in underserved areas to access specialist intellectual disability psychiatric care to aid in reducing mental distress. Additional health economic and environmental evaluations in differing healthcare systems could also clarify whether similar models of care are transposable to such systems. Specific evaluation of environmental benefits or effects would also be a useful outcome to evaluate in further research.

Conclusions

This study identified four telemedical psychiatric consultation studies in intellectual disability, mainly limited to children. While there is some evidence of cost-effectiveness, improvement in patient and carer satisfaction, and convenience, the fact that there were relatively few studies limited to North America would suggest there is a need to explore further these novel methods of enhancing current psychiatric services.

Telepsychiatry models appear to aid in the empowerment of this patient group, as well as providing cost savings. However, further studies are required in other countries and across a wider age range before concluding that telepsychiatry in intellectual disability is an effective, acceptable and satisfying approach for providing psychiatric services for this underserved population group.

Giri Madhavan is a Specialist Trainee (ST6) in Psychiatry of Intellectual Disability at Coventry and Warwickshire Partnership NHS Trust, Coventry, UK.

This is a comprehensive resource for professionals working with students in higher education. Subsections of the book address in turn the student experience, caring for students with mental health issues and how to foster mental health in

distinct student populations. The book takes an academically robust approach to supporting student self-care, wellbeing and development of resilience.

Individual chapters go on to address key presentations around substance misuse, suicidality, mood and anxiety disorders, psychotic illness, autism, ADHD, trauma, sleep and eating disorders. There is also an important focus upon the role of university mental health services for students who have faced sexual violence, those from military backgrounds and first generation university attenders, as well as students identifying as part of the LGBTQ community. It is in the last chapter where the challenges for ‘medical students, residents and fellows’ are explored, albeit somewhat briefly. The writers identify the unique stressors for this group and reflect upon the obstacles to seeking help such as stigma and confidentiality. It is noteworthy that all medical students in the American system are postgraduate and therefore usually older than British students, most of whom enter medical school straight from sixth form/college and are less prepared for the expectations of professionalism at this early stage of their development.

Although written from the perspective of the American educational system, in general the content is still eminently transferrable to UK institutions. Throughout the book, its contributors make few assumptions as to prior knowledge, detailing everything from the risk-taking behaviours that develop during ‘emerging adulthood’ to the descriptive psychopathology for different major mental illnesses. Each chapter’s utilisation of ‘key concept’ bullet points and case examples further increase its accessibility to the reader.

Ultimately the book makes recommendations not only on how student health programmes can achieve excellence by successfully managing students with major mental illness, but also on how all students can be supported to reach their full potential. It is a valuable resource for teachers in higher education.

1.4.25 Harold Bourne, MB BS, DPM, FRANZCP, FRCPsych

Brian Barraclough brian.barraclough@xtra.co.nz

date

2019-8

Contents

- *Harold Bourne, MB BS, DPM, FRANZCP, FRCPsych*

Formerly Senior Lecturer in Psychiatry, Otago University, Dunedin, New Zealand; Consultant Child and Adolescent Psychiatrist, Charing Cross Hospital, London, UK Harold Bourne at 94

Those who pioneer new treatments in psychiatry are usually held in high esteem. Those who successfully question established but potentially harmful interventions, though equally important, are often forgotten. This has been the case with Harold Bourne, who died recently at the age of 95 in London. In the early 1950s, while working at Netherne Hospital (a 2000 bed mental hospital in Surrey), Bourne began to question the use of insulin coma in the treatment of early schizophrenia. He wrote a notable paper, 'The Insulin Myth',¹ published in *The Lancet* in 1953. It was a review of the evidence for the effectiveness of insulin coma for schizophrenia and it concluded that the treatment was ineffective. Insulin coma, sometimes enhanced with electroconvulsive therapy during the coma, was the standard treatment for schizophrenia from the early 1930s until the late 1950s and all mental hospitals had insulin units to administer it. For a 30-year-old junior doctor this was a courageous act which challenged the authority of the profession's leaders. In 1957 (4 years after the publication of Bourne's paper), Brian Ackner and colleagues published the results of a controlled trial showing there was no difference in outcome between barbiturate-induced coma and insulin coma.² Shortly afterwards, all insulin units began to shut and this dangerous treatment went out of use.

Two other papers deserve mention. Bourne's paper on convulsion dependence³ described persistent psychoses which remained in remission only with long-term electroconvulsive therapy. This was before depot phenothiazines became available. Further, from his experience at the 600-bed Fountain Hospital for the severely mentally handicapped came his neologism 'protophrenia', a term for the dwarfing effect on mental development in children due to socially impoverished child-rearing, which could be mistaken for mental handicap caused by neuropathology.⁴ This latter observation preceded the description of psychosocial short stature or deprivation dwarfism by some 15 years.

Harold was the elder son of Jack Baum and Rachel, née Oster, and born in 1923 into a traditional London East End Ashkenazi Jewish family. His father was a tailor from Poland; his mother a school teacher. She was born in London, the daughter of Jewish migrants from Eastern Europe. Her brother was a family doctor which may have influenced Harold in his choice of career. The family anglicised their name to Bourne in 1934 but Harold always remained proud of his Jewish heritage.

Harold, known as 'Boy' in his family, won a scholarship to a grammar school in Islington, Dame Alice Owen's School. He then read medicine at University College London. His life-long interest in psychoanalysis which had begun at school was developed through his friendship with Charles Rycroft (1914–98), a contemporary at University College Hospital. Rycroft, 10 years older, was then completing his own analysis while studying medicine.

Following qualification, after 2 years of National Service at a 400-bed military psychiatric unit at Banstead Hospital and posts at Netherne and the Fountain Hospital, in 1955 Bourne was appointed Lecturer in Psychiatry in the Faculty of Medicine at the University of Otago, ultimately becoming Senior Lecturer and Senior Psychiatric Physician at Dunedin Hospital. The move to Dunedin, so he said, was to distance himself and his family from the European nuclear war he saw as imminent.

Bourne was a breath of fresh air in Dunedin, then an inward-looking academic community isolated by distance from its parent culture. He introduced the ideas of Freud and the belief that psychoanalysis could explain the causes of mental disorder and provide a treatment for them. In the absence of staff to provide this specialised treatment he used electroconvulsive therapy and drugs.

Bourne's charm, intellect and capacity for friendship influenced students and junior doctors to consider psychiatry, which was then a neglected and stigmatised specialty. He was an inspiring teacher of psychiatry with many protégées. Among those he influenced and who had careers in psychiatry in England were John Denford, Margaret Rich, John Steiner and myself. At least ten others had careers in Australia and North America.

In 1974 Bourne returned to London to a National Health Service child and adolescent psychiatry post at Charing Cross Hospital. He also established a therapeutic community at St Bernard's Hospital.

On retirement at 65 years of age in 1988 he became a psychotherapist to the expatriate anglophone community in Rome. Infirmary compelled a return to England in 2014 where he lived in a Jewish old people's residential home in Golders Green until he died.

Bourne married three times. In 1945 he married Winifred Hickson, known as Freddie. They divorced in 1980. In 1981 he married Niloufer Hickman-Fitter, divorcing in 1988. In 1989 he married Flavia Donati; they separated in 1998. With Freddie he had five children, with Niloufer one and with Flavia two. He is survived by Niloufer, Flavia, eight children, nine grandchildren, two great-grandchildren and his brother Stanford (known as Sandy) – a London psychoanalyst.

Harold Bourne was born in London 9 April 1923 and died in London 6 November 2018.

1.4.26 Addressing shame in medical professional identity: is there such a thing as a good enough doctor?

Norella Broderick Roisin Vaughan

date

2019-12

Contents

- *Addressing shame in medical professional identity: is there such a thing as a good enough doctor?*

The author of 'Addressing shame in medical professional identity'¹ is to be congratulated for bringing this topic to the fore of our consciousness. It is welcomed along with the recent surge of popular literature focusing on the emotional challenges of medical practice (particularly among trainees), including Adam Kay's *This is Going To Hurt* and Danielle Ofri's *What Doctors Feel*.

We know that shame affects the self-care of doctors; it increases the risk of mental health problems by making us less likely to access support when needed. Mental health is currently a critical issue, especially among junior doctors, who have higher levels of clinically significant mental health problems than the general population;^{2,3} junior trainees are less likely to disclose mental distress,² and the more junior a doctor is, the less likely they are to know how to access

support.³ Further, failure to disclose mental distress and access help perpetuates stigma. There remains a high rate of presenteeism,² probably mediated by shame.

We also know that shame affects patient care experiences. The author notes that shame leads to reticence among doctors to disclosure errors. This means that teams are less able to learn from the mistakes of members, and the service does not have the opportunity to improve.

The author discusses what is not helpful in addressing shame (mandated reflective writing) but is vague on practical solutions – although there is a citation of Brown, reflecting that self-compassion is the antidote to shame. To our minds, this notion comes from Prof. Paul Gilbert's school of thinking and his team's extensive research on compassion-focused therapy (CFT) to address shame in a variety of clinical settings. They found that CFT training (a three-day workshop) for healthcare providers increased self-compassion and reduced self-critical judgement in clinicians.⁴

We suggest that CFT training could be provided to doctors as part of our suite of regular training courses. Hand hygiene training is ubiquitous, and we propose that mental health hygiene training is equally important. This could be accessed through the training colleges or from employers directly, like hand hygiene education.

In considering self-compassion as a profession, we encourage doctors to view themselves as 'good enough'. Drawing on the work of Winnicott⁵ in finding that 'good enough mothers' are what babies need, we suggest that 'good enough doctors', rather than perfectionist, shamed doctors, are what patients need.

Shame can only be addressed as above if we try to commit to a culture of disclosure and of self-compassion among doctors. As the author above describes, shame is endemic in medicine. As a step towards openness, and towards addressing shame, we ask readers to consider: can I (let myself) be a good enough doctor?

1.4.27 The effect of integrated care on self-management and emergency department attendance

Nikki Scheiner Sarah Cohen Ruth Davis Tim Gale Amanda Agyare

date

2019-6

Abstract

Aims and method

The Frequent Attenders Programme is a joint initiative between Hertfordshire Rapid Assessment, Interface and Discharge service and the Emergency Department of the West Hertfordshire NHS Trust, which aims to divert frequent attenders from the emergency department by addressing their unmet needs. This paper describes the range of interventions put in place from the time that the service was set up in 2014 until the introduction of the new national Commissioning for Quality and Innovation 2017–2019, which tasked National Health Service trusts to improve services for people with mental health needs who present to Accident and Emergency. The terms emergency department and Accident and Emergency are used interchangeably, reflecting the practice in policy documents. A subsequent article will report on the impact of the Commissioning for Quality and Innovation in Hertfordshire.

Results

Analysis of the interventions indicated a highly significant ($P < 0.0001$) mean reduction in attendances. Lower gains were made in patients whose primary presentations were alcohol-related. A failure to effect change in two patients led to a significant revision of their respective care plans, resulting in a subsequent reduction in their attendances.

Clinical implications

An integrated approach to patients with complex presentations was associated with high levels of both patient and referrer satisfaction. It is hypothesised that dismantling the barriers between physical and mental health may lead to similar successes in frequent attenders in other in-patient and community medical and psychiatric services.

Declaration of interest

None.

In 2014, there were approximately 21 million visits to hospital emergency departments in England; in 2016, this number had increased to 23.57 million. The increase between 2015 and 2016 was 5.2%, equivalent to an average of 3216 more people attending each day.¹ Among these, there is a small population of patients who attend on a frequent basis, despite not experiencing a medical emergency. Analysis of the data in Hertfordshire consistently indicates that more than 80% of these patients are either currently open or known to mental health services, a figure that underscores a strong relationship between mental health difficulties, unmet needs and a search for urgent help. The lack of an integrated approach to mental health has been implicated in the significantly reduced life expectancy of those suffering mental illness.²

Rates of frequent attendances to UK emergency departments

The definition of a frequent attender varies, with some National Health Service (NHS) trusts focusing on the admission rate of repeat attenders, and others focusing on the inappropriate attendance rate. In Scotland, a frequent attender is defined as someone who attends the emergency department 10 times or more in a 12-month period, or more than 5 times in a 3-month period. In England, in 2012–2013, 12 000 people made more than 10 visits in a 12-month period to individual emergency departments, with just over 150 attending on more than 50 occasions; some individuals attended nearly 250 times in 1 year.

Official concern about these rates coincide with the release of official figures in early 2015 that recorded the NHS's worst performance in emergency department for a decade, with 8.4% of patients forced to wait for more than 4 h after arriving at hospital. In February 2015, the *London Evening Standard*, using information obtained under the Freedom of Information Act, reported that 'hundreds' of patients are visiting London hospitals on more than 20 occasions each year.³ In February 2016, the London Ambulance Service disclosed that they currently had 47 768 'non-managed' frequent callers in the capital, resulting in an excess of 183 000 conveyances to hospital.⁴ In June 2017, the *Quarterly Monitoring Report* of The King's Fund, reported that in the previous 12 months, 2,500,000 people in the UK had spent more than 4 h in emergency departments, and that the finance leads of the Clinical Commissioning Groups stated that the pressures on emergency departments are their highest operational concern.⁵

Hertfordshire initiative to improve care offered to frequent attenders

The awareness of the widespread negative consequences of inappropriate attendances at emergency department led to the creation of The Hertfordshire Rapid Assessment, Interface and Discharge (RAID) Frequent Attenders Programme. This paper describes the development of a joint initiative between Hertfordshire Partnership University NHS Foundation Trust and Watford General Hospital to offer standardised care to frequent attenders. Both the successes and the challenges of implementing individualised and co-produced care plans are discussed, and are followed by reports of the outcome data for the first 2 years of the programme.

The pathway reflected the shared understanding that patients suffering mental health problems face long waits in environments not suited to prevent crisis escalation; many self-discharge before receiving a mental health assessment. Additionally, individuals may face negative attitudes from general hospital staff toward people experiencing a mental health crisis, particularly toward those who self-harm.⁶ Consequently, their needs continue unmet and their attendances persist. At the same time, resources are diverted from patients requiring medical treatment.¹

¹ Hertfordshire RAID is currently working with the police to harmonise the risks assessments that the NHS and the police use to determine the most appropriate course of action when a patient leaves the emergency department before assessment.

Method

The West Hertfordshire Frequent Attenders Pathway

Aims

The West Hertfordshire Frequent Attenders Pathway was set up in early 2014, expanding on an earlier RAID initiative that solely focused on frequent attenders to Watford General Hospital who were also known to mental health service. The revised remit extended to include prolific attenders either not known or not currently open to services. This reflected the finding that in the absence of a bespoke care plan, the frequency of patients' attendances either remained consistent or increased over a 12-month period. A core group comprising the RAID Consultant Psychiatrist and Consultant Psychologist, an Emergency Medicine Consultant and Senior Sister from the Emergency Department at Watford General Hospital and liaison workers from the country drugs and alcohol service Change, Grow, Live, initially met on a monthly basis (now bi-weekly) to identify patients who had attended the emergency department more than 15 times in a 12-month period, or who showed a recent escalating pattern of attendance (*Fig. 1: 2009–2013*). *Fig. 1* Presenting complaints of frequent attenders to Watford General Hospital.

Method: from single intervention to biopsychosocial assessment and multiagency meetings

Before the 2017–2019 Commissioning for Quality and Innovation (CQUIN), which tasks NHS trusts to achieve a 20% reduction in attendances of patients with mental health difficulties to Accident and Emergency (A&E) departments, referrals were accepted from clinical navigators in the acute general hospital and all staff working in the emergency department and the RAID teams. Cases were prioritised according to clinical need, and individual interventions put in place as appropriate. In some cases, this was as simple as sending an email to a specialty consultant asking for a review of the patient's condition, or involving district nurses in ongoing care of patients' daily needs.

Patients with comorbid physical and mental illness, or only with mental health difficulties, were invited to an assessment with the consultant psychologist. The key features of the assessment were its comprehensive evaluation of all areas of the patient's life (domestic, social, occupational), whether problematic or not, and the lack of time constraint. This enabled the clinician and the patient to achieve a joint understanding of the precipitating and maintaining factors for the frequent emergency department attendances, and formulate a bespoke and dynamic care plan, which could be modified as the patient's circumstances changed.

Patients with more complex presentations, for example, with multiple comorbidities and/or psychosocial difficulties, were discussed at a multiagency meeting, with the patient's general practitioner (GP) playing a pivotal role. To maximise attendance of involved professionals, invitations were sent out 2–3 weeks in advance, and followed up by a telephone call. Meetings were often arranged to take place at the patient's local surgery to accommodate GP clinic schedules; alternatively, conference call facilities were arranged. Participating agencies included the emergency services (the police, the east of England ambulance service, and – on occasion – the fire service), social services, specialty consultants, pain nurses, housing associations, children and family services, community mental health services, service managers and representatives of the two trusts' respective legal departments. In cases when key stakeholders were unable to attend or contribute by telephone, the findings, together with the meeting's draft care plan, were mailed to them.

The care plan

The patient's and/or carer's involvement in the planning meeting varied between individuals. In cases where guardianship is discussed, family/carers are routinely invited; where there are known engagement difficulties, the patients and their families (if they so wished) were invited to join the second part of the meeting, which would typically be attended by fewer clinicians to reduce potential stress for the patient. Following the agreement with, or at least the acceptance of the draft plan by all stakeholders, it was signed by the patient and a nominated health professional (usually the patient's care coordinator) and then distributed to all agencies and services, including the Mental Health Helpline. A copy of the care plan, including its review date, is kept in the patient's emergency department folder, so that it can be accessed whenever they attend, including out of hours, when junior doctors often come under pressure from patients to provide inappropriate treatments.

A more flexible approach was adopted with patients whose lives tended to be more chaotic often because of psychosocial issues such as homelessness and addiction. The Multi-Disciplinary Team discussion of the needs of these individuals would typically end with an agreement that if they attended the emergency department, the RAID psychologist would be advised so that (if possible) an on-site assessment could be conducted. If this was not possible, the patient would be invited to a biopsychosocial assessment. If the patient did not attend, an attempt was made (with the patient's consent) to meet at their GP surgery. Assessments have also been conducted at a homeless hotel, an intervention dependent upon both the assessor's availability at the time the patient presented and the patient's state of sobriety.

In all cases, emphasis is placed on the therapeutic ethos of the care plan: professionals attempt to balance what is given to the patient (for example, a referral to psychological therapy or access to community activities) with what is taken away from the patient (for example, ambulance conveyance to the A&E department on demand). If the patient's circumstances change, an earlier review meeting may be called.

Non-engagement

Patient non-engagement with services does not preclude the implementation of a multiagency care plan. It may change, however, the nature of the interventions. *In extremis*, the emergency services (both the police and the ambulance service) imposed a malicious telephony fine for wasting emergency services' time or, on very rare occasions, made an application to the court to demote the security of tenancy or evict a tenant whose frequent calls and troublesome behaviour significantly affected the mental health of vulnerable neighbours. The Frequent Attenders Programme trialled a collaboration with an organisation that worked with those with chaotic lifestyles (typically homelessness and substance misuse) who cost the NHS in excess of £75 000 *per annum*. The organisation, Reducing Chaos, provided transport to patients to support them to attend medical appointments, benefits interviews, addiction groups and meetings relating to their housing.

Data confidentiality

Terms of Reference for the Frequent Attenders Programme are sent to the Caldicott Guardian of all participating agencies and services to enable the sharing of information on a need-to-know basis.

Results

In demographic terms, the largest number of frequent attenders were women in the 26–39 years age group. In terms of cost to the NHS, the most expensive group were the over 65 years age group of both genders. These patients typically lived alone, had limited social networks and appeared to derive considerable comfort from the care and attention they received in the emergency department. Young adults (18–25 years) were disproportionately represented in the cohort, highlighting both the lack of good transition services between child and adult mental health services, and the need for improvement in treatments for those with emerging personality disorders.

In the first 2 years of the Frequent Attender Programme, 126 patients were referred to the Frequent Attender Pathway, 90 of whom were deemed appropriate. Of the 36 not accepted, 12 fell below the threshold rate for inclusion on the

Pathway; 24 patients reduced their attendances before an intervention was put in place, reflecting an improvement in their housing status. The number includes some out-of-area patients and a small cohort not been previously known to mental health services. Notwithstanding, the majority (>70%) are or have been open to community mental health teams in the county. As expected, most of these patients present with complex needs, including dual diagnosis (mental illness and substance misuse) or dual diagnosis together with a physical health problems. The primary diagnosis of the Hertfordshire frequent attender population is represented in *Fig. 1*, although it should be emphasised that there is considerable overlap between most of the conditions.

Results for the first 40 patients to complete 12 months after the RAID intervention, whether in the form of a biopsychosocial assessment and simple care plan for a new frequent attender or a multidisciplinary care plan for a patient with chronic and more complex needs, showed a substantial reduction in attendances for just under 90% of patients. In the 12 months pre-intervention, the mean number of attendances was 19.9 (mean, 19.88; s.d. 14.49); this figure dropped to a mean of 6 (mean, 6.00; s.d. 9.95) in the 12 months post-intervention ($t(40) = 6.32, P < 0.0001$). The mean associated cost similarly reduced from £7557 (mean, 7557.58; s.d. 5545.79) 12 months pre-intervention to £2097 (mean, 2097.29; s.d. 3904.20) in the 12 months post-intervention ($t(40) = 6.12, P < 0.0001$). The reductions in both attendance and cost are highly significant ($P < 0.0001$).

In terms of attendances, the highest number for any individual in the 12 months before the RAID intervention was 61; this patient has only attended once in the subsequent 24 months (*Table 1*). In financial terms, the cost of the most expensive patient on the Pathway was £21 567. The average cost of attendance was £354, as compared with a minimal intervention cost of £67.00 (advice only) and the next level of intervention, which costs £87.00 (advice plus painkillers).² In another case, a patient attended 34 times before the care plan and 4 thereafter. *Table 1* Patient vignettes Vignette 1 Vignette 2 Vignette 3 Presenting factors 45-year-old male malingerer; long forensic history 67-year-old woman with history of childhood sexual abuse and social deprivation made multiple daily calls to ambulance service;

asked ambulance crew to stop at Costa on the way to hospital; asked for sandwiches on arrival at A&E 50-year-old man relapsed 2 months after leaving a private alcohol rehabilitation programme; because of the risk he posed to his children, he was obliged to leave the family home, and ended up sleeping on the streets Rate of attendance 45 attendances throughout A&E departments in South-East England 45 A&E attendances to West Herts 11 A&E attendances to West Herts Care plan RAID psychiatrist worked with the police to place him on the Police National Computer, and negotiated a high threshold for detention under section 136 to avoid reinforcing maladaptive behaviours Following a professionals meeting, and with her agreement, she was rehoused in supported accommodation Urgent intervention, facilitated by the Hertfordshire FAP, the emergency department Medical Registrar, CGL and the Crisis Team found him a crisis bed in a residential placement, where he completed a community detox with chlordiazepoxide Outcome and new rate of attendance One in the 24 months following the plan Zero in the 24 months following the plan Zero in the 24 months following the plan³

As shown in *Fig. 1*, alcohol is the primary presenting issue in 34% of referrals. Patients with alcohol dependence often lead chaotic lives and tend to present to the emergency department only when drunk, making a meaningful assessment difficult. They also tend to ‘disappear’ for extended periods of time, either because they move between counties or because they are sentenced to prison sentences, typically for theft of alcohol. Their attendances also trace a different

² Figures do not include unscheduled GP attendance or East of England triage (£97 for ‘hear and treat’; £237 for conveyance). The costs of residential care placements are similarly excluded.

³ A&E, Accident and Emergency; West Herts, West Hertfordshire hospitals; RAID, Hertfordshire Rapid Assessment, Interface and Discharge service; FAP, Frequent Attenders Programme; CGL, Change, Grow, Live service.

pattern to other frequent attenders: typically, they have cycles of abstinence alternating with cycles of relapse.

Discussion

Analysis of the results of the Hertfordshire Frequent Attenders Programme underscores that the most effective way of reducing inappropriate attendances and enhancing patient self-management is locating the frequent attender at the centre of the care plan. The Programme demonstrates that close collaboration between RAID and the emergency department, an integrated multiagency approach and a holistic assessment of the patient's needs improve outcomes. Although individualised care plans can, at least in theory, be drawn up by the Multi-Disciplinary Team in the absence of the patient, the patient's involvement, which may range from a brief assessment in the emergency department up to active co-production, is associated with a greater reduction in attendances. In complex cases, co-production demands a high level of flexibility on the part of the RAID team, including the willingness to offer an outreach service if required. Giving the patient the time they need to explain their difficulties is, unsurprisingly, reflected in individual behavioural change.

The Hertfordshire initiative, as well as programmes set up by other NHS mental health trusts, highlights that many patients who are frequent attenders to their hospital emergency departments have received suboptimal care or simply fallen through a gap in service provision. It is clear that the reasons for non-emergency attendances are complex, and multifactorial. Further, mental illness may or may not be involved in patients' presentations: 24% of the frequent attenders referred to the North-West London local CQUIN (2013–2014) were reported to have complex psychiatric morbidities. Geographical variations reflect different socioeconomic demographics and patterns of migration. What emerges equally clearly is the close relationship between patients receiving suboptimal care and the lack of integration both within and between NHS trusts, and between the health and social care systems. The outcome is either silo provision, gaps in care or duplication.

Several factors are implicated in the failure to provide comprehensive integrated care. Separate commissioning arrangements for substance misuse (a common reason for frequent attendance) and mental health result in disjointed service provision for patients. A lack of communication both between agencies, such as social services, the police and the acute general hospital, and between community and acute teams, forestalls any attempt of a seamless service provision. The problems of commissioning and communication (service factors) are exacerbated by the sizeable number of frequent attenders, often with dependency issues, who access urgent care centres or attend hospitals outside their own trusts (patient factors). In the first scenario, they may provide an alias, or simply not give their full details. In the second case, there is, to date, no communication between trusts unless a dedicated and savvy emergency department consultant alerts colleagues in neighbouring trusts. Requests from neighbouring trusts for information related solely to the number of attendances of an individual are often delayed or even lost in information governance systems. It seems highly probable the current figure of the 200 000 annual unscheduled frequent attendances are an underestimation.

It may be significant that frequent attenders typically make a high number of complaints about the medications and investigations offered, and/or their perceived treatment by emergency department staff. Some inappropriately request admission; others self-discharge prematurely. Many are angry; most are lonely. Those with limited psychological insight may project their frustration with their lives on to the emergency department. The experience of the Hertfordshire Frequent Attender Programme underscores that a multidisciplinary and, where appropriate, multiagency approach helps professionals manage their own emotions and enables patients to reflect on their own difficulties and make meaningful change. The strong therapeutic ethos of care-planning and individual interventions deepens stake-holders' understanding of the interplay between the medical, social, psychiatric and biological vulnerabilities of patients, and is reflected in the positive feedback from both patients and referrers. Exploring the reasons for inappropriate attendances at the emergency department in an unhurried manner, with compassion and an absence of judgement, helps identify not only the predisposing and presenting factors in an individual's maladaptive coping strategies, but also the biopsychosocial perpetuating factors. Once the problem has been clarified, it becomes possible to look for solutions.

Other frequent attender programmes and future directions

Early work with frequent attenders in 2012–2013, undertaken by the West London Mental Health NHS, led to the development of a local CQUIN in Central North-West London. Building on the work undertaken by the West London Mental Health NHS Trust in 2013–2014, a local CQUIN initiative was developed to identify the most frequent attenders in each of the nine A&E departments, and to create a sustainable model to reduce their unscheduled attendances. The most common primary reason for presenting at an A&E department in this cohort of 128 patients was substance misuse and attendant problems (34%), followed by long-term medical conditions, either with or without a comorbid mental health condition (27%). The elderly frail with globally deteriorating physical health accounted for 15%, and the remaining 24% mainly comprised complex psychiatric morbidity.⁷

A smaller pilot project ($N = 20$) targeting frequent attenders in the Royal Bournemouth Hospital in 2013 reported that, ‘in many cases’, medically unexplained symptoms drive unscheduled presentations to the A&E department.⁸ This finding may be contextualised in light of the report by Bermingham *et al* into the cost of somatisation among the working population in England and Wales in 2008–2009 which found the cost to the Exchequer of patients with medically unexplained symptoms to exceed £18 billion, a figure that may be compared with the cost of caring for people with dementia.⁹ Costs to the NHS (investigations, treatments, consultations) amounted to £3 billion, with the rest being accounted for by benefit payments, loss of productivity through unemployment and reduced quality of life. In the time since the publication of the report, these figures have increased (Senior Policy Advisor, Centre for Mental Health, personal communication, 2016).

Further analysis was provided by Clifford Mann, President of the College of Emergency Medicine, who identified two cohorts of inappropriate frequent attenders at the emergency department: those unwilling to wait for a GP appointment and migrants, unfamiliar with the English system of healthcare.¹⁰

The initiatives outlined above together with the work in Hertfordshire indicates that the scope for developing the model is considerable. An assertive outreach pathway is already being trialled by the Watford RAID service. The pathway could additionally be extended to include frequent attendances to GPs and to primary and secondary community services, as well as to admissions to the acute general hospital. Integrated commissioning with other projects that target unmanaged complexity and frequent service use is already under discussion. The potential both for sharing good practice, training and education at a local, regional and national level is considerable. Helping people improve their quality of life through self-management, as well as bringing about significant savings to health and social care economies, benefits individuals and the wider society.

Limitations

The limitations of the study relate to both internal and external validity. The study design does not allow causality to be established between the intervention (the care plan) and the outcome (the frequency of attendances). Aware that the use of a control group or a randomised methodology were both ethically problematic, the researchers compensated by collecting both retrospective and prospective data. Future studies will seek to establish internal validity by increasing the size of the population studied and extending the follow-up period to 3 or 5 years.

The regional focus of the study limits its generalisability. Relative to London, Yorkshire and North-East England, Hertfordshire (and other regions of the East of England) has a small refugee and migrant population. Comparing interventions and outcomes with the results in areas with large populations of asylum seekers and migrants, who typically use the emergency department as their first port of call, will improve the level of evidence, perhaps leading in time to the development of a national protocol for improving the lives of frequent attenders.

We would like to thank Dr Niall Galbraith for his invaluable support, expertise and kindness as a mentor under the *BJPsych Bulletin* author mentoring scheme.

1.4.28 Correcting inaccurate assumptions underpinning Transforming Care in England

Jean O'Hara

date

2019-6

Contents

- *Correcting inaccurate assumptions underpinning Transforming Care in England*

John Taylor¹ is an experienced responsible clinician looking after offenders with intellectual disabilities and/or autism presenting with complex needs. I can accept the perceptual position he has taken on some of the challenges outlined in his editorial. However, his assertion that underpinning Transforming Care is an assumption 'that the hospital is always bad, and community is always better' is inaccurate. We have explicitly said that some people will need specialist in-patient care, treatment and support at times. When this is needed, we should strive to deliver better quality care, a reduction in restrictive practices, therapeutic environments, improved patient experience and reduced lengths of stay. At the start of the national learning disability programme, we had a five-fold variation in the 'need for admission' to a mental health/learning disability bed across the country. This has now reduced to a three-fold variation. The National Health Service (NHS) Long Term Plan (www.longtermplan.nhs.uk/wp-content/uploads/2019/01/nhs-long-term-plan.pdf) is explicit about its focus on increasing investment in intensive, crisis and community support and improving the quality of in-patient care across the NHS and independent sector.

I am the clinical lead for the national learning disabilities programme in England

1.4.29 Care programme approach – time to move beyond?

David Kingdon

Correspondence

David Kingdon (dgk@soton.ac.uk)

date

2019-6

Abstract

The Care Programme Approach (CPA) has been instrumental in embedding principles of holistic collaborative assessment and management into mental health care. Initially, its implementation was assisted by targeting those at greatest need. However dichotomising patients into more and less

severe is now considered unhelpful and has been demonstrated to be unreliable. Division of patients into severe and not severe categories is no more logical than such a division of patients with physical health problems. CPA principles are now applied to all patients in mental health services and practice needs to move to individualised care, focusing on meeting quality standards and achieving positive outcomes. A system based on evidence-based clinical pathways and reliable measures of severity and need should replace the current approach.

- *Care programme approach – time to move beyond?*
 - *CPA and clinical pathways*
 - *Do we need CPA?*

The Care Programme Approach (CPA) was established in 1991 in England to ensure that a safety net of care was provided for people with severe mental illness.¹ It set out requirements for health and social care assessment, including risk assessment, involving patients, carers, the multidisciplinary team and other agencies. It was a response to the Spokes inquiry into the death of Isobel Schwarz, a social worker whose death, it concluded, resulted from a lack of effective coordination of the care of a person who was severely mentally ill.² Patients accepted by mental health services were required to have a key worker, a care plan and a review date. The policy described two levels, basic and enhanced. In practice, this generally meant that patients on a basic CPA were seen by a single practitioner, often a doctor in the case of out-patients, while those on an advanced plan saw a doctor, a non-medical mental health professional (later designated as a care coordinator) and, where involved, other agencies.

In 2008, the CPA was refocused on the enhanced level, although the previous requirements remained for all those under mental health services.³ The impetus for this ‘refocusing’ came from the recognition that allocation to CPA was inconsistent, and that there was a need to improve care coordination and reduce bureaucracy. A set of criteria were introduced to determine eligibility for ‘new CPA’, and principles for working with patients on CPA were described in detail.

CPA was therefore revised to describe a group of patients with more severe mental illness. Targets have been set by the government (Monitor and now NHS Improvement) for all CPA patients to have a care plan reviewed every year and, under the National Commissioning for Quality and Innovation payments framework, to receive at least an annual physical health check. The number of people on CPA is also sometimes used as a proxy for the severity of illness of individuals in services and on caseloads, and for use in service redesign.

Services have now progressed such that the broad principles of CPA are fully accepted by professionals and regulatory bodies (*Fig. 1*). However, there is no evidence as yet that CPA criteria are applied consistently across services, or that this has improved over the years:⁴ current figures range from 1.7% to 23.5% of patients allocated to CPA,⁵ which is not proportional to morbidity. Similarly, there is no sign that the quality as opposed to quantity of care plans or health checks and interventions is adequate. The CPA definition is broad and subjective, and applying a ‘tick box’ approach to care plans and physical health checks is at best only a first step towards improving their application. Dichotomising patients into CPA or not is overly simplistic and allocation of resources has not explicitly followed, although managers probably give consideration to providing increased resources and time for increased need (whether on CPA or not). It has also contributed, despite the emphasis on its being primarily a clinical process, to an administrative rather than a person focus: ‘Care plans were described as administratively burdensome and were rarely consulted. Carers reported varying levels of involvement. Risk assessments were central to clinical concerns but were rarely discussed with service users. Service users valued therapeutic relationships with care coordinators and others, and saw these as central to recovery’.⁶

Fig. 1 Care programme approach.

When it was introduced, CPA was intended to lead to a prioritisation of service delivery to people according to their needs. The allocation to enhanced CPA can be argued to have initially achieved this, and refocusing on CPA provided further reinforcement. Such prioritisation remains necessary, but allocation to CPA is a blunt instrument. In practice, applying targets to CPA and the bureaucracy that has often developed have also been disincentives to allocating patients to it.

An option to remedy this might be to seek to improve reliability of allocation to CPA by using outcome measures which profile severity, such as the Health of the Nation Outcome Scales (HoNOS). Symptom and/or social measures on HoNOS or Clinical Outcomes in Routine Evaluation (CORE)⁷ and risk ratings could be used in combination, for example, all patients rated as having severe mental illness (i.e. high symptom scores, or moderate with significant disability) and a medium or high risk rating according to national guidance⁸ for more than a month could be included. The criteria also might include consideration of a range of other issues, for example, multi-agency involvement and carer stress, but these would be more difficult to quantify reliably.

CPA and clinical pathways

The principles of CPA have therefore been accepted as an essential foundation on which improvement of the quality of community services has been based, and broad consensus has been reached that it should be applied. However, CPA may no longer be assisting in moving services towards systematic application of the evidence-based clinical guidelines and quality standards which have been developed since it was instigated. The National Institute for Health and Care Excellence (NICE) has described these for a range of clinical conditions, and they have been operationalised into care pathways describing ‘what should happen when’.⁹ This requires individuals to be allocated to care pathways in accordance with their needs, which go beyond ‘severe’ and ‘less severe’ categories. These quality standards and outcome measures are relevant to pathways and need to be systematically implemented and monitored. Clinical measures such as the HoNOS and patient-rated measures such as DIALOG¹⁰ support this and are relatively simple and quick to use. DIALOG asks how satisfied the person is about key issues in their lives: not just mental and physical health, but accommodation, leisure, safety and relationships. It profiles need and clinical state, provides a patient-rated experience measure and links directly to care plans by eliciting the specific issues with which the individual wants help (*Fig. 2*). *Fig. 2* Pathways, outcomes and standards.

Such outcome measurements can allow the development of definitions of recovery, meaningful improvement, stability and deterioration. These may be more complex than those used for Improving Access to Psychological Services, but, in practice, it is feasible to set service definitions using these measures and other available information, e.g. relapse or disengagement from services. Recovery or improvement can be reflected by using a balance of increased satisfaction levels, symptoms, functioning and lower needs. Quality and outcomes can be improved and payment systems developed to replace block contracts, which have been blunt and ineffective instruments to fund services and are very vulnerable to arbitrary cuts. Subdivision into costing groups will become possible as data develops with greater clinical validity and reliability than the current ‘clustering’ system.¹¹ These costing groups can use some of the principles and practice used in ‘clustering’, but by using condition pathways and severity scores linked to clinical guidelines and quality standards.

A starting point, therefore, is allocation to pathways, e.g. psychosis, affective, emotionally unstable personality and organic mental disorders, using broad NICE clinical guidelines which can be expanded to the further pathways, e.g. within affective disorders, bipolar, depressive and individual anxiety disorders, as these are embedded in services and reach across the lifespan. Although patients may have multiple conditions, primary pathways can usually be allocated in practice. HoNOS and other measures can then be used to determine symptom severity to provide groupings and weightings for physical health issues, and social needs can be incorporated. Use of pathways and severity can lead to more meaningful prioritisation than attempting to allocate to CPA or non-CPA across all patients with mental illness. Prioritising within each pathway in terms of need and risk is more meaningful for measuring whether standards are being met and directing evidence-based care.

Our experience with replacing clustering with allocation of pathways, DIALOG, HoNOS and standards assessment with an algorithm for severity/pathway ‘clusters’ has been positive, with ready acceptance by mental health staff (over 5000 allocations made within the first 3 months). This algorithm is now providing clinically relevant data to redesign, support and manage services, and is being developed with local clinical commissioning groups for costing purposes.

Do we need CPA?

So do we need to retain CPA? 'Allocation to CPA' is currently a means of defining a level of severity, but allocation to clinical pathways and use of outcome data to profile groups is a much richer and more reliable approach to identifying and quantifying need. Clinical practice is not dependent on whether someone is on CPA or not, but is an individualised process. CPA has been invaluable in setting principles and practice to follow as services in the community have developed, but mental health services now need to move beyond it. CPA might possibly have a role in differentiating those with greater risk and need from those with less risk, but is this really helpful in clinical practice, service design and benchmarking?

Why should NHS Improvement, as currently, expect 12-month reviews of care plans only for people on CPA? Isn't this relevant to all people in mental health services, although the complexity and length of a care plan will vary according to the needs addressed? Is the physical healthcare of people on CPA, another target, more important than that of those who are not? There is certainly an issue of prioritising resources to ensure the most effective care, but isn't a person who is not on CPA with diabetes at least as in need of linking with primary care as one who is on CPA but lacks a physical health problem? CPA has done an invaluable job, but time has passed and more individualised and sophisticated pathway-based systems should now be adopted.

I acknowledge the Southern Health NHS FT/Hampshire CCG CPA and care planning group and the UK Routine Clinical Outcome Measures group, whose comments have contributed to this article.

David Kingdon is a professor of Mental Health Care Delivery at the University of Southampton, and Clinical Director (Adult Mental Health) and honorary consultant psychiatrist to Southern Health NHS Foundation Trust. Rehabilitation services in Hackney, London, led by John Reed (then senior psychiatrist in the Department of Health), and in Bas-setlaw, Nottinghamshire where David Kingdon was clinical director, were the inspiration for the CPA policy after the professional bodies at that time had been unable to agree a way forward. After moving to work in the Department in 1991, dissemination of CPA was a key part of the role as a senior medical officer. David Kingdon's interest in the CPA process and development has continued since appointment as a professor of mental health service delivery and through involvement in many policy, research and management initiatives, and in developing and implementing evidence-based practice for severe mental illness.

1.4.30 Provision of weight loss programmes and their influence on weight after 1 year: follow-up survey of usual care in the STEPWISE study

Lizzie Swaby Richard Holt Rebecca Gossage-Worrall Daniel Hind

date

2019-10

Contents

- *Provision of weight loss programmes and their influence on weight after 1 year: follow-up survey of usual care in the STEPWISE study*

In 2014, the National Institute of Health and Care Excellence (NICE) recommended that people with psychosis, especially those taking antipsychotic medication, should be offered a combined physical activity and healthy eating intervention.¹ Moreover, from 2014, Commissioning for Quality and Innovation (CQUIN) supported these recommendations by introducing annual financial incentives to mental health trusts in England to improve their provision of physical healthcare.² However, our previous survey conducted in 2015 of ten UK National Health Service mental health trusts participating in the STEPWISE trial³ highlighted that such interventions were largely unavailable, and where programmes were offered these were variable and not always widely accessed.⁴

As a follow-up to our previous survey,⁴ and in conjunction with the STEPWISE study,³ we investigated changes in usual care provision of physical activity and/or healthy eating programmes during the course of the STEPWISE trial. As with the initial survey, mental health professionals completed the survey on behalf of the same ten participating STEPWISE sites.

The number of trusts offering trust-led lifestyle programmes declined from eight to four out of ten during the study. In those trusts not offering programmes, patients were often signposted to externally run services, such as council or voluntary-sector programmes, which was also the case in the first survey.

Seven sites reported changes in services since the previous survey. These included an increased awareness of the need for physical health monitoring; expansion of existing services such as dietitians, healthy living services and gyms; and new provision of services, for instance, one trust had formed a planning group to develop a trust-led programme.

More trusts reported offering support to stop smoking than in the first survey (60% v. 30%), with three trusts either being or becoming smoke free since baseline, and more sites providing access to smoking cessation advisors.

A similar number of surveyed trusts reported recording biomedical measures prior to starting antipsychotic medication, but more trusts reported ongoing monitoring of physical health measures at 1 year than in the first survey, indicating a move towards compliance with the NICE guidelines.

This follow-up survey suggests that trusts are beginning to implement some aspects of NICE physical health recommendations, but the availability of lifestyle programmes offered to patients remains limited. Possibly reflecting the influence of the national CQUIN programme, awareness of the importance of physical health in mental health is increasing, and staff are reportedly more knowledgeable about the services that are available to patients within their trust, including programmes and facilities offered by external services.

Further research would be needed in order to generalise these findings to all UK mental health trusts, as only STEPWISE participating sites were surveyed, which may have resulted in a biased sample. In addition, a longer-term follow-up may have revealed more substantial changes by allowing more time to overcome barriers and implement processes.

1.4.31 Praxis makes perfect?

Cate Bailey

Correspondence

Cate Bailey (cate.bailey@nhs.net)

date

2019-6

Abstract

Cate Bailey outlines the origin and goals of the new trainees' section of the *BJPsych Bulletin*. 'Praxis' will involve two components. The first will be clinically inspired and problem based. Trainees will have an opportunity to collaborate with experts from different disciplines to examine how existing literature and knowledge can be applied to practice, with a clinical scenario forming the basis for discussion. The second component will be made up of commissioned or proposed editorial-type articles on subjects which fall broadly under the heading of personal and professional development. This will offer a space for reflection on relevant contemporary topics such as resilience, burnout, supervision, and patient involvement and co-production.

Declaration of interest

C.B. is editor of the *BJPsych Bulletin* trainees' section.

Contents

- *Praxis makes perfect?*

It was a surprising, not to mention slightly terrifying honour to be offered the role of Editor of the new trainees' section of the *BJPsych Bulletin*. Three years after achieving my membership of the Royal College of Psychiatrists, I find I have stumbled into the heart of the institution itself. So perhaps I am justified in experiencing an episode of acute (on chronic) imposter syndrome. Each of the RCPsych journals were, to my colleagues and I training in Australia, the most esteemed publications one could imagine. Until now, my own attempts to grace these pages had been limited to poetry – though those two small references, I think, have added significant gravitas to an otherwise relatively slim academic CV.

The *BJPsych Bulletin* has a long history of offering trainees opportunities where they can gain editing experience. Since 1999, the *Psychiatric Bulletin*, as it was formerly known, held posts for trainees to sit on the Editorial board, engage in peer reviewing and develop an individually selected project during their three-year tenure.¹ This new post, however, represents a unique challenge to create an entirely new section focusing on trainees and education. It is already apparent that the *Bulletin* regularly publishes on topics of education and training, and on clinical issues relevant to trainees. This is perhaps why it is one of the most frequently read journals among trainee psychiatrists in the UK.² So, how to take this further?

While preparing for the interview for the post, I allowed my mind to run wild with all the things I would like to read about: issues I felt were pertinent to the trainees of today, and the psychiatrists of tomorrow, in the current climate of uncertainty and austerity. These are strange times indeed. Core trainee recruitment is up by a third, at least in part thanks to the RCPsych #choosepsychiatry campaign, which aimed to challenge the perceptions that patients with mental health conditions don't get better, and portrayed the specialty as a unique chance to understand a person from multiple perspectives.³ These figures are more impressive still, given that applications to specialty training are falling overall and junior doctors are apparently leaving in droves.⁴ However, the life of psychiatry trainees is far from rosy, as eloquently outlined in the trainee-led review into morale and training in psychiatry, aptly titled 'Supported and Valued?'.⁵

The new section, is of course, a work in progress and will no doubt evolve in response to the limits of reality, time and what is achievable in the medium of print. Having said that, one of my goals is to find ways to engage readers beyond the

traditional journal form, through online content, Twitter discussions and podcasts. Although a reluctant millennial, and generally inept user of social media, I've been inspired in this area by my enthusiastic geriatrician colleagues @MDT_podcast, and by psychiatrists Katherine Adlington (clinical editor @bmj_latest and @Kateadlington), Derek Tracy (@Derektracy1; Editorial board member and social media leader @TheBJPsych) and none other than the Twitter queen herself: our distinguished president Wendy Burn (@wendyburn). These represent a handful of the growing number of clinicians and researchers who are connecting creatively, finding novel and inclusive ways of sharing, discussing and debating information. The Bulletin will be regularly tweeting updates including news about the trainees' section via #BJPBulletin.

Naturally the first task when developing any new section (after buying fresh stationery) is to think of a snappy name. Inspired by phenomenology and psychopathology, I found myself immediately searching for German words. It was tempting to settle upon 'weltschmerz' (meaning world weary, or 'mental depression or apathy caused by comparison of the actual state of the world with an ideal state').⁶ Though perhaps a little too sullen, it did capture something of the zeitgeist and the mood of many junior doctors. Other contenders, although clever, were slightly esoteric, e.g. 'verstehen' ('empathic understanding of human behaviour').⁷ Perhaps if I had been more Twitter-savvy I would have conducted a poll. But the aforementioned limits of reality (particularly time) meant it had to be an executive decision. And so we came upon 'Praxis'.

Derived from Greek, praxis means 'the exercise or practice of an art, science, or skill' or 'practical application of a theory'.⁶ In a more occupational or neurological sense, it is the ability to plan or execute movement (<https://medical-dictionary.thefreedictionary.com/>). It also has further connotations in educational theory. Paulo Freire, one of the most influential thinkers about education in the late 20th century, regarded praxis as more than an action based on prior knowledge. Rather, he described a dedication to human well-being, truth, and a perpetually shifting interaction between question and answer: the application of knowledge to action for change.⁸ That sounds a lot like psychiatry, and what I hope we can achieve in some small way with this section.

The section will involve two components. The first has been modelled on *BMJ* Endgames, and is clinically inspired and problem based. This section aims to capture the fertile discussion of local case presentations with more comprehensive analysis and varied perspectives. Psychiatric presentations sit at the intersection of the biomedical, social, cultural, and interpersonal, the past and the present. This section will explore these often knotty and interconnected aspects, with a clinical scenario forming the framework for discussion.

Trainees will have an opportunity to collaborate with experts from different disciplines to examine how existing literature and knowledge can be applied to practice. In any given scenario, possible avenues for discussion could include neuroscience, diagnosis, formulation, treatment, transference and countertransference, practicalities, real-world service provision, and ethical and legal considerations.

The College is in the process of developing a new curriculum, and the collaboration with the Gatsby Foundation and the Wellcome Trust has already seen 'Brain Camps' being held around the country.⁹ This new section may be a place where new neuroscience can be woven into a holistic approach. Patient involvement will be strongly encouraged, and we have been helpfully guided by the *BMJ* in this regard.¹⁰ A template for these clinical types of paper will be available on the website shortly.

The second component will be made up of commissioned or proposed editorial-type articles on subjects which fall broadly under the heading of personal and professional development. This will offer a space for reflection on relevant contemporary topics. Subjects I hope we can explore include psychodynamic and systemic approaches to resilience and burnout, consideration of what supervision should entail, trainee experiences of organising their own personal therapy, the experience of discrimination in psychiatric training, and what meaningful patient involvement and co-production looks like in practice and education. In commissioning for this section, I propose to work closely with the Psychiatry Trainees' Committee and the College to ensure we are responding to the needs of trainees.

As Dr Poole has said in his editorial, the future of the journal depends on you.¹¹ The success of the trainees' section depends on trainees and trainers pitching ideas for articles. If you're facing a complex clinical scenario, the chances are that someone else is too. And if you think you might never see your name in this journal – believe me, I've been in your shoes. Praxis is about dialogue, so get in touch. As Freire said, 'knowledge emerges only through invention and reinvention, the restless, impatient, continuing, hopeful inquiry beings pursue with the world and with others'.¹²

1.4.32 Against the stream: early diagnosis of dementia, is it so desirable?

Carol Brayne Sarah Kelly

Correspondence

Carol Brayne (cb105@medschl.cam.ac.uk)

date

2019-6

Abstract

The Prime Minister's challenge on dementia called for improved dementia diagnosis rates, based on assumptions of benefit to individuals and those who care for them. Subsequent policies have led to increased target drives for clinical practice to achieve early diagnosis of dementia through intense case identification. However, the current evidence base and treatment options do not support screening for dementia, and there is little empirical evidence that such intensive case identification and early diagnosis for dementia is justified without a better understanding of the benefits, costs and potential harms to individuals and services.

Declaration of interest

None.

Contents

- *Against the stream: early diagnosis of dementia, is it so desirable?*

'Of course,' many would respond to the question in the title of this paper. The same response would be heard for any chronic disease. Surely it must be better to detect a serious condition as early as possible. Even to question this response could be interpreted as somehow unethical or immoral. It stands to reason that the earlier a health condition is detected, the more effective any intervention will be. Such is society's starting point, endorsed by the successes and widespread promotion of national population screening programmes such as screening for breast, cervical or colon cancer.

In the case of dementia, following this reasoning, early diagnosis would allow earlier treatment. The individual and his or her family would be able to plan more effectively for the future, for example, to access care and support and by making advanced decision plans.

To begin with, what is meant by 'early diagnosis' along the clinical pathway of dementia? There is evidence that dementia goes through an asymptomatic stage where there may be no clinical symptoms but precursor biological and neurological changes. This may progress to an early symptomatic stage, for example, with subjective memory complaints or mild cognitive impairment (MCI), before moving on to a later symptomatic stage where there is a clear effect on daily living with further progression to advanced dementia.^{1,2} Dementia is a complex syndrome with a gradual

evolution. In some people with dementia, however, these stages may not be consistent or clearly defined. For example, MCI has been defined as the grey area between intact cognitive functioning and clinical dementia,³ but not everyone with MCI will progress to a full diagnosis of dementia.^{4,5}

Further, there is a distinction between: population screening, that is, screening everyone at a population level, including healthy or asymptomatic individuals, with the aim of very early identification; applying a 'screening' test in a clinical setting, where a clinician detects symptoms during routine attendance; and using a 'screening' test in people who are theoretically at high risk but where there is no other concern for the clinician, the patient or family members.

This still leaves the question of what is meant by 'early'. The Oxford English Dictionary definition includes 'in good time', 'before the usual time', and 'prematurely'. Each of these definitions requires a different type of evidence. 'In good time' suggests a time that is appropriate for that individual within their context; 'before the usual time' suggests a pre-emptive or screening process without implication of benefit or harm; while 'prematurely' suggests the possibility of harm.

David Cameron's Prime Minister's challenge on dementia called for improved dementia diagnosis rates.⁶ However, it is unclear whether this challenge reflected a push for diagnosis earlier along the clinical pathway or a concern that much more advanced cases of dementia, were being missed. Whatever was intended, subsequent policies and rhetoric have led to strong, target-driven pressure for clinical practice in England to achieve greater levels of 'early' diagnosis of dementia through increased case identification. This drive for increased early diagnosis assumes it is beneficial for all people with dementia, without concern for the possibility that this might divert resources from other services.

A drive for diagnosis earlier along the pathway requires (1) screening and diagnostic methods with high sensitivity and specificity; (2) adequate support and follow-up to confirm the diagnosis; (3) the availability of effective treatment and support; and (4) the availability of sufficient services to provide diagnosis, treatment and support. There is an implicit assumption here that evidence-based intervention provides a positive change in prognosis for individuals and/or the well-being of those around them. Although this assumption is justified for the national cancer screening programmes described previously, this is not the case for dementia.

At the present time, population screening for dementia for all people aged over 65 is not recommended by the UK National Screening Committee,⁷ despite regular revisiting of the evidence. The UK's Committee concluded that the current best screening test for dementia does not accurately identify those people who have dementia and those who do not. For every 100 people aged 65 tested, 18 would test positive, but only six of these would have dementia and one case would be missed.⁷ A substantial proportion of those tested would therefore be 'false positives'. Crucially, in order to recommend screening, treatments need to be available that would slow or even prevent dementia. The Committee concluded that such treatments do not exist for dementia at present.

Additionally, for population screening programmes to be introduced, population-relevant evidence, usually in the form of trials conducted in relevant populations, is required. For those conditions where national screening has been introduced, the benefits to the population have been tested and estimated and there are effective treatments available.

Thus, to justify the introduction on a national basis of intense case identification, a robust and rigorous evidence base is required.⁸ To date, no trial of intensive case identification for dementia has examined the likely effects, benefits and harm. The only evidence that is currently available is from those people who have been identified through existing identification approaches, with no systematic attention to any harm that might have been experienced.

Individuals identified through intense case identification and screening will have different natural histories from those identified through services. They are more likely to be wrongly diagnosed or, if accurately diagnosed, to have a benign course. In the absence of a well-designed trial, the benefits assumed from early diagnosis, such as support and service provision, are inevitably exaggerated. While assumed benefits of early diagnosis include planning support and services, reducing crises and family stabilisation, a number of adverse effects such as anxiety, depression and uncertainty about the future have been reported.⁹ Excessive health anxiety can also be created by screening, particularly when findings are equivocal, leading to additional suffering and abnormal internet use (cyberchondria). There is also potential for diagnostic errors and diversion of resources and services from those clearly manifest cases of dementia where individuals and their families have sought help. Anxiety, depression and concern about the future have similarly been reported following a diagnosis of MCI.¹⁰

The process of diagnosis of dementia has been described as a 'collective, cumulative, contingent process'¹¹ that often

develops over time. A diagnosis of dementia affects not just the person with dementia, but also their family members and the services around them. Reactions to a diagnosis and readiness for a diagnosis vary between individuals with dementia and their family/carers,¹² so it is important that the diagnosis of dementia is ‘timely’ or ‘in good time’ both for the person with dementia and the people around them. This concept of timely diagnosis means disclosure of the diagnosis at the ‘right time for the individual with consideration of their preferences and unique circumstances’.¹³

The pathway from early identification of suspected symptoms usually involves referral to specialist secondary care assessment, often to memory clinics. The number of patients referred to memory clinics increased by 31% from 2013 to 2014,¹⁴ and those people with dementia estimated to have received a formal diagnosis increased from 42% in 2012 to 62% in 2015.¹⁵ However, confusion about complex referral criteria resulting from the drive for early diagnosis to memory clinics may have resulted in delaying referral, with a resulting negative effect on timely diagnosis.¹⁵

It has also been argued that relying solely on opportunistic diagnosis may lead to avoidable harm. For example, it is often stated that late diagnosis results in higher rate of falls of people with unrecognised dementia, or confusion after hospital admissions. Late diagnosis may leave people insufficient time to plan for the future. Diagnoses are still too often made after a crisis. However, these claims are difficult to test empirically – people who already have a diagnosis also experience these problems; it remains uncertain whether diagnosing dementia at an ‘earlier’ stage would have made a difference to an individual.

Research is needed to address these uncertainties, including experimental designs in the introduction of service changes. The introduction of major initiatives for vulnerable populations without evaluation is extremely costly and has an inevitable harmful effect on already overstretched services.

Currently, clinical efforts should be focused on achieving a *timely diagnosis* defined as when people with dementia and those around them are ready for and will benefit from it. Until there are effective treatments for dementia, and the benefits of early diagnosis to individuals and the effects of adequate support on individuals and services have been rigorously evaluated, the benefits, costs and potential harms of early diagnosis remain uncertain.

1.4.33 Still room for improvement: standardisation of clinical correspondence and experience in a rural crisis and home treatment service

Daniel Robinson Samuel Dearman

date

2019-6

Contents

- *Still room for improvement: standardisation of clinical correspondence and experience in a rural crisis and home treatment service*

The communication of important clinical information in the management of our patients continues to occur in the large part through clinical letters, electronic or otherwise. Poor letter writing which misses important information and does not highlight key considerations leads to suboptimal care. This is certainly true in the crisis and home treatment team environment, where patients present with increased levels of risk and are often discharged solely to the care of their general practitioner (GP). Unfortunately, omission of information often occurs. A study of letters from mental health services in London found a mismatch between what GPs felt they needed to know and what was being included; for example, only 17% of the letters in this study included a diagnosis.¹ Evidence suggests that structured letter formats take no longer to read, are preferred by GPs, improve comprehension of letters and reduce the risk of omission of information by the author and reader.²

Anecdotally, we observed variation in our medical

Correspondence

our

GP colleagues and thus undertook a quality improvement project looking at improving the quality and consistency of letters produced by our team. This project was used as a developmental opportunity for one of our trainees under consultant supervision to learn more about the quality improvement process and to solidify trainees' understanding of the psychiatric history, mental state examination and risk assessment as core psychiatric competencies. We determined clinical letter standardisation by including widely recognised components of the psychiatric history and the requirements of our service operational policy. We included diagnosis with ICD-10 code, formulation, risk assessment plan and capacity to consent to the care plan.

In phase 1, using our standardised template, we examined all existing letters from a randomly selected period (January and February 2018) within the service. Of these, 44% included past psychiatric history, 38% included past medical history, 19% included personal history and none included forensic history. Mental state examinations also contained omissions, with 62% documenting speech, 56% documenting thoughts and 63% documenting perception. From the perspective of a crisis and home treatment service, it was noteworthy that history of self-harm was included in 38% of letters, risk of suicide in 81%, harm to others in 50%, risk to dependants in none, and risk of self-neglect and vulnerability documented in 25% each.

The standardised letter template was developed collaboratively, communicated to and agreed with all medical practitioners of all grades in the service. It was universally implemented and allowed to be used for 6 months. After this we again assessed the content of medical letters, including all those produced for a second randomly selected period (September and October 2018). A significant improvement was seen. Following implementation of the template all aspects improved: past psychiatric history (96%), past medical history (92%) and forensic history (67%). It was reassuring that documentation of risk of suicide increased to 100%, self-harm to 96%, harm to others to 96%, harm to dependants to 80% and vulnerability to 84%. Regarding the mental state examinations, speech was documented in 92%, thoughts in 100% and perception in 96%.

Overall our results demonstrate that standardisation of doctor's letters continues to be an area for improvement within psychiatric services, but that relatively simple methods and collaborative efforts can lead to significant quality improvements. We hope our approach warrants consideration from the wider pool of colleagues as we meet our duties to improve the quality of services³ and especially commend engaging trainees in the process as a learning opportunity in an attempt to add as much value as possible.

1.4.34 Abuse of psychiatry in Iran

Giuseppe Spoto

date

2019-10

Contents

- *Abuse of psychiatry in Iran*

In the past, the Royal College of Psychiatrists has been very active challenging abuse in relation to psychiatry; I distinctly remember, for example, Dr S. Bloch and others successfully exposing abuse of psychiatry in the former Soviet Union in the 1970s.

Why is the College silent about the antediluvian treatment recently endured by Nazanin Zaghari-Ratcliffe in Iran? Simply by exposing such barbaric practice on the international stage and using its authority, the College may succeed where others have failed, namely in ensuring her immediate release.

Dr Giuseppe Spoto asks why the College has not made a statement about the treatment of Nazanin Zaghari-Ratcliffe in Iran and remembers that in the past it has spoken out against abuse of psychiatry in the former Soviet Union in the 1970s.

We remain active in responding to cases where we believe there has been abuse of human rights. We have to be very cautious about making public statements on these issues; we never act until we have taken advice from those working closely with the family and supporters of the individual concerned and from agencies such as Amnesty International. It would be easy to unwittingly make the situation worse for the people involved.

1.4.36 Suicide and the psychiatrist

: Commentary on... Effects of patient suicide on psychiatrists

Allan House¹

Abstract

Research into patient suicide indicates that it has an impact on the psychiatrists involved, but leaves a number of unanswered questions about which elements of the experience are most likely to cause problems, who is most at risk, what is the clinical or professional significance of any effect on the psychiatrist and how other professionals are affected. Despite these uncertainties, it is clear that a response is needed, with three bodies responsible in different ways for coordinating one: the relevant mental health trust, as employer; the Royal College of Psychiatrists, as the professional representative body; and the National Confidential Inquiry into Suicide and Safety in Mental Health, as mediator of social and professional impact.

Something like one in four of all those who die by suicide in the UK have had recent contact with mental health services, so it is not surprising that many psychiatrists will have close experience during their career of this worst of all outcomes. Neither is it surprising that there are emotional and practical consequences of such an experience for the psychiatrists involved.¹ A paper by Gibbons and colleagues in this issue² describes the findings from a survey of psychiatrists about their experiences of patient suicide and serves as a useful reminder of the importance of this aspect of psychiatric practice; at the same time the results raise a number of questions about the specifics that lie behind these apparently self-evident truths.

The nature of the experience of patient suicide

What we are considering here is the idea of patient suicide as a life event for the psychiatrist. That is, it is an occurrence that directly impinges on the individual practitioner and has the potential to provoke a response that may be transient and unremarkable or may reach the level of intensity and duration that amounts to a disorder. What exactly is the nature of the exposure being considered?

In life-events terms, patient suicide is a complex event. That is, it has a number of more-or-less essentially interrelated features. There is the death itself and its immediate circumstances; inevitably, there is a formal inquiry (or more than one) in which the psychiatrist is likely to be asked to account for their own involvement; colleagues and close others make their own responses; finally, there is likely to be media coverage.

In relation to the first element of this complex – the death itself – the mention of post-traumatic stress disorder (PTSD) raises a question about level of exposure and proximity to the event. The UK's National Confidential Inquiry into Suicide and Safety in Mental Health (NCISH) has defined recent service contact as being within the 12 months before death;³ the survey reported here asked about suicide of a patient the psychiatrist had 'been working with', which suggests, without being specific, a more immediate connection (proximity). Surely the death of an in-patient in which staff are directly involved with attempts at resuscitation will have different effects from the death of somebody seen as an out-patient weeks or months before it occurred? The question is – should we, in the name of efficiency, focus more on the effects of some suicides (or the suicides of some people) than of others or should we accept that all suicides merit a staff-support response?

Life-events research tells us that external events are not just shocking in some non-specific way, they have a meaning that shapes the response we make – loss causing depression, threat causing anxiety and so on. While it is not difficult to understand the patient's death itself as uncomplicatedly negative – with perhaps an element of loss, threat and (under certain circumstances) the existential threat that constitutes trauma – the other elements of the exposure outlined above are less clear cut. They may be negative – critical, blaming, inducing guilt – or they may be positive – conveying support, affirmation, exoneration. It is difficult to see that these other aspects of the experience can be avoided, so the question is – can they be moderated either by direct influence on other parties or by support for the involved psychiatrist?

Who is most at risk?

Life-events research has produced a certain amount of ambiguity about the cumulative effect of multiple events. If one event is not severe enough to cause an emotional problem, what about several subthreshold events, are they additive? One of the more surprising (to me) findings from the present study¹ relates to the number of respondents who had experience of multiple patient suicides. Is this a question of age (years of exposure)? Area of work? What difference does it make? Is this a situation where multiple exposure sensitises or desensitises? This sort of accumulated experience of patient suicide is not likely to be picked up by suicide review, where the focus is on the patient and their care. Rather, it raises a question about staff review and how uncommon but important events can be monitored over time.

What exactly are the effects?

One of the inevitable weaknesses of questionnaire surveys is that they leave certain questions underexplored, and in this case it is difficult to judge exactly how severe the reported responses were. Clearly, the emotional effect of such an event can be significant, but in clinical terms even in a selected sample only a very small number took time off work or thought they were ill. It is not clear how many respondents sought professional help for their mental health, although about a quarter said that some form of counselling or therapy would be a good idea. In conventional psychiatric terms most of this would be described as no more than mild or moderate disturbance and would be unlikely to be accepted for treatment following referral to the average community mental health team. Is this a matter for occupational health or for the marshalling of personal resources? The majority of respondents in this study acted as if they thought the latter, whereas the authors conclude that the answer ought to be more towards the former.

An intriguing question not raised by the authors is the degree to which the response to patient suicide might have a positive dimension. There is a substantial literature on personal growth consequent upon adversity, and another possibility is raised by the observation that women reported a greater sense of responsibility and effect on their clinical confidence. There is evidence from other areas of medicine that female doctors tend to practise differently, with better outcomes,⁴ raising the question of whether the problem in medicine is female diffidence or male overconfidence. A worried sense of responsibility and questioning of our competence may be stressful, but it is not necessarily bad for our patients if it leads^{1,5} to more vigilance and desire for involving others when managing patients perceived to be at risk of suicide.

What about other mental health professionals?

Most mental health practice involves multidisciplinary teams – ward teams, crisis teams, home treatment teams, community mental health teams. Even in out-patient services, the patient who sees a psychiatrist is quite likely to have contact also with a community psychiatric nurse or other professional. It is a striking feature of the present study – and a number of the others cited – that these other professionals are not mentioned. One wonders whether some part of the psychiatrist's involvement had been to contribute to team discussions about the implications of a patient suicide, or to offer support to a non-medical colleague? Certainly, there is no reason to believe that doctors alone are vulnerable to the stresses of clinical work.⁶

As a mild digression, it is interesting to note how little literature there is on the effects of patient suicide in clinical psychology and improving access to psychological therapies (IAPT). These services have a reputation for reluctance to take on patients perceived to be at risk of suicide, but even so it must be the case that some suicides occur while the patient is 'working with' or has had recent contact with the relevant professionals. For example, the wider impact of suicide is discussed in a recent British Psychological Society publication,⁷ but the effect on professionals is not covered. The implication is that, as in psychiatry, the expectation is for individual practitioners to manage for themselves.

A final question: what are the implications?

Gibbons and colleagues, no doubt wishing to avoid wandering too far from their data, make few recommendations about what should happen next. Nonetheless, there are implications of their findings.

First, patient suicide is a complex event with a number of components that represent relatively predictable challenges for the mental health professional. The most common perceived needs in the present survey were for instrumental and informational support in facing these challenges. It is surely the employing organisation's responsibility to provide such support, organised via the medical director. It would be helpful if the Royal College of Psychiatrists were to provide practical guidance. The NCISH could also have a role here. Researchers are expected to indicate to research ethics committees how they will ensure that participants from whom they collect information are aware of how to access help; the NCISH could act as a useful conduit for independent (from the employing trust) guidance to psychiatrists faced with the death of a patient on whom they are providing data.

Second, the 'exposure' in patient suicide varies in intensity and proximity, and the emotional and social impact also varies. This argues against, as does much other work in trauma response, a global approach to preventive intervention

at an individual level. Follow-up of staff at (say) 6 months after a patient suicide could readily be incorporated into staff review and support – especially for those in high-risk subspecialties or with multiple experiences of patient suicide.

Finally, we should embrace multidisciplinary in this as in other areas of practice. It would be a useful collaborative exercise for the College to convene a working group with other official bodies, to include at least the British Psychological Society and Royal College of Nursing, with the aim of producing a common set of guidelines on staff support after patient suicide – a small but important part of the larger question of health and well-being in the NHS workforce.

Abstract

This study focused on an evaluation over 2.5 years to establish if a frequent attenders’ service in an Emergency Department (ED) impacted on the overall number of patients attending as well as the numbers of their attendances. For this, three patient lists from April-September 2015 and three lists from a matched period in 2017 were randomly selected and the two samples compared. Results showed both a reduction in the number of total patients identified as frequent attenders as well as a reduction on the number of attendances to ED. The study suggests that the implementation of a frequent attenders’ service is associated with benefits, not only for the individual attendances per patient, but also in an overall reduction of the number patients classed as frequent attenders.

Patients who frequently attend the Emergency Department (ED) have been characterized as a heterogeneous group,^{1,2} often with complex healthcare needs who are at least as sick as non-frequent attenders^{2,3} and have been associated with a higher expected mortality rate.^{1,4} A recent national Commission for Quality and Innovation (CQUIN) aimed to improve the way services manage these patients. This was based on the Cambridge study⁵ which highlighted that there should be services designed to integrate physical and psychological needs of these patients at the ED interface. In the current CQUIN, a cohort of patients who attend frequently is identified, and the pre and post intervention attendances across the cohort are compared with a 20% reduction in attendances required to achieve the target.

However, in the UK, the longer term effect of a frequent attenders' (FA) service has not been evaluated in terms of whether such a service has an impact on the overall number of patients attending ED who are classed as 'frequent attenders'.

In Durham and Darlington a FA's service has been running since 2014 following the implementation of a local CQUIN with County Durham and Darlington National Health Service (NHS) Foundation Trust in 2014/2015 which aimed to reduce attendances in those attending the Emergency Department (ED) 20 times a year or more. Tees, Esk and Wear Valleys (TEWV) NHS Foundation Trust was also involved in providing mental health support via the Psychiatric Liaison team, and the North East Ambulance service were the third partner in this project. This CQUIN was commissioned in response to guidelines from the Royal College of Emergency Medicine (August 2014).⁶ Due to the relatively small numbers of patients attending over 20 times a year the service saw all patients attending 15 times a year or more.

The initial local CQUIN demonstrated a 46% reduction in attendances in the cohort over a 12 month period compared to the previous 12 months and every patient demonstrated a reduction in attendance. Similar outcomes have been showed in other studies.^{7,8}

This service has been in place 2.5 years at the time of this study and an evaluation of its impact over this time period was conducted. This evaluation aims to establish if a FA's service impacts on the overall number of patients attending frequently as well as the overall frequency of their attendances to the ED.

Methods

The Frequent Attenders Service has been set up between the ED of the University Hospital of North Durham in Durham and the Liaison Psychiatry team. Patients are identified as frequent attenders by the ED if they attend 15 times a year or more. Each month a list is produced from the ED of all these patients. The list will have on it any patient who has attended the ED department 15 times or more in the previous year with no other exclusion criteria applied. The patients on the list are discussed at a monthly Multi-Disciplinary Team (MDT) meeting with ED, Liaison Psychiatry and the North East Ambulance Service (NEAS). The number of patients in the list for each month is dynamic as each month there will be new patients who meet criteria, some patients will be discharged as they have reduced their attendances and others who will continue on from the preceding month's list.

For some patients already involved in services, liaison with their established care providers is undertaken as often those providers are not aware of the ED attendances and are able to address the situation with the patient effectively within current care provision. For other patients a letter is sent offering them an appointment with the Liaison Psychiatry team, sometimes in collaboration with a different team – e.g. a joint consult with the respiratory nurses and Liaison Psychiatry. Plans of care are put in place for all patients with contributions from the MDT and the patient, if the patient chooses to engage. If the patient does not engage, a plan is put in place anyway if there are sufficient concerns about risk e.g. a plan may ensure that a patient with health anxiety does not receive iatrogenic harm from unnecessary tests. Education is also done with ED clinicians to look at approaches to talking to patients who frequently attend and potential management strategies. Two liaison clinicians (consultant psychiatrist and advanced nurse practitioner) coordinate the service and contribute 1 session a week between them on average.

This evaluation was conducted by randomly selecting three patient lists between April-September of the year 2015 and comparing this data to three randomly selected patient lists from a similar period in 2017. This was done to ensure that the result was representative and not skewed by a single particularly good or bad month. Therefore, the total number of patients for each list was obtained and their average number calculated.

Other data collected to compare the two cohorts was: age, gender, and most common clinical presentation. One list from each year only was used for this extra information. During the evaluation we followed up the patients who had

attended in 2015 to analyse how many were still attending frequently in 2017. During this we noted how many had died and what their original reason for attending was. This mortality data is also presented in the results.

The data was collated and analysed using Microsoft Excel 2010. Consent from patients and ethical approval was not sought given that the study was a service evaluation of an established service and no patient identifiable information is presented.

Results

Analysis of the average number of patients attending 15 times a year or more

Considering the period between April-September 2015, an average of 43 patients were attending ED 15 times a year or more, whereas this number reduced to an average of 17 patients in 2017 as shown in *Table 1*. This equates to a reduction of 60% in the average number of patients attending 15 times a year or more over the period of 2.5 years. *Table 1* Total number of patients per list and respective descriptive analysis and t-test result

Month (List)	2015 Mean	2015 SD	2017 Mean	2017 SD	95% CI for Mean	T	Df	Sig. (2-tailed)
141	43.33	4.04	13.16	6.75	5.11	5.71	37	0.0025

An independent sample t-test was conducted to compare the means of the samples for 2015 and 2017. There was a statistically significant difference between the means of the number of patients per month in 2015 when compared to 2017 ($t(4) = 6.76, P = 0.0025$).

Analysis of the average number of total attendances amongst the frequent attenders over preceding 12 months in 2015 compared to 2017

As can be seen in *Table 2*, the average number of total attendances over preceding 12 months by patients attending 15 or more times a year reduced from approximately 833 to 437 which is 396 fewer attendances. This amounts to a 48% reduction on the total number of attendances across the 2.5 years of the study. This difference was shown to be statistically significant ($t(4) = 6.38, P = 0.0031$). *Table 2* Number of total attendances amongst the frequent attenders and respective descriptive analysis and t-test result

Month (List)	2015 Mean	2015 SD	2017 Mean	2017 SD	95% CI for Mean	T	Df	Sig. (2-tailed)
173	1833.33	89.97	393	436.67	59.16	22.04	569	0.0031

Descriptive analysis of age, gender and clinical presentation to ED

As stated in the methods section, for this part of the analysis only one random list of each year was considered. For both years, each list considered showed a small majority of female patients (55% in 2015 and 57% in 2017). The median age of patients in 2015 was lower than in 2017 (36 v. 43 years old) (IQR 28.5–53 v. IQR 33–65).

Both samples also showed a similar distribution for clinical presentation to ED. Personality disorders and alcohol and substance misuse lead the most common clinical presentations followed by pain, undiagnosed dementia and chest problems (most commonly patients with respiratory problems) as it can be observed in *Fig. 1*. The Figure also shows the general reduction in the number of patients attending ED. However, this reduction is not the same across the different clinical presentations with the categories of undiagnosed dementia, children under 18, complex physical health needs and other remaining unchanged from 2015 to 2017. On the other hand, a reduction is seen in patients attending with alcohol and drug misuse problems, respiratory problems, pain and borderline personality disorder. *Fig. 1* Clinical presentations to ED in absolute numbers. A/S misuse, alcohol and/or substance misuse; BPD, borderline personality disorder; HA/MUPS, health anxiety/medically unexplained psychiatric symptoms; PH, physical health.

Analysis of outcomes for patients across the 2.5 year period of the study

It was also observed that all the patients who had been identified as frequent attenders in 2015 reduced their number of attendances to less than 10 per year by 2017 (some were not attending at all) and consequently they were no longer on the FA list, with the exception of a single patient (Patient A). Patient A is the only patient to be present in the FA's list in 2015 and 2017 and has also the highest number of attendances per year of both groups.

Of 13 elderly patients who presented as FA throughout the 2.5 period analysed, 11 had a previously undiagnosed dementia and almost all of those eventually required residential care.

It was noted that of the patients who attended in 2015, 9 had died 2.5 years later. Of these 2 were elderly patients who died of natural causes, one was a patient with a terminal illness and 5 were patients with substance abuse, 4 of which were alcohol related. In fact, when examined more closely, of the 8 original patients with alcohol presentations in 2015, 4 died within 18 months of identification as being a frequent attender. Also, of note, none of the patients in 2015 who presented with a primary presentation of self-harm or suicide attempts had died in the following 2.5 years.

Discussion

The implementation of a MDT approach to reduce attendance to ED services by frequent attenders has been suggested as effective by a number of studies^{7,8} and has therefore been recommended by the College of Emergency Medicine. However, a significant number of studies regarding this have been done outside of the UK which has implications on how much information can be extrapolated towards the UK population given significant differences in the national health care systems.

This study observed that since the implementation of the FA's Service, a marked reduction of the number of patients classed as 'frequent attenders' occurred from an average of 43 patients falling into this category each month in 2015 compared to an average of 17 patients in 2017. The average number of attendances of these patients for the preceding 12 months also reduced from approximately 833 to 437. Both reductions were statistically significant.

The reduction in the number of patients on the monthly frequent attenders list from implementation of the service was unexpected. A number of factors might have contributed to this result. As it was presented in the results, with exception of patient A, all patients clustered as frequent attenders in 2015 reduced their number of attendances and did not qualify for this category by 2017, which means that the 2017 patients' list (with the exception of patient A) was made of new patients. This means that there isn't a cumulative effect by which the list expands year after year as new patients are added. This has also been discussed by other studies. In two studies^{2,8} it has been demonstrated that some patients will qualify as FA during a period of crisis which is not a situation that repeats year after year. Therefore, each cohort tends to have a new set of patients while others are removed from the list.

Another potentially contributing factor to this result is the educational component of the project in which ED clinicians are encouraged to identify patients earlier and utilise more effective management strategies thereby reducing the potential of the patients to become frequent attenders.

The reason why early identification of these patients contributes to reduction in their attendance could be related to early addressing of potential conditioned responses that some patients develop by going to ED. For example, in acute exacerbations of chronic pain, the patient learns that ED will provide IV analgesics which will be more effective than oral therapy due to associated immediate euphoria and deep relaxation rather than just the analgesic effect. Hence during acute exacerbations of chronic pain coming to ED becomes the learned response. There is also an association of hospital in general as a place of safety and comfort which has been referred to as the "brick mother" by psychotherapist Henri Rey. Therefore, the patient learns that his fear, which will greatly impact on pain, will be more favourably managed in hospital than at home and this gives rise to a further conditioned response. By acting early, this response can be addressed before it becomes deeply entrenched and therefore patients can be better managed in the community e.g. in conjunction with support from the pain team. Overall practice has changed as well, with fewer clinicians prescribing IV analgesics for acute exacerbations of chronic pain and there have been fewer patients attending with acute exacerbations of chronic pain as can be seen in *Fig. 1*.

Another way behavioural reinforcers have been addressed is by taking a positive risk approach to physical health presentations, in particular in patients with health anxiety. This has been done by minimizing the number of investigations carried out in patients who have been appropriately investigated and who do not present with new symptoms. This has benefits for the system as it reduces the cost of the emergency episode but also for the patient as it reduces iatrogenic harm by repeated exposure to unnecessary procedures and harmful ionising radiations. A consistent approach to this also helps stop the chain of reinforcement.

It has been noted that for some patients, simply being sent a letter informing them that they are a frequent attender and offering help to address this seems enough to stop them attending. For others it is about getting the relevant community services to work better for the patient – e.g. often mental health services will not be aware that a patient is attending ED frequently and this can be addressed through crisis plans. Working with the community respiratory team has been highly effective in helping patients who repeatedly present with respiratory concerns, or referring patients to the pain clinic to come up with innovative community ideas for managing acute exacerbations of chronic pain have helped. These interventions appear to be the most likely explanation to the difference in the reduction of different clinical presentations seen in *Fig. 1*, with the highest reductions in pain, respiratory problems and borderline personality disorder presentations.

In this study, female gender was predominant, whereas a number of studies^{3,9-11} have showed higher prevalence of males in groups of frequent attenders. The mean age of patients in the second cohort was 7 years younger and generally this study presented lower mean ages than other studies⁹⁻¹¹. Some studies¹⁻¹⁰ have also suggested that the age distribution is bi-modal with peak ages in younger patients (<40 years old) and old age (>65 years old).

Two unexpected groups emerged that warrant further research: firstly, older people who attended ED frequently often had undiagnosed dementia and potentially older people frequently attending ED could be a red flag for considering this. Secondly, substance misuse patients in this study have a very poor prognosis. Half of the 2015 patients identified as FA with substance misuse problems have now died. This has serious implications for how these patients are cared for – they often do not engage in usual substance misuse services and this warrants further consideration as to what services models are needed to best support these high risk patients.

Regarding the costs of frequent attenders to ED: Considering the distribution of common presentations to ED in our sample, it is likely that basic investigations such as blood analysis or an x-ray are done which means that the cost per presentation will be around £127.¹² If a more specialized investigation such as a computerized tomography (CT) or ultrasound scan is done, the cost further increases to around £207.¹² This calculation does not take into consideration inpatient admissions (average cost £400 per night), or the use of ambulances (average cost of £254 per attendance).¹³ More than this, though, are the costs related to excess mortality and morbidity in this group of patients, whose underlying conditions are not being optimally managed, potential iatrogenic harm from unhelpful tests, investigations and treatments, poor patient and clinician experience and the disproportionate amount of time these patients take up in the ED due to their complexity. Of note, in the original CQUIN of patients attending over 20 times a year, there was a reduction of 170 inpatient admissions to the acute trust in the 12 months prior to the intervention compared to the 12 months post intervention.

There are a number of limitations to this evaluation and results should not be interpreted too broadly. The sample was collected from the area covered by County Durham and Darlington NHS Foundation Trust hospitals which covers a population with its unique characteristics that differ from other areas. Moreover, the sample for the study was small and therefore limits generalization into the general population. Another important issue, as mentioned above is the availability of other services which conditions the type of patients presenting to ED. That said, most literature reviewed concentrated on the effects of service implementation and therefore focused on assessing a single cohort of patients pre and post intervention and analysis of those individual's reduction of attendance whereas this service evaluation was able to show broader benefits in terms of actually reducing the number of frequent attenders rather than only the number of attendances per patient.

In conclusion: a frequent attenders' service can be effective in reducing the overall number of patients attending ED 15 times a year or more. This has led to the service being able to see patients attending 10 times a year or more. The most effective elements of the service are hypothesised as being: the psychoeducation of clinicians; working with patients and other relevant agencies to help them manage their condition in the community more effectively; identifying and breaking the cycle of the conditioned response these patients show to emergency services and the liaison between different services.

Case study

Ms D had a long history of COPD exacerbated by anxiety and previously attended ED over 40 times a year. Following a period of brief intervention with the frequent attenders' clinic which involved: joint work with the respiratory community team; a plan with the ambulance service to differentiate between an anxiety episode and COPD; a management plan for ED; the patient becoming involved with a community support group with the respiratory team; support with the local housing and social support team. Since this intervention was put in place Ms D has attended ED only once a year in the last 2 years (both appropriately) and has had one additional ambulance call where the crew managed the presentation at home.

In recent years there has been a dramatic increase in compulsory in-patient psychiatric treatment in the UK. In 2016, National Health Service (NHS) Digital reported a 47% increase in the number of detentions under the Mental Health Act over the preceding decade.¹ The reasons for this are multifactorial and include reduced access to social care, changes in the provision of psychiatric services and reductions in the number of psychiatric beds. Another factor that must be considered is the Mental Health Act assessment itself. Approval under Section 12 of the Mental Health Act confers the ability to deprive individuals of their liberty and curtail their human rights. This is one of the most life-altering powers a doctor can hold.

There is a danger that clinicians are not equipped with the knowledge and skills to wield this power safely and effectively, which could have a marked effect on the number of detentions under the Mental Health Act. In light of the recent independent review into the Mental Health Act and consequent discussions about what modern mental health legislation should entail, it is imperative that we scrutinise the process for training and approving the clinicians who carry out these assessments. Although the specifics of mental health law vary widely across the world, there are shared fundamental principles and an examination of the training, skills and assessment of professionals carrying out detentions of mentally ill individuals is an important process for psychiatrists to consider.

This article seeks to evaluate these training, approval and revalidation processes for Section 12 doctors and suggests evidence-based improvements.

The current state of affairs

Under current legislation in England and Wales, the Secretary of State can grant approval under Section 12 of the Mental Health Act, provided the clinician meets the requirements set out in the Act. This responsibility is delegated to local Section 12 panels, which also hold responsibility for the accreditation of induction and refresher courses. A clinician can be approved for a period of up to 5 years; at the end of this period they can apply for revalidation,^{2,3} which is contingent on participation in a section 12 refresher course.

We sent a questionnaire to all 23 providers of Section 12 courses and obtained only 5 responses. Although this is a low response rate, we triangulated this information with other sources to acquire information about key features of the courses. Section 12 induction courses and refresher courses typically last 2 days and 1 day, respectively. The cost of an induction course will range between £200 and £400. Attendance is generally monitored using a sign-in sheet, with no verification of identity. The courses consist of a series of lectures covering the nationally mandated learning objectives (see *Box 1*). Some courses will include an interactive component such as a case discussion or a quiz. There is no requirement to summatively or formatively assess whether the learning objectives have been met. *Box 1* Section 12 course learning objectives³ To have a broad understanding of the provisions contained in Part 2 of the Mental Health

Act relevant to the initial detention of a patient under Sections 2, 3 and 4. Be able to describe the role of a Section 12(2) doctor and that of others when undertaking a Mental Health Act assessment. Understand the meaning of, and be able to refer to, the criteria for detention under Part 2 when making a medical recommendation. Be able to describe the guidance contained in the Code of Practice relevant to the role and responsibilities of a Section 12(2) doctor when undertaking a Mental Health Act assessment. To use knowledge of the impact that an assessment may have on patients and their carers to inform the approach to an assessment. Be able to complete the statutory forms lawfully.

This lack of formative assessment is particularly concerning considering that there is evidence to indicate that there are inadequacies in many psychiatrists' understanding of the relevant legislation. When a random sample of Section 12-approved clinicians in the West Midlands were interviewed, none of them were able to define 'mental disorder' as it appears in the Mental Health Act.⁴ In a similar study in Scotland, only 10% of consultant psychiatrists were able to give the statutory definition of mental disorder.⁵ This raises questions about the training, approval and revalidation processes.

On completion of the induction course, prospective Section 12 doctors must undergo an approvals process whereby they must provide two referees, with the requirement that one of the referees is an NHS consultant psychiatrist familiar with the work of prospective Section 12 doctors. In theory, this is an additional check that the prospective clinician has the required knowledge and skills. In practice, there is no framework for how a referee should assess whether the prospective clinician has the complex skills specific to Mental Health Act assessments. Furthermore, it is likely that clinicians seeking Section 12 approval will choose consultants who are also their line managers as referees. Therefore, it would be equally unlikely that the referee would have witnessed the aspiring Section 12 doctor complete a Mental Health Act assessment because of the Mental Health Act's need for an independent doctor.

Analysis

When analysing the educational effect of these training courses, three questions must be considered: What are the learning objectives? How does the training meet these learning objectives? And how are they assessed?

What are the learning objectives?

Miller⁶ described the assessment of clinical skills and competencies as four levels of increasing complexity as shown in *Fig. 1*. Taking the example of venepuncture: knowing what a blood test is and its indications would satisfy the lowest level of the pyramid. Being able to describe how to take blood would show that the clinician 'knows how' to perform the task. Assessing the individual performing a simulated blood test on a manikin would satisfy the third level of the pyramid and observing the competency being performed on a patient would demonstrate proficiency of the highest level on the pyramid. *Fig. 1* Miller's pyramid⁶ a framework for classification of assessment in medical education, can be used to align assessment with learning outcomes. EMQ, extended matching question; MCQ, multiple choice question; OSCE, objective structured clinical examination.

Biggs and Tang⁷ have aligned the imperative words used to describe learning objectives to levels on Miller's pyramid so that words such as 'identify', 'define' and 'describe' refer to learning objectives at the bottom of the pyramid and 'perform' and 'demonstrate' are associated with the highest level on the pyramid. By this analysis, the current learning objectives for Section 12 approval courses are only assessing the lowest levels of the pyramid. Indeed, the only practical skills required are 'completion of the statutory paperwork' and 'rectification of errors'. There appears to be a presumption that the clinician will develop the necessary skills elsewhere. This is not necessarily the case; for example, clinicians who have achieved membership of the Royal College of Psychiatrists are eligible to apply for Section 12 approval, but as an international examination, the MRCPsych does not assess UK mental health law.

Performing a Mental Health Act assessment is a complex skill requiring the ability to apply the principles of mental health law to challenging clinical situations; this is not reflected in the current learning objectives, which focus on simple knowledge and skills with relatively little emphasis on higher-order learning.

How does the training meet these learning objectives?

To motivate prospective Section 12 doctors and support them to achieve these higher-order learning objectives, the learning activities should be closely aligned with these objectives.⁸ At present, Section 12 courses rely heavily on lecture-based teaching, with a focus on conveying large volumes of factual content. This may be problematic because although lectures can be a useful didactic method for imparting factual knowledge, they are less effective at changing attitudes and behaviours. For teaching complex skills, the evidence base supports the use of active learning activities to engage learners in more effective and more sustained learning.⁹

How is it assessed?

There is an absence of any mandatory assessment in the Section 12 approval process, and this has significant implications. Assessment serves two distinct educational functions: it is used to evaluate whether the learning objectives have been achieved and it is used to drive learning.¹⁰ The widely held belief that ‘if it’s not assessed, it’s not important’ is backed up by substantial evidence demonstrating that trainees learn more effectively when they know they will be assessed.¹¹ If they are not formally assessed, they will not achieve the learning objectives. The ability to perform a Mental Health Act assessment is a complex skill, requiring a sound knowledge base and extended abstract thinking, and this needs to be reflected in the learning objectives, learning activities and assessment process.

Our solution

To optimise their educational effect, the design of training courses should be guided by the evidence base. Appropriate learning objectives should be created based on the knowledge and skills required of a Section 12 doctor, and the learning activities should be aligned with these objectives. We propose a teaching model similar to that used in Advanced Life Support (ALS) training run by the UK Resuscitation Council, whereby prospective Section 12 doctors would be given standardised educational material before the course, either as written material or as a series of e-learning modules. This could employ a variety of formats to suit different learning styles, and would allow clinicians the flexibility to work through the material at their own pace. A pre-course self-assessment quiz would allow them to test their level of understanding and identify learning needs, as well as ensuring engagement with the pre-course material.

Instructors should therefore have more confidence that the doctors will have decent levels of working knowledge of the Mental Health Act to build upon during the course. The face-to-face training course would then have scope to focus on higher-order skills such as applying their knowledge of the pre-course material to ‘real-life’ scenarios. Instructors would have flexibility to make their training course unique; for example, by using role play, case discussions and simulated Mental Health Act assessments.

Rather than simply signing an attendance sheet, there should be a formal identification check at the outset of the course. Furthermore, sign-off should be contingent on an end-of-course summative assessment with two key components: a written multiple choice test and a practical assessment such as a case discussion with the instructor. Concerns about failing a substantial number of prospective Section 12 doctors are understandable, but these fears are misplaced: if the assessment is criterion-referenced and aligned with the learning objectives, and the pass mark is determined by an appropriate methodology such as the Angoff¹² method, the assessment will uphold the minimum standard without failing candidates unnecessarily. For context, only 3.4% of candidates fail their ALS training.¹³ With something as important as Section 12 approval, minimum standards must be upheld and summative assessment is the only way to achieve this.

Of course, there are practical and cost considerations when implementing such an assessment. The development of a question bank and determination of an appropriate pass mark would be resource-intensive; nonetheless, it is still feasible and the advantages of incorporating assessment into the training far outweigh the disadvantages. The cost to the delegate of attending a Section 12 approval course are similar to those attending ALS. Therefore it is likely to be financially feasible to implement these changes.

We also propose a modification to the learning objective for Section 12 approval courses to reflect the changes in assessment and the complex nature of the Mental Health Act Assessment as detailed in *Box 2*. *Box 2* Proposed Section

12 course learning objectives aligned with assessment methods **Outline** the provisions contained in Part 2 of the Mental Health Act relevant to the initial detention of a patient under Sections 2, 3 and 4 of the Mental Health Act. With reference to the Mental Health Act Code of Practice, **describe** the role of the Section 12 doctor and other participants in a Mental Health Act Assessment. **Explain** the criteria for detention under Part 2 of the Mental Health Act. **Perform** a holistic assessment of a patient's history and mental state in the context of a Mental Health Act assessment. Based on a holistic clinical assessment, demonstrate sound and lawful **application** of the statutory criteria for detention under the Mental Health Act and **justify** the chosen course of action. **Demonstrate** lawful and accurate completion of statutory forms. **Reflect** on the patient's experience of a Mental Health Act assessment, and how this might affect their mental state and engagement with healthcare services.

Conclusion

The authority to detain someone against their will is one of the greatest powers that can be granted to our profession, and it is a responsibility that should be taken seriously. Future legislation (and indeed the Royal College of Psychiatrists) should revise the learning objectives of Section 12 courses to mandate a more appropriate standard than the bare minimum set out in the current format of the learning objectives. Efforts should be taken to ensure that this training is evidence-based, developed from sound educational principles and reinforced by appropriate assessment.

Abstract

Aims and method

To investigate the percentage of patients who commenced smoking after transferring out of a non-smoking forensic psychiatric unit, the corresponding clozapine dose adjustments, the effects on plasma clozapine/norclozapine concentrations and observed changes in mental state. We reviewed the notes and plasma clozapine/norclozapine concentrations of 46 patients transferred to medium secure units between July 2008 and December 2013.

¹ Declaration of interest None.

Results

Thirty-five patients commenced smoking. Their median clozapine dose was increased by 50 mg/d. In the non-smokers, the median clozapine dose remained unchanged. Plasma clozapine/norclozapine concentrations were significantly reduced in smokers despite dosage adjustment. Eighteen patients experienced deterioration in mental state after transfer; almost all these patients were smokers.

Clinical implications

Approximately three-quarters of patients who were non-smokers by virtue of being in a secure non-smoking environment commenced smoking after transfer. Monitoring of clozapine serum levels and assessment of mental state in the immediate period after a change in smoking status is indicated.

Clozapine use in schizophrenia

Clozapine is the only antipsychotic licensed for use in patients with treatment-resistant schizophrenia. It has a narrow therapeutic index and pre-dose plasma clozapine concentrations between 0.35 and 0.60 mg/L are associated with optimal response, although patients may show such a response at lower or indeed higher plasma concentrations.¹ Adverse effects are more likely at plasma concentrations above 0.6 mg/L.²

Clozapine metabolism

Clozapine is primarily metabolised to its principal plasma metabolite *N*-desmethylclozapine (norclozapine) by the cytochrome P450 (CYP) isoenzyme CYP1A2, with possible additional contributions by CYP2C9, CYP2C19, CYP2D6 and CYP3A4.^{3,4} There are significant differences in plasma concentrations of clozapine between patients receiving the same dose, owing to factors including age, gender and exposure to tobacco smoke.^{5,6} The magnitude of the effects of the polycyclic aromatic hydrocarbons in tobacco smoke in increasing CYP1A2 activity are second only to dose on plasma clozapine concentrations.⁷ A systematic review of the effects of smoking cessation on plasma clozapine concentrations found clozapine dose reductions of between 30 and 40% were required to achieve pre-cessation concentrations.⁸ Neither the nicotine in cigarettes nor nicotine replacement therapy products have an effect on clozapine metabolism.⁸

Schizophrenia and smoking

Patients with schizophrenia are more likely to smoke cigarettes, and in greater quantity, than the general population.⁹ An evaluation from a UK forensic psychiatric medium secure unit found 84% of in-patients were smokers before the introduction of a smoking ban, and cessation rates after smoking reduction programmes are less than 7%.^{10,11}

Ashworth Hospital is a high-security psychiatric hospital serving the population of Northern England and Wales. The hospital has approximately 200 male in-patients who are detained under various sections of the Mental Health Act 1983; none have unsupervised community leave. The hospital became a non-smoking unit on 1 July 2008. Tobacco products are not permitted in the hospital. This is a policy that is effectively implemented as all hospital staff, patients and visitors are subject to rigorous security measures, including searches in and out of the hospital and x-ray scanning of personal possessions. Patients no longer requiring treatment in a high secure unit are transferred either to prison or to medium secure units. At the time of this evaluation, all the medium secure units to which patients were transferred permitted smoking.

Clozapine and smoking

We could find no published study that documented changes in smoking status and clozapine dose requirement after transferring out of a non-smoking psychiatric unit. We decided to investigate the percentage of patients who commenced smoking after transfer, the corresponding clozapine dose adjustments performed, the associated effects on plasma clozapine and norclozapine concentrations and observed changes in mental state.

Method

The service evaluation was registered within Mersey Care National Health Service (NHS) Foundation Trust. We identified patients prescribed clozapine who were discharged to medium secure units (both NHS and independent) from Ashworth Hospital from July 2008 to December 2013. Patients transferred to a medium secure unit on trial leave remain under the nominal care of the Responsible Clinician at Ashworth hospital and are routinely reviewed by clinical staff from Ashworth Hospital; trial leave is for a minimum period of 6 months and can be longer, allowing an opportunity to review case records and changes in smoking status. From the clinical notes we collected data on clozapine dose, plasma clozapine and norclozapine concentrations, smoking status and mental state in the 6 months pre-transfer and up to 12 months post-transfer. Patients who were either discharged without a period of trial leave, or remitted directly to court or prison were excluded. Plasma clozapine and norclozapine concentrations were monitored as necessary to help guide clozapine dose adjustment. The last clozapine plasma measurement on file was used as a measure of post-transfer plasma clozapine and norclozapine. Information routinely recorded when requesting plasma clozapine assays include the time and date of sample, time and date of last clozapine dose, clozapine dose (milligrams per day), mode of administration (tablets or suspension), duration of clozapine treatment, age (years), gender, body weight (kilograms), smoking status (yes/no) and other relevant information that could aid interpretation of the result, such as co-prescribed drugs and the reason for the assay request.

Statistical significance of analysed data was calculated using paired *t*-tests and Fisher's exact test as appropriate.

Ethical approval

The service evaluation was registered within Mersey Care NHS Foundation Trust. Ethical approval was not required; no individual patient is described.

Results

Forty-six male patients with complete data were identified. All had a diagnosis of schizophrenia (ICD-10 F20).¹² Ethnicity was White British ($n = 27$), White Irish ($n = 2$), Black Caribbean ($n = 3$), Black African ($n = 2$), other Black background ($n = 4$), Pakistani ($n = 2$), Indian ($n = 1$), other Asian background ($n = 1$), and other mixed background ($n = 4$). The median age at the start of trial leave was 37.1 years (range, 24.8–56.0 years).

Plasma clozapine and norclozapine concentrations had been measured in all patients before transfer (median time before transfer, 89.5 days; range, 1–315 days). The median number of plasma clozapine assays performed after transfer to a medium secure unit was 2 (range, 1–9). Plasma clozapine was first measured on average 45 days post-transfer (range, 2–345 days). A total of 72% of patients had plasma clozapine and norclozapine measured within 1 month of starting trial leave; this increased to 87% of patients at 3 months post-transfer.

Thirty-five patients (76%) commenced smoking after transfer and eleven (24%) remained non-smokers (*Table 1*). The average duration of follow-up was 6.6 months in both the smoking and non-smoking groups. *Table 1* Comparison of pre- and post-transfer data: clozapine dose (mg/d) and clozapine concentration (mg/L)

	Smokers ($N = 35$)	Non-smokers ($N = 11$)	P -value ^a
Pre-transfer	275 (150–550)	250 (125–500)	
Post-transfer	350 (175–750)	250 (200–400)	
Mean (s.d.) clozapine dose (mg/d)	306 (101)	376 (133)	<0.01
Mean (s.d.) plasma clozapine concentration (mg/L)	0.58 (0.20)	0.43 (0.15)	<0.01
Mean (s.d.) plasma norclozapine concentration (mg/L)	0.34 (0.12)	0.28 (0.12)	<0.01

^aTwo-tailed paired t -test.

In the smoking group the median clozapine dose before transfer was 275 mg/d and this increased to 350 mg/d after transfer; an increase of 27%. The median dose increase was 50 mg/d (range, 75 mg/d decrease to 375 mg/d increase) and there was a statistically significant decrease in both plasma clozapine concentration and plasma norclozapine concentration after transfer in the smoking group. In the non-smoking group the median prescribed dose before transfer was 250 mg/d and this remained unchanged after transfer (range, 100 mg/d decrease to 125 mg/d increase). We found no plasma clozapine concentrations >1 mg/L in either the smoking or non-smoking group post-transfer.

Mental state deterioration was defined as either a worsening of residual symptoms after transfer or emergence of new psychopathology. Eighteen (39%) patients showed evidence of deterioration in their mental state and of these, all but one were in the smoking group ($P < 0.05$; Fisher's exact test). The median time to mental state changes was 54.5 days after transfer as recorded in the clinical notes (range, 6–175 days). Ten patients, all within the smoking group, experienced an exacerbation of psychotic symptoms (*Table 2*). For three patients who experienced increased psychotic symptoms, the trial leave period was extended as a consequence. Notably, no patients in the non-smoking group experienced either a worsening of psychotic symptoms or emergence of new psychopathology. The remaining eight patients, seven of which were in the smoking group and one in the non-smoking group, experienced non-psychotic changes in mental state, including increased self-harm, sexual disinhibition, amotivation, agitation and anxiety. In all cases ($N = 18$), the mental states of these patients improved with an increase in clozapine dose and no patients required readmission to the high-security psychiatric hospital as a consequence of a change in their mental status. *Table 2* Symptoms experienced after transfer

Psychotic symptoms (10 patients)	Paranoid delusions 7	Auditory hallucinations 3	Religious delusions 1	Delusional memory 1
Non-psychotic symptoms (8 patients)	Agitation 3	Anxiety 3	Amotivation 1	Worsening self-harm 1
	Sexual disinhibition 1

Discussion

A not unexpected finding was that most patients commenced smoking despite being provided with nicotine replacement therapy and smoking cessation advice both before and after transfer. Studies have shown that enforced tobacco abstinence in secure environments has little effect on post-release smoking status.^{13,14}

There is an established association between tobacco smoking and the pharmacokinetics of clozapine, with higher clozapine doses generally required in smokers when compared with non-smokers. A previous evaluation of plasma clozapine concentrations before and after implementation of a hospital-wide smoking ban found a mean increase in plasma clozapine of 36% in non-smokers when outliers were excluded.¹⁵ We found a mean clozapine dose increase of 23% (median increase, 27%) occurred in smokers prescribed clozapine and this is less than the 40% dose increase recommended where one or more packs of cigarettes are used per day¹⁶ and less than the recommendation to increase the clozapine dose by a factor of 1.5 over a period of 2–4 weeks.¹⁷ This difference may be because of the effect of restricted time periods off the ward for patients in our sample, who were in a medium secure unit, which is likely to have limited their consumption of tobacco. However, it may also be that clinical teams were cautious in increasing clozapine doses, or patients were reluctant to take more clozapine, given the observed changes in mental state in the smoking group.

We found that receiving clinical teams were aware of the association between plasma clozapine and smoking status and the need to proactively monitor and adjust doses accordingly. As noted earlier, 72% of patients had plasma clozapine and norclozapine measured within 1 month of starting trial leave and this increased to 87% of patients at 3 months post-transfer. There were nevertheless adverse changes in the mental state of almost half of patients who had recommenced smoking. It is possible these symptoms were secondary to the observed reduction in plasma clozapine concentrations. Previous studies investigating the effects of smoking on mental state have focused on patients with neurosis rather than psychosis.¹⁸ We found that most patients experiencing changes in mental state had psychotic symptoms, although this may reflect the symptoms of this particular population from a high secure psychiatric unit. However, structured rating scales were not used in our survey given the nature of this evaluation.

Our study population was of a modest size and data were collected over a minimum follow-up period of 6 months, allowing ample time for changes to clozapine dosing schedules and changes in mental status to have been observed. A limitation of this study is our use of case notes as a source of patient data as case notes do not always include all data that would otherwise have been collected systematically via a structured interview. Our recording of patient mental status before and after smoking resumption is therefore open to assessment bias. Additionally, the post-transfer plasma clozapine and norclozapine concentrations used in this study were not necessarily performed before the recorded dose adjustments. Given the nature of this study (i.e. a service evaluation), we did not control for clozapine dose when measuring the effect of smoking on clozapine and norclozapine plasma concentrations. It should be noted that the non-smokers had a statistically significant lower norclozapine plasma concentration after transfer; we are unable to explain this finding. Finally, we cannot be certain that the non-smoking patients were entirely abstinent as we relied on patient notes to classify smoking status; we did not measure plasma or urine cotinine to confirm smoking status.

This evaluation is a reminder to clinicians that changes in smoking status may cause marked changes in clozapine plasma concentration, and require substantial adjustments in clozapine dosing. We anticipate this evaluation will assist clinicians in the management of patients prescribed clozapine who commence smoking after a period of abstinence and advocate close monitoring of plasma clozapine concentrations, clozapine dose and mental status in patients who change their smoking status, to minimise the risk of relapse.

Jean O'Hara is correct in saying that I am a responsible clinician working with people with intellectual disabilities with offending histories and complex needs – in both in-patient and community settings. As such, my experience of the impact of the Transforming Care national plan is concrete and real rather than 'perceptual'.

It is nonetheless encouraging to learn that NHS England recognises that some people with intellectual disabilities and/or autism need high-quality in-patient care and treatment at times. The question is, post Transforming Care, where are they going to receive it given the wholesale closure of specialist NHS services – including some rated by the Care Quality Commission as outstanding? The options would appear to be either the profit-focused private sector, or acute mental health in-patient units where the specialist care and treatment required is not available.

I note that Dr O'Hara doesn't refer to the data that indicate clearly that the Transforming Care national plan has failed to significantly reduce the number of people with intellectual disabilities and/or autism in in-patient facilities. Rather, she introduces a new metric of the 'need for admission'. This is not defined but seems to refer to admission rates. It is suggested that the national plan has been successful in reducing the variation in the 'need for admission' across the country. Given that a reduction in the geographical variation of admission rates could be achieved by closing beds in some areas whilst maintaining (or increasing) bed numbers in others, with no overall reduction in the number of beds across the country, one might wonder whether this is another case of smoke and mirrors?

Three-and-a-half years on, the Transforming Care programme has failed to invest the tens of millions of pounds in community services in England promised in the national plan. Can we then be comforted by the news that the NHS Long Term Plan 'is explicit about its focus on increasing investment in intensive, crises and community support', or is this just another example of 'jam tomorrow and jam yesterday, but never jam today'¹ for people with intellectual disabilities?

I am employed by Northumberland, Tyne and Wear NHS Foundation Trust; however, the opinions expressed in this response are my own and do not reflect the views of the Trust.

(rahul.bhattacharya@nhs.net)

date

2019-6

Abstract

Aims and method

The Tower Hamlets Crisis House (voluntary sector), in partnership with the local home treatment team, offers a brief residential alternative to psychiatric hospital admission. Here, we review clinician-reported (Health of the Nation Outcome Scales; HoNOS) and patient-reported (DIALOG) outcome scores collected from successive admissions between June 2015 and December 2016, to assess the effectiveness of the service model. We identified 153 successive admissions, and of these, 85 (55.6%) and 91 (59.5%) patients completed both admission and discharge DIALOG and HoNOS questionnaires, respectively. We analysed ten out of twelve HoNOS domains and eight patient-reported outcome measure DIALOG domains.

Results

We found a statistically significant improvement in nine out of ten domains of HoNOS and three out of eight domains of DIALOG.

Clinical implications

A partnership between a home treatment team and crisis house can result in positive outcomes for patients, as determined by both clinicians and patients.

Declaration of interest

None.

 - *Discussion*

What is a crisis house?

Over the past decade, a nationwide drive to reduce and consolidate in-patient psychiatric beds across the UK National Health Service (NHS) has resulted in a concomitant growth in alternative models of intensive care in community settings, including an increase in the number of crisis houses.¹ A crisis house offers provision for people who find themselves in a mental health crisis as a community-based alternative to hospital admission.² The Tower Hamlets Crisis House (THCH) offer a short-term, community-based service for people who find themselves in significant mental distress, which is recognised to be potentially less stigmatising, coercive and institutionalised.³ A mental health crisis may be because of a variety of reasons, ranging from suicidal behaviour with or without intent, panic attacks or extreme anxiety, psychotic episodes or other behaviours that can potentially endanger the patients themselves or others.⁴

Outcomes in Mental Health

Healthcare outcomes are the results of care in terms of patients' health over time.⁵ Outcomes can be assessed by the patient, in the form of a patient-reported outcome measure (PROM), or by the clinician, in the form of a clinician-reported outcome measure (CROM). Over the past decade, increasing emphasis has been placed on medical interventions that yield high value for patients, with value defined as the health outcomes achieved per unit currency spent.⁵ If value improves, both patients and commissioners can benefit as the economic sustainability of the healthcare system increases. Although home treatment team (HTT) services are known to have inexpensive resource utilisation and foster better patient experiences,⁶ there is little research exploring their outcomes, particularly PROMs. The DIALOG intervention is an 11-item PROM that assesses patients' well-being on a 7-point Likert scale. Only the first eight questions of the DIALOG intervention assess patient-reported outcomes, whereas the last three domains assess patient experiences. The Health of the Nation Outcome Scales (HoNOS) intervention is a 12-item CROM intervention assessing four domains on a five-point Likert scale (0–4): behavioural problems, impairment, symptomatic problems and social problems.

Aims

To our knowledge, there is a paucity of agreed methodology for the analysis of CROM data.⁷⁻⁸ Similar challenges exist in analysing PROM data, given no nationally agreed methodology exists to assess these outcomes. The aim of this study was to measure the effectiveness of the THCH, using routine collection of PROM and CROM data.

Method

Data were collected as part of a routine service key performance indicator by the voluntary sector provider in partnership with the NHS trust and reported to the commissioners. The study received ethical approval as a service evaluation from the East London NHS Foundation Trust because the process did not involve any additional data collection or patient contact.

In this retrospective case series, we reviewed HoNOS and DIALOG data from successive patients admitted to the THCH at both admission and discharge (two-point data), between June 2015 and December 2016. Data were collected from quarterly reports submitted as a part of quarterly reporting. To avoid double-counting, e.g. in patient episodes that spread over more than one quarter, data were reconciled to ensure patients who were admitted and discharged over two different quarters were identified as single patients and double-counting was therefore avoided.

For the analysis, the authors compared HoNOS (CROM) and DIALOG (PROM) ratings at admission and discharge. Therefore, we did not analyse the three patient-reported experience measures in the DIALOG intervention (questions 9–11). This study did not assess domain four (cognitive problems) of the HoNOS, as most of the patients presenting to the THCH did not have cognitive difficulties. We also decided not to assess domain eight of the HoNOS intervention (other mental and behavioural problems: specify A, B, C, D, E, F, G, H, I or J, where A is phobic, B is anxiety, C is obsessive–compulsive, D is mental strain/tension, E is dissociative, F is somatoform, G is eating, H is sleep, I is sexual and J is other, specify) because of the heterogeneity of conditions that are assessed in this domain. As a secondary outcome measure, the number of patients who required acute hospital admission or terminated their treatment in an unscheduled manner over this period were noted.

Results are displayed as the means \pm s.e.m. Statistical significance between the two-point PROM and CROM data-sets were determined by a paired *t*-test. All statistical tests were performed with GraphPad Prism, version 6.0d for MAC OS (GraphPad Software Inc., San Diego, CA, USA). Statistical significance was assumed when differences were at $P < 0.05$.

Results

There were 153 admissions during the time period. Two-point DIALOG and HoNOS data were available for 85 (55.6%) and 91 (59.5%) admissions, respectively. Among those for whom two-point DIALOG data were unavailable ($n = 68$): 47 customers did not complete the discharge PROM but had a planned discharge, 6 customers did not complete the discharge PROM as they were either admitted to hospital or abandoned occupancy, and for 15 patients there was no admission or discharge DIALOG score (see *Fig. 1*). Two-point and one-point HoNOS data were available for 91 (59.5%) and 62 patients (40.5%), respectively. There was >85% matching in the cohort of patients who completed the two-point DIALOG and HoNOS interventions. For HoNOS scores, we show a statistically significant improvement in nine out of ten assessed domains, where domain five (physical illness or disability problems) was the only outcome that did not reach statistical significance (see *Fig. 2*). Among the eight DIALOG scores assessed in this analysis, we show a statistically significant improvement in domains one (mental health), five (leisure activities) and eight (personal safety) (see *Fig. 3*). Comparing similar domains in the HoNOS and DIALOG (see *Table 1*), we show some degree of mirroring in the clinician and patient responses, although there is some discrepancy, e.g. comparison numbers four, seven, nine and ten. *Fig. 1* A flow diagram of patients in the study. Discussion

Over the past decade, commissioning in health has rightly turned its focus from commissioning for activity towards commissioning for outcomes. The Five Year Forward View for Mental Health stresses the importance of funding psychiatric services that have transparency around quality and outcomes, and suggested these should be in place by 2017–2018 for adult mental health services.⁹

In recent years, the patient–doctor relationship has evolved: from a paternalistic approach to one that is more collaborative with increased respect for patient autonomy.¹⁰ Given this evolution in the healthcare model, there is increasing recognition of the importance of involving patients in the development and evaluation of healthcare service delivery and quality improvement. PROMs are the tools that have been developed to ensure both a valid and reliable measurement of patient-reported outcomes. PROMs are directly reported by the patient without interpretation of the patient’s response by a clinician or anyone else and pertain to the patient’s functional status associated with healthcare or treatment.¹¹ Capturing both PROM and CROM data in clinical practice provides a more complete understanding of the impact of a healthcare intervention.

HoNOS is mandated as the nationally recommended generic CROM, to be administered by mental health professionals.⁹ Although HoNOS has been around for 20 years,¹² currently no universally agreed methodology for analysing this score exists in the literature.⁸ The DIALOG intervention was developed as part of a multicentre trial developed from Mensa, and then further developed as a solution-focused therapy tool.¹⁴ The DIALOG intervention is suggested by NHS England as an effective PROM intervention, but there are several alternatives, including the Questionnaire about the Process of Recovery and Short Warwick & Edinburgh Mental Well Being Scale.⁹ The analysis of PROM scores around DIALOG is in its infancy.

To our knowledge, this is the first report to systematically compare outcomes of the HoNOS and DIALOG interventions in a crisis house and HTT partnership. Given no standardised approach to analyse HoNOS and DIALOG data-sets exists in the literature, we analysed each item in the HoNOS and DIALOG interventions individually to achieve maximum granularity of data, as well as to allow us to compare similar fields in DIALOG and HoNOS, which would permit a degree of triangulation of clinician and patient perspectives. Our study shows that improvement in CROM scores is not always reflected by an improvement in PROM scores.

It is encouraging that mental health (DIALOG domain one) and personal safety (DIALOG domain eight) – the domains in which a mental health crisis service would be expected to have maximum impact – both feature statistically significant improvement in PROM scores. This finding is supported by statistically significant improvement in similar CROM scores assessing overactive, aggressive, disrupted or agitated behaviour (HoNOS domain one); overactive, aggressive,

¹ DIALOG, PROM, patient-reported outcome measures; HoNOS, Health of the Nation Outcome Scales.

² This study did not assess domain four (cognitive problems) or domain eight (other mental and behavioural problems: specify A, B, C, D, E, F, G, H, I or J, where A is phobic, B is anxiety, C is obsessive–compulsive, D is mental strain/tension, E is dissociative, F is somatoform, G is eating, H is sleep, I is sexual and J is other, specify; all items are scored on a range from zero to four).

³ This study did not assess domain nine (How satisfied are you with your medication?), domain ten (How satisfied are you with the practical help you receive?) or domain 11 (How satisfied are you with the consultations with mental health professionals?). All domains are assessed on a range from one to seven.

⁴
 $P < 0.05$, $**P < 0.005$.

disrupted or agitated behaviour (HoNOS domain one); non-accidental self-injury (HoNOS domain two); problem-drinking or drug-taking (HoNOS domain three); problems with hallucinations and delusions (HoNOS domain six) and problems with depressed mood (HoNOS domain seven).

Broadly speaking, there are four models of community base community-based crisis services:³ (a) clinical crisis houses, providing residential services with staff onsite through the night and have a high level of clinical staff involved in providing onsite care; (b) specialist crisis houses, which share similar features to clinical crisis houses but are aimed at specific groups such as women and people with early psychosis; (c) crisis team beds, which provide a small number of beds aimed at short stays and are fully integrated with Crisis resolution and home treatment (CRHT) teams and (d) non-clinical alternatives, which are mainly managed by the voluntary sector with few clinical staff but many have also forged strong links with CRHT teams. Not all crisis houses have the same degree of collaboration with CRHTs, nor do they all offer residential support; for example, the Dial House in Leeds, UK.¹⁵ The THCH, established in 2010, is a partnership between the voluntary sector provider Look Ahead and East London NHS Foundation Trust (ELFT). The THCH service is embedded within the HTT, which ‘gate-keeps’ all admissions to the accommodation. There were initially five beds in the facility, which expanded to a ten-bed service in 2012. We would consider our model a hybrid of model (a) and (c) and our results indicate that such a model is effective in facilitating patient recovery. Given the heterogeneity of crisis house models, our outcomes cannot be generalised to other models of crisis house.

Our study is not without limitations, one being the limited sample size. Indeed, patients have a right to refuse to complete the DIALOG questionnaire, which explains the relatively little DIALOG data compared with HoNOS (85 v. 91). Although we attempted to administer the HoNOS scale to all patients, this could be done more predictably at admission: unscheduled discharges or very short admissions limited the opportunity to obtain discharge, and consequently, two-point data.

Unfortunately, the data used to analyse CROM and PROM outcomes did not include demographic details or ICD-10 codes. This information would have clarified the groups of individuals who most benefitted from the crisis house intervention. A previous multicentre study comparing the crisis house model to an in-patient psychiatric service noted that patient populations using both services were different with regards to gender, ethnicity and ICD 10.¹⁶ This dissimilarity could mean crisis houses are not a ‘true’ alternative to hospital admission, as the crisis house service could be treating patients who are not as unwell. This is an issue that does not affect the THCH: in a separate analysis performed by our group in 2015, we reviewed the patient profiles of crisis house clients ($n = 299$) and compared these with admissions to an acute in-patient ward ($n = 677$), and found that patients matched on gender, ethnicity and ICD-10 code (results were presented as a poster at the RCPsych International Congress¹⁷).

For (the majority of) patients who demonstrated an improvement in HoNOS and DIALOG scores, we are unable to comment on the precise intervention, or indeed the interplay of interventions, that facilitated improvement in their mental health. Was it being in a safe environment, the therapeutic relationship, pharmacotherapy, practical support or natural resolution of their social crises? In the absence of specific documentation of diagnoses, interventions offered and a ‘control’ group (e.g. an in-patient population), we are unable to discern the elements of the crisis house admission that were effective. It is also possible that this study has overestimated the impact of a crisis house intervention in the HoNOS and DIALOG scores, given patients for whom two-point data is available are more likely to have had a favourable course of treatment, as they would have been more engaged with staff and not made an unscheduled departure or required acute hospital admission.

In conclusion, we report evidence that a crisis house and HTT partnership can result in favourable results particularly around patients’ mental health and safety as assessed by both the patient and clinician. Our findings support the effectiveness of a novel partnership model, supporting its continuance, and providing data to help mental health commissioners elsewhere in determining their local model of crisis care. Despite the study’s limitations, its findings are worth disseminating, given that the evidence base for HTTs is inadequate and is even less established for crisis houses. Furthermore, the routine use of clinical outcome measurements in adult mental health remains patchy, despite significant national drivers. Our findings make a sizeable contribution to the limited literature describing the crisis house service, which is often poorly understood and infrequently commissioned. We hope this study encourages similar services to routinely collect and analyse PROM and CROM scores to develop a rich evidence base in this field.

1.4.42 Personal resilience for psychiatrists: systematic review

Francis Stella Sophia Senthil

date

2019-12

Contents

- *Personal resilience for psychiatrists: systematic review*

I read with interest this article¹ which explores the factors that promote and maintain psychiatrists' well-being, particularly personal, workplace and non-work-related factors such as increased self-awareness, extending job roles, discrete work activities, and/or support from family or social environment.

John. D. Yoon and Brendan M. Daley, studying the association between a sense of calling and physician well-being,² reported that a higher sense of calling in primary care physicians and psychiatrists was associated with an increased level of job satisfaction and resilience from burn-out. This reflects the deeper sense of meaning and purpose that work can bring, which generates and even sustains motivation and enables working with vision. However, there are reported challenges relating to the bureaucratic and technological demands that physicians experience, which mean the sense of calling can be hard to sustain.

A report from the Association of American Medical Colleges published in February 2019 highlights the misalignment between practitioners' values and practices and those of organisations, which can contribute to burn-out and diminished well-being.

Authors Adam M. Brenner and John Coverdale, in their update on trainee wellness,³ report on voluntary resident-led peer group reflective practice for medical students as an intervention for social connectedness. Although the study was of small sample size and lacked a control group, social belonging appeared to be a positive predictor of well-being, diminished imposter syndrome and tolerance of diverse perspectives, suggesting that this model deserves further attention as a potential means of improving resilience in trainees and professionals or psychiatrists.

The authors quote in their update Winston Churchill's famous saying: 'Now this is not the end. It is not even the beginning of the end. but it is, perhaps, the end of the beginning'. These words express hope for momentum towards victory; we are still in the early stages of addressing burn-out and improving well-being, but perhaps we are moving in the right direction.

Christine Montross, in her book *Falling Into the Fire: A Psychiatrist's Encounters with the Mind in Crisis*,⁴ describes 'patients who are so difficult to diagnose or treat – uncertainty it arises', 'I hold my trust in medicine up to the light, I see that it is full of cracks and seams. In some places it is luminous. In others it is opaque. And yet I practice'. She discusses how over time she has developed trust in the daily work of talking, treating and attempting to heal: 'you have to be anchored to the shore – to the people and things that are central to your own life'.

1.5 2018**1.5.1 41. RECONSIDERING THE EVIDENCE FOR CLOZAPINE FOR TREATMENT REFRACTORY SCHIZOPHRENIA**

James MacCabe

date

2018-4

Abstract

Overall Abstract: The superiority of clozapine for treatment refractory schizophrenia was, until very recently, seen as one of the few unshakeable truths in psychiatry. But the pre-eminence of clozapine has recently been called into question by meta-analyses. What are we to make of the fact that meta-analyses of clinical trials, supposedly the pinnacle of evidence based medicine, fail to show an effect which seems clearly evident to most clinicians, and on which many of our guidelines are based? Have we believed in a fairytale for the past three decades? Or do biases in RCTs and methodological limitations of meta-analyses explain the results? These questions will be discussed by Dan Siskind.

Another way to address the question of efficacy is to examine the pharmaco-epidemiological evidence using population-based registers. Jari Tiihonen will present data from his seminal studies of mortality and readmission rates under clozapine treatment versus other antipsychotics, as well as other data. These data seem to show powerful positive effects of clozapine at the population level. Furthermore, more recent evidence suggests a role for clozapine in reducing rates of violent offending, with new data presented for the first time by Vishal Bhavsar.

Finally, despite clinical guidelines recommending the use of clozapine, the actual rates of clozapine use are much lower than expected, with large regional and international variations. There is evidence that the burden of blood monitoring deters physicians from prescribing clozapine. Yvonne van der Zalm will present new data from a cluster randomised trial testing the efficacy and safety of an intervention to increase rates of clozapine prescribing by employing nurse practitioners trained in the initiation and monitoring of clozapine.

John Kane, author of the first, seminal RCT of clozapine in 1988, will lead the discussion.

1.5.2 41.1 WHAT DO META-ANALYSES TELL US ABOUT CLOZAPINE'S EFFICACY AND EFFECTIVENESS FOR TREATMENT REFRACTORY SCHIZOPHRENIA?

Dan Siskind Steve Kisely Rachel Land Lara McCartney

date

2018-4

Abstract

Background

Clozapine has long been considered the gold standard antipsychotic for treatment refractory schizophrenia (TRS). There have been a number of recent meta-analyses of efficacy of clozapine on psychotic symptoms and effectiveness in reducing hospitalisations that have sparked debate on the role of clozapine.

Methods

Current literature regarding the efficacy of clozapine for TRS, including pair-wise and network meta-analyses of RCTs with reported outcomes of total psychotic symptoms, positive symptoms and negative symptoms were reviewed. We also examined the results of a meta-analysis of the effectiveness of clozapine on reducing hospitalisations based in RCTs and observational studies.

Results

Two recent meta-analyses: Samara et al (2016), a network meta-analysis in JAMA Psychiatry; and Siskind et al (2016) a pairwise meta-analysis in BJPsych, found similar equivocal results for total psychotic symptoms. However, Siskind et al (2016) found clozapine to be superior to other antipsychotics for positive symptoms. Factors influencing the difference in results included pair-wise vs network methodology and sensitivity analyses of pharmaceutical industry support. Of note, only 40% of people with TRS responded to clozapine. Clozapine's effectiveness for reducing hospitalisations was significant, with a relative risk of 0.74 (95%CI 0.69–0.80).

Discussion

There are a lack of recent non-industry funded randomised control trials of clozapine compared to SGAs, which hinders an equivocal statement about the superiority of clozapine for total psychotic symptoms. However, there is evidence to suggest that clozapine is superior to other antipsychotics, including SGAs, for positive symptoms. In terms of effectiveness, initiation of clozapine can reduce the proportion of people hospitalised and reduce bed days. Use of clozapine needs to be balanced against its adverse drug reaction profile. There remains a need for more effective treatments for TRS, and biomarkers to identify TRS.

1.5.3 40.4 LOW-DOSE RISPERIDONE TREATMENT IN ADOLESCENCE PREVENTS THE DEVELOPMENT OF NEUROINFLAMMATION IN THE MATERNAL IMMUNE ACTIVATION MODEL

Ina Weiner Shani Pery Jasbeer Dhawan Anat Biegon Yael Piontkewitz

date

2018-4

Abstract

Background

Postnatal consequences of prenatal immune activation mimic a broad spectrum of neuro-psychopathological features phenotypic of schizophrenia (SCZ). We previously showed that SCZ-relevant behavioral and brain structural abnormalities emerging in adult offspring of moms exposed to the viral mimic polyI:C, are prevented by treatment with the atypical APD risperidone (RIS) in adolescence, prior to the emergence of structural and behavioral abnormalities. Given the increasing centrality of neuroinflammation in SCZ and its treatment and/or prevention, here we assessed whether adolescent RIS is able to prevent neuroinflammation in the polyI:C offspring.

Methods

On gestation day 15, pregnant Wistar rats were injected IV with polyI:C (4 mg/kg/ml) or saline. Pups were weaned on postnatal day (PND) 21. Preventive treatment with RIS (Janssen, Belgium; 0.045 mg/kg) was administered daily on PNDs 34–47. Offspring were sacrificed on PND48, prior to full spectrum of structural and behavioral abnormalities, or on PND90, after the emergence of structural and behavioral abnormalities. Microglial activation was assessed in ten regions (nucleus accumbens, striatum, substantia nigra, frontal, anterior cingulate and occipital cortices, dorsal hippocampus (sub-regions CA1, CA3 and dentate gyrus [DG]) and ventral hippocampus (vHPC), using quantitative [3H]PK11195 autoradiography. Another cohort of offspring underwent behavioral testing and imaging.

Results

ANOVAs of [3H]PK11195 binding in offspring sacrificed on PND48 revealed no significant effects of prenatal polyI:C in any of the regions assessed. In adult male offspring, [3H]PK11195 binding was significantly increased in the CA1, CA3 and DG hippocampal subfields as well as in the frontal and occipital cortices, compared to controls. No such increases were observed in polyI:C offspring treated with RIS in adolescence (significant prenatal x preventive treatment interactions, and significant difference in [3H]PK11195 binding between polyI:C-VEH and saline-VEH but not between polyI:C-RIS and saline-VEH offspring in post-hoc analyses, in each of the regions). In females, [3H]PK11195 binding was significantly increased only in the vHPC, occipital cortex, and nucleus accumbens. Such increases were not observed in polyI:C female offspring treated with RIS in adolescence. In a second cohort of offspring, prenatal poly-I:C led to structural abnormalities in the hippocampus, striatum, prefrontal cortex and lateral ventricles, as well to deficits in selective attention, executive function, working memory and social interaction, all of which were prevented by RIS.

Discussion

Increased [3H]PK11195 binding in the brains of adult poly-I:C offspring is consistent with increased uptake of [11C]PK11195 in patients with SCZ, measured in-vivo by PET. Microglial activation emerged in adulthood, with no such activation in young (PND48) offspring. Late emergence of microglial activation parallels the developmental course of behavioral and brain structural abnormalities in poly-I:C offspring (Piontkewitz et al, 2011a, 2012a; Piontkewitz et al, 2009), suggesting that these late-emerging abnormalities are linked. The latter is supported by the fact that RIS in adolescence prevented the emergence of behavioral and brain structural abnormalities as well as microgliosis in the adult offspring. These data suggest that prevention of adult microgliosis is one of the mechanisms underlying RIS capacity to prevent polyI:C-induced behavioral and neuroanatomical deficits, however, a causal relationship remains to be established.

1.5.5 Implementing National Institute for Health and Care Excellence smoke-free guidance in a secure facility: an evaluation of the prescribing costs in clozapine users

Stephen Noblett Jane Beenstock James Noblett Joanne Ireland Sarah Ormiston

Correspondence

Stephen Noblett

(steve.noblett@lancashirecare.nhs.uk)

date

2018-4

Abstract

Aims and method

The increased rates of smoking in people with mental illness is well documented, and establishing smoke-free mental health environments has been emphasised over recent years. This article examines the financial costs of implementing smoke free guidance and assesses the cost associated with patients who were prescribed clozapine and who committed to stopping smoking cigarettes for the duration of the study period.

Results

Patients (38) who were prescribed clozapine were included in the study. A moderate reduction in dose was noted with a moderate reduction in prescribing costs. The total increase in cost for the whole group, however, was £17 624, largely due to the use of nicotine replacement therapy and an increase in the number of clozapine assay tests.

Clinical implications

Further studies on implementing this important policy change are needed. The positive effects must be balanced with increased financial pressure on Mental Health Trusts.

Declarations of interest

None.

Cost of smoking

Smoking imposes a huge economic burden on society. Action on Smoking and Health has concluded that the costs to society in England are approximately £13.9 billion per year. Around £2 billion of this is the cost to the National Health Service (NHS) of treating diseases caused by smoking.¹ For adults with a common mental disorder such as depression and anxiety, smoking rates are almost twice as high compared to adults who are mentally well, and three times higher for those with schizophrenia or bipolar disorder.² Smoking is thus a key contributor to the health inequalities that exist between people with a mental health disorder and the general population, which result in a difference in life expectancy of 15–20 years.^{3,4} Nationally there has been a growing recognition that providers of mental health services should be smoke free and support patients with nicotine addictions to stop smoking.^{5–7}

National Institute for Health and Care Excellence guidance

In particular, National Institute for Health and Care Excellence (NICE) guidance⁵ advocates that all NHS settings should be smoke free because of the health benefits to the individual, the wider community and healthcare providers. They emphasise that healthcare providers should promote healthy environments for their staff and patients. In this Trust the guidance was implemented through a nicotine management policy as, learning from other Trusts, the focus was on supporting people who have a nicotine addiction rather than banning smoking. The policy contents are similar to smoke-free policies in other Trusts: admitted smokers may no longer have smoking breaks and should manage their nicotine addiction through the use of nicotine replacement therapy (NRT) with behavioural support. Consequently, people admitted to smoke-free mental health units need to be supported to cease smoking tobacco cigarettes during their admission. Ideally, this would lead to permanent smoking cessation. *Table 1* summarises some of the consequences in terms of cost or benefit to the individual and to the wider organisation. *Table 1* Summary of the costs and benefit consequences of smoking cessation following the introduction of a smoke-free policy in a mental health provider unit

Consequence	Cost or benefit?
Smoking cessation aids such as nicotine replacement therapy (NRT) and medications such as bupropion	Cost
Behavioural support	Cost
Increase in number of clozapine assay tests required	Cost
Reduction in amount of antipsychotic medication required, with opportunity for fewer side effects from the medication	Benefit
Reduction in staff time spent supervising smoking breaks	Benefit
Improvement in mental health	Benefit
Reduction in premature mortality and in levels of morbidity	Benefit
Potential lower costs of prescribed antibiotics for lung infections or other smoking-related physical health problems	Benefit

Public Health England estimates the long-term quit rate for long-term patients is 40%, and 25% for short-term patients

Intervention	Cost	Benefit
Public Health England estimates that the intervention could cost approximately £1430 per annum to the health and care system on average over 10 years	Cost	Benefit
Public Health England estimates net savings of approximately £1460 per annum per person to the health and care system on average over 10 years	Benefit	Benefit

NRT and the associated costs and savings

NRT provides nicotine to the body without using cigarettes. The aromatic hydrocarbons found in cigarette smoke are known to increase the metabolism of some drugs due to induction of the cytochrome P450 enzyme system.¹⁵ NRT does not influence these metabolic enzymes.¹⁶ Plasma levels of clozapine are altered in the absence of tobacco smoke. Therapeutic-drug monitoring of clozapine is therefore useful with a recognised therapeutic range to regulate the required prescribing dose. Failure to monitor plasma levels in the context of stopping smoking may result in prescribing the incorrect dose. Following smoking cessation, clozapine doses may be reduced, decreasing the medication cost for the NHS in mental health. Smoking cessation could be financially beneficial to the NHS because the resources used to supervise smoking could be used elsewhere to improve health and well-being. This, however, may be offset by increased requirements for therapeutic-drug monitoring and the cost of NRT. Whereas there is extensive published literature demonstrating the long-term benefits of smoking cessation, in both the general population¹⁷ and in the population of people with a mental health disorder;¹⁸ there is limited published work describing the short-term costs and benefits.

Aim

This project aimed to review the costs of providing NRT, clozapine and clozapine assay testing in the context of the new nicotine management policy within a secure mental health population. In January 2015, the secure mental health service implemented a nicotine management policy (NMP) in response to the publication of the NICE public health guidance 48.⁵ This evaluation focused on the costs and savings relating to clozapine and NRT because these are the two most direct expenditures from supporting people who smoke to manage their nicotine addiction without smoking tobacco cigarettes. NRT is required to manage the nicotine addiction and clozapine is commonly prescribed in the specialist services. Patients on clozapine who stop smoking are likely to have lower prescribing costs because of the need for lower dosages of medication when stopping smoking.¹⁹

Method

Setting

Guild Lodge is a secure mental health facility which provides care for 164 male and female patients within medium, low-secure and step-down ward environments. It also provides regional medium and low-secure care for males with acquired brain injury. The service provides a seamless transition of care between different levels of security in preparation for support in the community. The service is made up of 12 in-patient wards, 3 of which care for a total of 24 women. Ethical approval was not required as no patient information was identified. Advice was sought through the audit department within the Trust.

Context

The study looked at a cohort of patients who were prescribed clozapine for a 12-month period at the time the NMP was implemented at Guild Lodge in January 2015. These people stopped smoking cigarettes at this time and maintained their smoke-free status for the duration of the study. This was monitored in the context of the secure in-patient and hospital grounds smoke-free environment. Prior to the implementation date, data was collected in an effort to try to anticipate where there may be particular risks due to elevated clozapine plasma levels for individual patients. Data included clozapine dose, plasma level (with current dose) and if any anticonvulsant medication was also prescribed.

The 6 month period prior to the implementation in January 2015 was considered in terms of dosage of prescribed clozapine and the number of clozapine assay tests undertaken. In the following 6 months, until July 2015, information relating to the dose of prescribed clozapine, number of clozapine assays and prescribed NRT was collated.

The total financial cost for this group, in the 6 months before and after implementation of the NMP, was calculated based on the cost to the organisation of clozapine, clozapine assay tests and specific NRT, including patches, lozenges and inhalators.

Results

A total of 38 patients were included in the study, representing 23% of the total in-patient population. Of these, 8 were women (21%) and 30 were men (79%). Data was obtained from each of the 12 wards within the service. In total, 48 out of 164 patients were prescribed clozapine in the service at the time. Ten of these were non-smokers and were therefore not included in the study. At the time of the study, the hospital site became a smoke-free environment, although there was occasional evidence of illicit smoking within the secure setting.

The results demonstrated a small reduction of 6.5% in mean clozapine dose from 381 mg to 356 mg in the 6 month period following the NMP implementation. However, the number of clozapine assays carried out in this period increased by 200%, with the mean number of assays rising from one to three. The increased number of clozapine assays had a significant financial effect (*Table 2*), although the number of required assays is likely to reduce as plasma levels stabilise following smoking cessation. *Table 2* Total cost before and after implementation of National Institute for Health and Care Excellence smoke-free guidance

	Total cost of clozapine dose before intervention (£)	Total cost of clozapine dose after intervention (£)	Total cost of assays before intervention (£)	Total cost of assays after intervention (£)	Total cost of nicotine replacement therapy (£)	Total cost before intervention (£)	Total cost after intervention (£)	Total difference in cost after 6 months (£)	Total cost for service
	7489.41	6991.44	878.75	228016	818.96	8368.16	26 090.40	17 623.66	Mean cost per patient
	197.09	183.99	23.13	60442.60	220.21	686.59	463.78	Range of individual costs	77.61–362.18
	77.61–362.18	77.61–362.18	71.25	23.75–142.50	0–871.92	101.36–385.93	127.23–1184.25	0–930.24	

Table 2 demonstrates the specific prescribing costs for medication and for clozapine assays for the service, as advised by the pharmacy department. These figures are based on the costs of clozapine over the two 6 month periods for the organisation, costs for each assay test and total cost of NRT. Costs did not include any additional phlebotomy or laboratory costs.

A total of 5 out of the 38 patients had no clozapine assay tests taken in the 6 month period prior to stopping smoking, which may have represented clinical stability and consistent dose prescribing in this group. A total of 28 patients (74%) were prescribed NRT throughout the 6 month period with the majority using patches (53%) and inhalators (45%). This resulted in a cost of £16 819 for the 6 month period.

There was only a moderate reduction in the cost of prescribed clozapine because of limited dosage change, but also due to the relative in-expense of clozapine itself. For 18 out of the 38 patients, the cost of clozapine remained the same, indicating that the dose was unchanged during this period. Although the patients had committed to stopping smoking, it is possible that they continued to smoke cigarettes at times, leading to an increased cost of prescribed NRT, as this may have had little clinical benefit for these individuals.

For 35 patients, representing 92% of the sample, there was an increased cost in the 6 month period following the implementation of the NMP, with a total cost of £18 641.66 for the whole group during this time.

Discussion

This study showed that in the 6 months following the introduction of the NMP in this unit there was a slight decrease in the costs from prescribed clozapine, and increased costs generated by more assay tests and the use of NRT.

These results will have been influenced by the take-up rate of NRT patients, and the extent to which they were compliant with not smoking cigarettes during the 6 month period. This will have affected the amount of NRT prescribed and the consequent impact on clozapine plasma levels. Current and future costs will also be affected by the number of patients who use e-cigarettes.

The current culture and practice around smoking has been evolving since the 6 months reviewed in this study. Recently, the use of e-cigarettes has been piloted and a much more robust approach to implementing the NMP has affected attitudes and behaviours in relation to the NMP. In addition, patients have been given less time in the grounds where they have been likely to smoke cigarettes, especially when they have access to the community on leave. This may begin to change the culture of leave within the grounds to be more therapeutic and less about gaining access to cigarettes.

This study has not included all the financial costs that could be affected by the introduction of the NMP, such as prescription costs for physical health problems related to smoking, and staffing costs for supervising patients who have smoking breaks.

Although there is good evidence that the overall benefits of smoking cessation are greater than costs for both individuals and society in the longer term, in the short term there are some immediate financial pressures generated for Mental Health Trusts. Further work is needed to understand if these results are likely to be the same for other Trusts implementing this important policy change that is needed to improve the mental and physical health of people using mental health services. Smoke-free policies challenge the culture in mental health units,²⁰⁻²³ but the financial pressure involved should not derail the ambition to be smoke free because it is consistent with national policy and is of significant benefit to people with a mental health disorder.¹⁸

1.5.6 Choice of provider for out-patient treatment is not working

2018-4

Abstract

In 2012, the coalition government introduced the legal right for National Health Service (NHS) patients in England to choose their mental healthcare provider for out-patient treatment. This was a significant step towards parity of care between mental and physical ill health, and NHS Improvement and NHS England have provided sensible guidance on its implementation. However, several factors prevent the system from working as it was intended: lack of awareness of the principle of patient choice for out-patient treatment; complacency from some trusts and commissioners; mental health trusts operating outside the e-referrals system; misuse of care pathways; lack of direct access by many general practitioners for out-of-area referrals; and delays in authorisation for funding. I describe how I have come to this conclusion and suggest some solutions.

Declaration of interest

The author is employed by a trust that potentially benefits from ‘patient choice’.

 - *Conclusions*

The Royal College of Psychiatrists has campaigned for parity of care between mental and physical ill health and has secured some notable success in raising awareness and pushing mental health up the political agenda. One issue in parity of care, which remains problematic, is the right of patients to choose their out-patient provider in defined circumstances. Thus, if you visit your general practitioner (GP) with a cancer, you can choose your treatment provider, using a variety of criteria such as reputation, outcomes, waiting times and location. Paradoxically, choice is not often a

priority in physical healthcare.¹ When surveyed, people most value proximity, a short waiting list and ease of transport to healthcare. This is perhaps because the quality of physical healthcare is more similar across providers compared with, say, the delivery of a protocol in cognitive-behavioural therapy (CBT) for a particular disorder.

Background

In 2012, the Rt Hon. Norman Lamb and the coalition government introduced the legal right for National Health Service (NHS) patients in England to choose their mental healthcare provider for out-patient treatment.² This was a significant step towards parity of care and allowed patients suffering mental disorder to choose their *out-patient* provider, in the same way as they could if suffering from a physical condition, without the need for discussion at a funding committee. Older readers will remember that choice for mental health out-patient treatment used to be available on the NHS up until the early 1990s.

The way the change in law is interpreted is outlined in the document *Choice in Mental Health*, published by NHS Improvement, who are now responsible for the regulation of patient choice.³ NHS England have also published some helpful documents and guides on patient choice, from which some of this article is drawn.⁴⁻⁶

The guidance by NHS Improvement and NHS England is clear. Nevertheless, introduction of the change is being hampered by several factors: lack of awareness on the part of both professionals and the community; poor commitment by trusts and commissioners; and various loopholes that I will go on to describe. As it remains cheaper for a patient to be treated by a block contract with a local provider, some of the apparent lack of compliance may flow from an effort to contain costs. To follow the guidance for patient choice, out-patient treatment needs to follow a typical package of care at a service that has a standard NHS contract. This can be at two levels of stepped care.

Primary care – Improving Access to Psychological Therapies (IAPT)

This consists of a psychological therapy with no consultant involvement. Thus, legally the GP and patient may decide they wish to go to a different provider even if a clinical commissioning group (CCG) has a block contract with a local IAPT service.

Secondary care – consultant-led service

Where a patient with moderate to severe symptoms requires a more experienced therapist and medication advice in a consultant-led service, this can also be accessed under patient choice by a GP. The treatment must be *clinically appropriate*, without the need for local community mental health team (CMHT) involvement or integrated social care. Here, the service acts as the secondary care provider. Again, under patient choice, the existence of a care pathway with a block contract for a local CMHT or psychological therapy service is irrelevant if the GP and patient decide they wish to go to a different provider. Clarity over the right of patients to choose may be particularly important where there is a need for assessment or treatment in one of the many ‘Cinderella’ services in psychiatry, such as anxiety disorders and trauma, attention-deficit hyperactivity disorder (ADHD), chronic fatigue or medically unexplained symptoms, where local services may not be well developed. It might involve out-patient child and adolescent services if other local services are not required. However, there is no obligation on the provider of a CMHT to travel to the patient; in effect, choice depends on the patient traveling to an out-patient provider.⁵

In brief, NHS England⁵ state that a patient is *not* entitled to choose where to be referred in the following cases. ¹The patient’s needs cannot be addressed by a typical package of care that lies outside National Institute for Health and Care Excellence (NICE) guidance or is not routinely commissioned on an ongoing basis through a NHS standard contract. An example for which choice of provider does not exist might be repetitive transcranial magnetic stimulation for depression, because it is not routinely commissioned. An example of where choice would exist is CBT for post-traumatic stress disorder (PTSD), which would be commissioned to be treated at a local IAPT or secondary care service.²The patient’s needs mean that an outside referral is *not* clinically appropriate. For example, urgent care for a patient with significant risk factors (such as self-neglect or a risk of suicide), which are best served by local CMHT involvement. Patients cannot choose their level of care (such as residential or in-patient over out-patient care) unless it is clinically appropriate (for

example, intensive CBT on a residential unit for severe obsessive–compulsive disorder). Nor are patients entitled to choose a non-local provider if treatment is likely to need integrated care with social services or a CMHT because of the level of risk. These are examples of where it is not clinically appropriate for a GP to refer that patient to an out-patient service. If patients need a local CMHT, then the GP cannot refer to a specialist service. If appropriate, the CMHT will make an individual funding request to a CCG for assessment or treatment at a national specialist service as part of tertiary care.

The principles developed by NHS Improvement and the Patient Choice department of NHS England⁵ are sensible, but parity of care is not working in practice. I highlight some of the key problems and possible solutions below.

Lack of awareness of patient choice on the part of patients and GPs

Patients and GPs remain broadly unaware of patient choice. It seems very strongly embedded in the culture that mental healthcare is differently regarded from physical care and that only in exceptional cases can patients be referred out of area. I have read refusals for funding from commissioners in mental health, which cite unapologetic expectation that routine patients be treated in a locally commissioned service. I have lost count of the patients who report that their GP swiftly dismissed any suggestion that an out-of-area referral is possible other than in exceptional circumstances (i.e. a tertiary care option) or where ‘local resources have been exhausted’. On the NHS Choices website, psychiatric hospitals are commonly listed as providing a service for their local population. There is no listing of, say, a clinic for anxiety disorders, ADHD or eating disorders that will accept referrals from GPs all over England.

Linked to this problem, the NHS Choices website specifies no waiting times, or details of outcomes, awards or patient feedback for any individual clinic. Neither do hospital or IAPT websites make clear when a service can receive a direct referral from a GP from around the country or when it requires a CMHT to make the referral. Where patient-reported outcome measures (PROMs) are available, presentation is very patchy (and tends to refer to an IAPT service in one borough, rather than a service like our own at the Centre for Anxiety Disorders and Trauma which accepts a selection of patients across different IAPT services). There appears to be little desire by trusts to develop special interests, and so trusts that do provide a ‘specialist’ service appear to regard them still as only available in complex cases or for tertiary care, for which patient choice does not apply. This is not the case. Services such as our own not only have funding streams for treating patients with severe cases in tertiary care but also treat patients within primary care (IAPT) and secondary care as described above. NHS Improvement published further guidance earlier this year in user-friendly language. The leaflets⁵ were sent directly to all CCGs.² Although Mind and other mental health charities also publicised the initiative, the message is still not getting through to GPs or patients who would like the option of choice for out-patient treatment where it is clinically appropriate.

It would undoubtedly help if NHS Digital and providers were to publicise on their websites those services that are directly available to GPs, accompanied by clear data. At present, NHS Choices tends to describe the hospital but not individual clinics, although I acknowledge they are dependent on the information provided. NHS Choices does, however, provide a list of private therapists, which seems odd on an NHS website. ‘Specialist’ services on hospital websites appear to be solely relevant for tertiary care rather than open for GP referrals. The NHS Choices and individual hospital websites need to encourage the reporting of standard PROMs and other meaningful information such as waiting lists for individual clinics. Patients find it difficult to make choices unassisted and currently seem to rely mainly on reputation and charity helplines. This is not good enough.

Mental health foundation trusts are not part of ‘e-referral’ systems on GPs’ computers

Only a small number of mental health providers have joined e-referral (or the old ‘Choose and Book’ system) in the same way as physical care providers do. This prevents GPs from using the system as intended, while feeding the misperception that they are obliged to use the local service. Thus, if you have a physical health problem, your GP can book you into a clinic of your choice on his/her computer. Waiting times are generally known for competing hospitals providing physical healthcare. Mental health trusts appear to prioritise their CMHT services over implementation of e-referrals and other mechanisms to assist with the guidance.

Misuse of care pathways

A 'care pathway' is a way of describing *how* a patient is assessed and treated for a specific problem. Many hospital trusts and CCGs have care pathways which are helpful. They are generally based on NICE guidance, although there are often areas in which there is not sufficient evidence and a pathway is based on other evidence and expert opinion. Care pathways are sensibly used for long-term physical conditions such as diabetes, which require local joined-up solutions. However, care pathways in mental healthcare are often misused; they may state *the location* of a local service without highlighting the need to discuss patient choice when there are no significant risk factors or any need for local social services or a CMHT (as required by NHS Improvement). Other misuses of care pathways include referrals for a patient with a certain condition (e.g. chronic fatigue) being directed to a specific care provider that has a block contract, with no discussion about choice.

My view is that NHS Improvement needs to ensure that, when a patient does not have significant risk factors (e.g. suicide, neglect) or any need for integrated social services, a local care pathway includes a discussion of choice and relevant documents are easily available on a local website (rather than, for example, obtained under the Freedom of Information Act). Here, NICE could highlight the role of choice in out-patient treatment for problems that do not require local CMHT or social services.

Lack of direct access by GPs to IAPT providers out of their area

Increasingly, CCGs prevent their GPs from directly referring to a non-local IAPT provider. GPs may refer to a local IAPT service, but anything else is directed to a local triage assessment or to a funding panel. In other words, not all providers are treated equally, and delays are created for patients referred to triage or a funding panel. Triage can be helpful when a patient is likely to need a local CMHT (for example, if a patient has significant risk factors or is likely to need mental healthcare integrated with social services). An IAPT patient by definition does not have significant risk, so this is an example of inherent bias (or lack of parity). Triage is not required for referral to a local IAPT level of service, but it may be required to determine whether the patient needs to be referred to a CMHT. Indeed, people are entitled to self-refer without even needing to involve a GP, yet if they have the temerity to go out of area, they have to be triaged to discuss the benefits of the local IAPT service, thus delaying treatment.

At present, NHS Improvement allows CCGs to set up care pathways as they see fit. They believe that a triage assessment can be used to determine whether the referral is clinically appropriate, so long as choice is discussed. However, local triage services do not collect the relevant PROMs or waiting times, or keep a current list of specialised clinics of other IAPT providers around the country. Sample documents have shown that it is not normally part of the policy to discuss choice of provider (and certainly choice of IAPT provider). Many CCGs just ban their GPs from referring out of area, and such requests have to go to a funding panel where the GP is required to request special circumstances, which is inconsistent with patient choice. In practice, patients conduct their own research and discuss it with their GP or hope that the GP has specialist knowledge and can advise them. IAPT services are perfectly capable of saying when treatment with them is not appropriate, without local CMHT involvement. Patients do not need another triage assessment – otherwise they would not be allowed to refer themselves directly to a local IAPT provider.

In summary, IAPT represents the lowest level of stepped care. Patients are often entitled to self-refer. The principle of a triage service for IAPT patients who wish to be referred to an out-of-area provider is therefore nonsense. In my view, NHS Improvement needs to ensure that IAPT patients can be assessed at the provider of their choice. Referrals to non-local providers need to state clearly which service is sought (for example, IAPT rather than secondary care).

Lack of direct access by the GP to a secondary care provider

By secondary care provider we mean a consultant-led service which deals with more complex problems than IAPT does or where medication advice may be required. Again, GPs are often prevented from directly referring outside the area or are restricted in doing so until after triage by their local provider. Local triage services are appropriate when local CMHT or social services involvement is likely to be required. Again, NHS Improvement does not define how referrals should be managed *so long as choice is discussed* at a triage service. As we have seen above in discussing IAPT services, this is naïve: triage services do not have regular access to information about other services, relevant PROMs and care pathways. In practice, despite the guidelines, triage services do not discuss the importance of patient choice in their policy documents, and not all providers are treated equally. Alternatively, such referrals are just blocked at funding panels, and the patients and GPs are unaware of their rights.

In my view, NHS Improvement needs to ensure that all triage services include a full discussion of choice in their policy documents or care pathways, and that they can provide details of other relevant services. In addition, such cases should not be discussed at funding panels. Referrals to providers need to state clearly that they are seeking a secondary care service rather than IAPT, and that they require assessment and treatment by a consultant's team.

Delays in authorisation of funding for assessment

When a patient is finally referred, there must be pre-authorisation for funding by the CCG. Referrals for mental disorders out of area are still widely treated as something unusual, and the funding panels question why the patient cannot be treated locally or use a care pathway that states where a patient must be referred (because that is where there is a block contract). There are many examples at my own service of patients referred by their GP who wait several months, even a year, for applications to be ignored, and then find that funding is never authorised. About 50 patients who have been referred by their GPs to my department at the Centre for Anxiety Disorders and Trauma are waiting for authorisation for funding from CCGs, either for an assessment or, when they have been assessed, for treatment. Of the 50 I recently audited, seven have been waiting more than a year, 13 for more than 36 weeks, 25 for more than 24 weeks, 38 for more than 12 weeks, and the rest for more than 4 weeks. The picture has been similar in previous years. We recently reviewed our list and found that some patients had given up: some accept local treatment; some seek private care they can't afford. The people who can choose the location of their treatment are either lucky (depending on their postcode), or extremely persistent and articulate, or helped by an advocate. Once a patient has been assessed by a provider and treatment is recommended, there may then be delays obtaining funding for treatment. This is wrong, because the guidelines direct that in such cases, the CCG concerned cannot then require the patient to switch to its own provider for treatment. Although the NHS Improvement guidance on this does appear clear, the message is still not getting through to CCGs. My own trust has hundreds of outstanding requests for authorisation of GP referrals for assessment or treatment (not just for our department). Much time is wasted by the trust and by patient advocates in chasing CCGs, and patients experience delays in treatment, resulting in avoidable distress to patients and their families. If these same patients were suffering a physical health problem and required out-patient treatment, no authorisation for funding would have to be made: an invoice for activity would just be presented at the end of a treatment episode. Funding should only be refused if the treatment is not clinically appropriate (and not, for example, because the applicant should be treated in the local care pathway), and any such process should not unduly delay assessment or treatment. GPs and patients can complain directly to the regulator at NHS Improvement (<https://improvement.nhs.uk/contact-us/>) if they feel they are being denied their rights.

Conclusions

Some patients want to be able to choose their treatment provider for out-patient treatment. This will mainly affect more 'specialist' services such as anxiety disorders, chronic fatigue and ADHD, where a local service may be less well developed. They have a legal framework and guidelines from the regulator to support them. However, more than 4 years after the system was introduced, it is not working effectively to deliver the care intended.

I acknowledge salary support from the National Institute for Health Research (NIHR) Biomedical Research Centre for Mental Health at the South London and Maudsley National Health Service Foundation Trust and the Institute of Psychiatry, Psychology and Neurosciences, King's College London.

1.5.7 The alignment of law, practice and need in suicide prevention

Helen M. Stallman Geneva L. Ohan

Correspondence

Dr Helen Stallman

(helen.stallman@unisa.edu.au)

date

2018-4

Abstract

Help-seeking is important for patients with suicidal ideation. Currently, a risk management paradigm is used with patients who express suicidality; however, this may limit support and increase stigma, reducing future help-seeking. Coping planning is proposed as a paradigm shift that overcomes these problems by focusing on patient needs and strengths.

Declaration of interest

None.

Contents

- *The alignment of law, practice and need in suicide prevention*

There has been a plethora of research related to help-seeking and mental illness; for example, a Google Scholar search for 'help-seeking and mental health' provided 2.17 million results. Perhaps this is not surprising in light of the considerable efforts that have been undertaken to raise awareness of mental illness and promote help-seeking. But an important question is: why would someone with a mental illness seek professional assistance to begin with, and what is the need

when he/she asks for help? Although help-seeking is an important first step in accessing all treatment, here we will focus on help-seeking from the perspective of the patient disclosing suicidality.

Suicidal ideation can be seen as a coping strategy, occurring when the person has inadequate healthy and other unhealthy strategies to cope and starts to wonder whether suicide is a solution for his/her distress.^{1,2} Disclosing suicidal ideation – rather than acting on it or ruminating about it – is a healthy coping strategy. The main message that a person who is confiding suicidality is saying is, ‘I’m having trouble coping right now. I need you to help me.’ Seen in this way, the need from help-seeking is immediate support. The disclosure comes with trust that the confidante can and will help, providing minimally-sufficient support – that supports coping, but does not undermine a person’s strengths and autonomy – until the person can cope independently again.³

However, this message is not always what the health professional may hear, or is trained to hear. Rather, what may be interpreted instead when a person discloses suicidality is, ‘I am at risk of harming myself – now that I have disclosed this risk, you are responsible to stop that from happening.’ Managing this risk is the dominant paradigm in responding to suicidality.^{4,5} Its focus is on ensuring the patient’s safety and preventing death. A risk perspective reflects a society that is motivated by a commonality of anxiety about the future, rather than a commonality of need in the present.⁴ Legally, this is reflected in mental health acts, which allow the detention of people who are judged to be at risk of harm to themselves, including suicide. The risk-focused response of the clinician, then, is to assess symptoms and manage or mitigate risk, which includes assessment of suicidal thoughts and other risk factors and safety planning (e.g.⁶⁻⁸). Within an emergency department setting, disclosure of suicidal ideation is met with a triage system that prioritises externalising behaviours and the severity of suicidality to determine the risk of harm and the urgency of treatment.⁹ Assessment of risk relates to the potential for harm without treatment, not the needs for support. Thus, the law and clinical practice are aligned.

In this common scenario, however, the needs of the patient, as expressed through seeking help and disclosure, have been neglected. Moreover, a risk management approach to assessing suicide risk actively harms the patient through stigma. Stigma is a mark of disgrace – one that reduces a person in their social status to being tainted and now shamed by society – such as through presumed dangerousness or contagion of disease.¹⁰ Stigma affects people with mental illness broadly, including those with suicidality; for example, people who have attempted suicide describe experiencing a range of stigmas, including being seen as contagious, attention-seeking ‘drama queens’, manipulative, incompetent, weak, dangerous and hopeless.¹¹ By responding to a disclosure of suicidality with an assessment of an individual’s dangerousness to himself/herself and considering coercive and isolative treatment, professionals who use the risk management approach are making efforts to keep the individual safe. However, in so doing they risk begetting or promoting these stigmas, as setting these individuals apart from others implies social unacceptability. Consistent with this concern, people who have attempted suicide in the past describe being stigmatised by health professionals. By reacting to disclosures using a risk management approach, health professionals were seen to lack empathy for and dismiss their distress, and instead overreact to the potential for danger.¹¹ Not surprisingly, these individuals describe feeling mistrusted and full of shame after disclosing suicide, and are often motivated to hide any future suicidality from professionals.¹¹⁻¹² Thus, patients who disclose and feel stigmatised through being dismissed, labelled as hopeless or considered dangerous may be likely to conceal future suicidality.

Clinicians in all professions often report feeling ill-prepared to work with people who are experiencing suicidality (e.g.¹³). The cause of this anxiety and fear may be the futility of the task – risk and protective factors that clinicians have long based their assessments on have been shown to be poor predictors of death by suicide.¹⁴ Additionally, risk is only associated with the probability of negative outcomes and with assigning blame,¹⁵ which creates additional fear in many clinicians. Through the concept of ‘otherness,’ that is, conceptualising another person as substantially different from the self,¹⁶ the risk approach also discourages clinicians who may be feeling distressed or suicidal from seeking help, as doing so might mean that they are seen as no longer capable of being the professional. Thus, the risk management approach has the potential to harm the clinician as well as the patient.

It is time to make a change to how we approach suicidality. An alternative paradigm that has been proposed is coping planning.¹ This is a paradigm shift from a future-focused, risk approach to a present-focused, needs approach. Coping is a universal human behaviour. Feeling suicidal ideation is a normal human coping strategy to overwhelming distress. Rather than trying to determine the incalculable risk of a single endpoint (suicide), coping planning focuses the clinician’s attention on the needs of the patient (i.e., helping them cope with their distress). This involves: (1) caring; (2) collaborating; and (3) connecting.³ The first step involves just listening and attending to the person’s distress. The sec-

ond step is to collaboratively identify the person's existing coping strategies and help them strengthen their coping plan by including additional strategies or professional support. The final step is connecting the person with higher intensity support, if needed. The needs assessment could show that the patient has: (1) low needs, being able to cope independently after talking about their problems; (2) moderate needs for additional professional support that may include having *ad hoc* supports in their coping plan, such as telephone helplines or their general practitioner; or (3) high needs, requiring immediate more intensive supports.¹ The triage system for suicidality cannot be based on the same criteria as physical illnesses.¹⁷ The response received at disclosure can affect the progression of the distress. Attending to distress at this point needs to be a priority to meet the needs of patients presenting for problems with coping to prevent subsequent harm.

Responding to disclosures of suicidality with coping planning has real potential to overcome some of the stigmas towards people who experience suicidality. Coping is a universal experience, including for those who experience suicidality.¹ Attending to distress, rather than moving to the practitioner task of risk assessment, can be a minimally sufficient intervention for many people.³ Unlike assessments of risk for danger and the potential need for coercive treatment, viewing disclosure of suicidality as an invitation to support a patient sends a socially inclusive message that the person is capable and cared about, and that they should not feel ashamed. With the focus on caring, listening and supporting, and away from assessment of future danger, there is the potential for professionals to feel competent, rather than ill-equipped and fearful. Moreover, collaborating with the patient using the coping planning approach eliminates the 'otherness' that is endemic to risk management, which may also improve the help-seeking of the helpers when needed.¹⁸

In summary, although current practices align with the risk assessment and management work of mental health acts, neither meet the needs of patients. Practice needs to focus on meeting the needs of patients when they disclose distress to promote help-seeking and prevent stigma and suicide. Consistent with our current health practices that aim to be patient-centred, coping planning provides a strengths-focused framework to respond to patients in distress who are seeking professional support. Mental health legislation needs updating to reflect current knowledge about risk and to place patient needs at their core.

2018-4

Contents

- *Known but unpredictable – an argument for complexity*

Since the seminal paper of Pokorny in 1983,¹ the prediction of suicides has not improved, as Large *et al* have pointed out in their current paper² and in previous meta-analyses.³⁻⁷ In opposition to most current recommendations in suicide prevention, which still require clinicians to formulate levels of suicide risk,⁸ Large *et al*² suggest that clinicians should

give up risk formulation and instead focus directly on the individual needs of patients to deliver optimal care. They argue that uncertainty in the prediction of suicide is largely aleatory (dependent on random processes) and also epistemic (lacking knowledge). We think that one important explanation is missing: complexity.

Complexity refers to behaviours produced by nonlinear dynamic systems, which cannot be predicted in the long term, even if the generating system operates completely deterministically and is known in detail. The most prominent type of complex dynamics is deterministic chaos, which became familiar as the ‘butterfly effect’. During chaotic dynamics, even the smallest differences in initial conditions lead to a massive divergence of trajectories over time. Owing to complex behaviours such as chaos, from a nonlinear dynamical perspective, the failure of long-term predictions of suicidal behaviour could be a consequence not only of incomplete epistemic knowledge (e.g. unspecific or unknown risk factors) or aleatory processes (random noise), but also of the inherent complexity of the underlying system.

Are there any alternatives for predicting suicidal behaviour from a nonlinear dynamical perspective? Natural sciences (e.g. geophysics) have developed methods for the short-term prediction of extreme events (e.g. tsunamis), based on continuous monitoring of appropriate signals and identification of nonlinear dynamical precursors.⁹¹⁰ This might be a promising approach for suicide research as well. Given the recent improvements of scientific methods, an empirical application of complexity theory in suicide research seems realistic.¹¹¹² However, it still has to be demonstrated that such novel approaches are feasible in clinical practice and that they can in fact improve the prediction of suicides.

We believe that suicidology needs to take complexity theory into consideration. If not, much time, effort and money will continue to go into approaches that, from the viewpoint of complexity theory, lead to a dead end. This includes the search for novel risk factors or combinations of risk factors (e.g. by applying machine learning) without acknowledging the underlying complex processes.

1.5.9 Against the Stream: Generalised anxiety disorder (GAD) – a redundant diagnosis

Peter Tyrer

Correspondence

2018-4

Abstract

The diagnosis of generalised anxiety disorder is a distraction of no value. It is highly unreliable, co-occurring with many other disorders of firmer diagnostic status, and has intrinsic connections to personality dysfunction. It is argued that classification would be heartily relieved to rid itself of this unnecessary appendage and for the symptom of anxiety to remain as a descriptive term only.

Generalised anxiety disorder (GAD) describes an excessive and disproportionate anxiety or worry about minor matters that would not trouble most people. In addition to mental tension, consequent muscle pain and inability to relax, people with GAD almost always have bodily symptoms such as shaking, nausea, tingling sensations, a variety of gastrointestinal symptoms covering the full extremity from mouth to anus, sweating, palpitations, breathlessness and other respiratory symptoms. It is a recurrent disorder and often lasts for many years. This is an easily recognisable syndrome that is found to be one of the most common in population epidemiological surveys.

So why do I suggest that the letters GAD would better stand for godawful diagnosis? It is because all the characteristics that make a diagnosis useful in psychiatry – clear and reliable presenting symptoms, predictable outcome and treatment response – are lacking. Each of the components of the diagnosis has been systematically stripped away, leaving an ill-defined core of excessive worry only, which makes the diagnosis so grossly comorbid as to be useless. Let us take each of these elements in turn.

Excessive and disproportionate anxiety

If there is sudden and dramatic anxiety occurring without obvious reason, particularly when accompanied by bodily symptoms such as palpitations and shortness of breath, the condition is described as panic disorder. There is no difference between the symptoms of panic disorder and GAD; only their speed of onset separates them. Panic disorder is like an overpowered car that can go from zero to 60 mph in 5 s, while GAD is like a reconditioned Morris Minor that takes at least a minute to get to 60 mph and then groans with it and about it, for years. The removal of panic makes GAD into worry only.

Bodily symptoms

Mid-gastrointestinal – irritable bowel syndrome

Irritable bowel syndrome is now so well known that even the general public refer to it as IBS. Most people with IBS are anxious¹ and often have other bodily symptoms of anxiety, but these are subjugated to the gastrointestinal ones. There are now a number of specific and effective treatments for IBS that either ignore the generalised anxiety components or describe them in terms that are specific to the organ system concerned.

Muscular pain and tension – fibromyalgia

Fibromyalgia is a complex word, but pain and tension are the most prominent symptoms. There are many who doubt the value of this diagnosis, but few can deny that it has taken two important symptoms away from GAD.

Other bodily symptoms – somatic symptom and somatoform disorders

There are many other bodily symptoms that have been given formal titles in general medicine – non-cardiac chest pain, respiratory distress syndrome, functional dysphagia – but they all are selective in picking out one of the symptoms of GAD and ignoring the others. Somatoform disorders are ripe for justified criticism,² but they are overshadowed by a proto-diagnosis that is not liked for its aetiological nihilism, ‘medically unexplained symptoms’; it gets a great deal of interest and attention, especially in primary care, again taking a chunk away from the GAD superstructure.

Worry about health matters

People with the symptoms of GAD whose main symptom is worry about their health are now diagnosed with illness anxiety (in the USA) or health anxiety (outside the USA), but as these describe the same condition we should not get too concerned. In health anxiety, minor worries about health are amplified into a full anxiety syndrome that includes all the symptoms of GAD. One of the core parts of treatment is for the patient to learn to appreciate that these ‘minor matters’ should remain minor, so chipping away at another GAD limb.³

Recurrent disorder that may be lifelong

Anxiety is a personality trait as well as a symptom, and it has been appreciated for many years that anxious or avoidant personality features are very common in people with GAD. ‘I’ve always been a worrier’ and ‘I come from an anxious family’ are very common spontaneous comments made by patients at assessment. So, when patients with GAD construct a life chart of their anxiety, it is easy to identify a range of outcomes from one episode only to dozens of clear-cut episodes over time, with many others that may not reach the threshold for GAD. The patient often does not make much of this diagnostic distinction, as the handicap created by the symptoms at different times is very similar. But it makes prognosis extremely difficult to determine.

There is so much overlap between personality status and GAD that a strong case can be made for a condition called the ‘general neurotic syndrome’ (or the ‘general nervous syndrome’ for those who abhor the word ‘neurotic’), in which certain personality features such as obsessiveness and dependence, as well as anxiousness, contribute to the biaxial diagnosis.⁴

Mixed anxiety–depression (cothymia)

“‘The study of anxiety and depressionTeaches us one important lessonThough their separate study often pleasesWe must remember they are not diseasesLike wind and rain in stormy weatherThese symptoms always come together’5”

This is the real cruncher that fells GAD completely. Nosologists have tried desperately for years to keep anxiety and depression apart, insisting that they are distant relatives, not siblings, but the family bonds are too strong and the two always hover together threateningly at diagnostic gatherings. The analogy is appropriate, as the genetic evidence has shown repeatedly that anxiety and depression have a common genetic structure⁶ and so should be thought of together, despite the obvious differences in symptomatology.

Despite the valiant efforts of David Goldberg⁷ and several others, there has been great reluctance to accept mixed anxiety–depression as a full syndromal diagnosis in either the DSM or ICD classifications. If this was agreed, and it is becoming increasingly likely this will happen, the separate diagnosis of GAD would be weakened severely.

Unreliability of diagnosis

Some of these criticisms could be overcome if clinicians were pleased with the criteria for the diagnosis and used them consistently. But they do not. In the recent field trials of DSM-5, the interrater reliability of GAD was 0.20,⁸ which the authors regard as ‘questionable’, but which most clinicians would regard as unacceptable.

Replacement of GAD

If we abandoned GAD, what would replace it? There are three possibilities here. The first is to elevate mixed anxiety–depression to a more robust diagnosis instead of an apologetic afterthought. But of course, some would argue correctly that generalised anxiety can occur in the absence of depression. The second is to be really bold and join up the common personality characteristics of anxiety, dependence and obsessionality with the mood disturbance to constitute a ‘general neurotic syndrome’. This is a condition, usually combined with depression, that runs a chronic course and has a worse long-term outcome than either anxiety or depressive disorder alone,⁴ especially when the personality disorder is more severe.⁹ The third option is to think of GAD as an adjustment disorder.

Adjustment disorder

Many people receive a diagnosis of GAD when they are somewhat anxiety prone and then experience a major life event, especially one that is perceived as threatening. Although for many years adjustment disorder had been thought of as a subsyndromal diagnosis, and as a consequence largely ignored,¹⁰ it is now being examined more seriously as an important and measurable element of the trauma-focused disorders.¹¹ The importance of this in clinical practice is that these life event-precipitated forms of GAD could be treated by relatively brief psychological therapies and be less likely to lead to long-term iatrogenic disease.

Conclusions

The old concept of ‘anxiety neurosis’ has gone and been replaced by a host of different labels. In the course of this process, the original core of free-floating anxiety coming from out of the blue and surrounding each patient with a mist of uncertainty and threat has become redundant. It is persistently comorbid with other conditions and has no central elements that deserve separate classification. It should be quietly laid to rest and little mourned.

1.5.10 A review and update of the Health of the Nation Outcome Scales (HoNOS)

Mick James Jon Painter Bill Buckingham Malcolm W. Stewart

Correspondence

Mick James via

(Emma.George@rcpsych.ac.uk)

date

2018-4

Abstract

Aims and method

The Health of the Nation Outcome Scales (HoNOS) and its older adults' version (HoNOS 65+) have been used widely for 20 years, but their glossaries have not been revised to reflect clinicians' experiences or changes in service delivery. The Royal College of Psychiatrists convened an international advisory board, with UK, Australian and New Zealand expertise, to identify desirable amendments. The aim was to improve rater experience by removing ambiguity and inconsistency in the glossary rather than more radical revision.

Results

Changes proposed to the HoNOS are reported. HoNOS 65+ changes will be reported separately. Based on the views and experience of the countries involved, a series of amendments were identified.

Clinical implications

While effective clinician training remains critically important, these revisions aim to improve intra- and interrater reliability and improve validity. Next steps will depend on feedback from HoNOS users. Reliability and validity testing will depend on funding.

Declaration of interest

- * *Implications*

The Health of the Nation Outcome Scales (HoNOS)¹ is a 12-scale clinician-rated measure developed by the Royal College of Psychiatrists to guide everyday clinical practice and measure health and social care outcomes in secondary care mental health services for working-age adults (18–65 years). The HoNOS was designed to: (1) be short and simple for routine use and acceptable to a range of mental health professionals (2) have adequate coverage of clinical and social functions (3) be sensitive to improvement, deterioration or lack of change over time (4) have demonstrable and acceptable reliability (5) have a known relationship with more established scales.² Over its 20-year lifespan, the HoNOS has demonstrated adequate reliability, validity, clinical utility^{2,3} and sensitivity to change.^{4,5} Subsequent to its development, a family of related measures have been developed for different age groups and clinical populations.^{6–8} The HoNOS has been translated into at least 12 other languages and is routinely used in clinical practice and research around the world. England, Australia and New Zealand, have also mandated the HoNOS for routine monitoring and outcome measurement across their mental health services at a national level.^{9–12}

Although the basic soundness of the instrument is recognised, two decades of training, routine use and analysis of the resultant data, together with substantial advances in psychiatry and mental health services, have shown that updates to the supporting documentation are required to improve use of the HoNOS.^{3,4,13} As copyright holder for the HoNOS family of measures, the Royal College of Psychiatrists elected to undertake a limited review (rather than a full redevelopment and revalidation) that aimed to use expert opinion to improve the utility of the HoNOS in contemporary mental healthcare, while remaining true to its original aims and maintaining comparability with existing HoNOS data-sets. This paper outlines the review process, its scope, the issues identified and the set of revised scales.

Method

In recognition of each country's mandated use of HoNOS at a national level,^{9–12} and to ensure their interests were incorporated, an advisory board (chaired by the Royal College of Psychiatrists' national HoNOS advisor) was drawn from representatives from England, Australia and New Zealand. Nominations from the respective national governments were made, with members being required to have extensive experience in either: HoNOS staff training; using HoNOS in practice; using HoNOS data at a macro level; or providing oversight at service, professional or governmental level.

Advisory board members were asked to use their professional networks to canvas widely for clinicians' opinions regarding aspects of the tool that required refinement. To facilitate this, a standard recording form, covering each scale (as well as the overall rating guidelines) was provided, which, when collated, acted as a review template (*Table 1*). The board also considered the evidence and recommendations previously prepared in the review by Trauer and Buckingham³ commissioned by the Australian Government Department of Health. *Table 1* Summary of issues raised

Scale/Section	Issues recommended for consideration
Overall rating guidelines	• Need additional guidance about incorporating cultural factors into ratings • Improve clarity of the scoring system in relation to clinical significance • Improve clarity regarding what is to be rated (i.e., most severe problem or usual level of difficulty in past 2 weeks) • Clarity about when the scales should be used
Scale 1. Overactive, aggressive, disruptive or agitated behaviour	• Ensure all four behaviours are considered and clarify how many need to be present • Clarify to what extent behaviours here should be related to mental health problems • Provide guidance about how to address relevant cultural factors and context • Consider adding expansive mood as underrepresented by Scale 8
Scale 2. Non-Accidental self-injury	• How to address relevant cultural factors and context • Clarify that this is not an assessment of risk • High-risk thoughts/intentions currently underrated relative to overall severity • Increase consistency of dimensions of risk considered at different levels.
Scale 3. Problem drinking or drug-taking	• Provide clarity on the rating of tobacco use • Clarify how behaviours associated with addiction are rated • Improve clarity of rating for binge drinking and the reference to social norms that can lead to subjective rating • Clarify how ratings should take into consideration people on substitution programmes (e.g. methadone)
Scale 4. Cognitive problems	• Clarify where formal thought disorder and a lack of insight should be rated • Perceived to be a large gap in severity between rating 2 and rating 3 anchor points • Descriptors focus primarily on dementias, not other

cognitive difficulties • Review problems associated with transient versus enduring cognitive impairments within this scale

Scale 5. Physical illness or disability problems • Glossary descriptions reported by many to be unclear and/or unhelpful, especially in comparison with the HoNOS 65+ descriptors

Scale 6. Problems associated with hallucinations and delusions • Clarify where body image disturbance related to eating disorders should be rated • Improve description of ‘odd or eccentric ideas’ • Clarify where ‘lack of insight’ should be rated

Scale 7. Problems with depressed mood • Clarify that this scale is about depressed mood rather than clinical depression, as other symptoms of clinical depression cause confusion in the field • Change examples used to clarify ratings, as these were not found to be helpful in the field (e.g. guilt or self-accusation)

Scale 8. Other mental and behavioural problems • Consider whether any changes could be made that would retain the current features of the scales while addressing the high levels of use of labels A and D in this scale • Relatively poor reliability for this scale • Consider the addition of an option for elated mood, as this is not represented elsewhere in the scales • Clarify whether stress should relate to general life stress or specifically acute stress reaction and post-traumatic stress disorder • Clarify where body image disturbance should be rated

Scale 9. Problems with relationships • Improve clarity about whether clinicians should score worst or usual level of relationship difficulties • Improve glossary examples to better ensure full range of relationship difficulties identified (e.g. destructive or unhelpful relationships, active or passive withdrawal)

Scale 10. Problems with activities of daily living • Improve instructions on how to combine assessment of deficits in basic and complex skills into a single rating • Clarify how clinicians should determine the effects of existing supports • Review and evaluate the perceived disproportionate jump in severity from rating 2 to rating 3

Scale 11. Problems with living conditions, and Scale 12. Problems with occupation and activities • High missing data rates from in-patient settings • Provide additional clarity regarding the use of the 2-week rule for these scales • Review the perceived inconsistencies between the descriptors for the different levels of severity • Provide more formal clarification about how to rate these scales for long-term in-patients and residential settings

Other matters • Review the terms used for patients, staff and carers • Explore the feasibility and desirability of trying to build consistency between the HoNOS and the HoNOS 65+

This review template formed the basis of a scale-by-scale review. Some suggestions for change were more radical than others; hence, the board developed criteria with which to gauge their viability. For a change to be supported, it needed to represent a tangible improvement (e.g. removal of anachronisms or ambiguities, or simplifying the instrument’s use) whilst also: (1) maintaining the original instrument’s integrity as much as possible (2) ensuring that individual and aggregated outputs were likely to remain comparable with existing data (3) supporting HoNOS as a summary of clinical assessment(s) (4) adhering to the HoNOS ‘core rules’ i.e. • each item is a behaviourally anchored 5-point scale • rate items in order (1–12) • use all available information to make a rating • do not include information already rated in an earlier item • rate the most severe problem/worst manifestation from the preceding 2 weeks • a problem is rated according to the degree of distress caused and/or its effects on behaviour • must be rated by a mental health professional trained in clinical assessment • rate problems regardless of cause.

2 Some changes identified had consequences/implications for other items, and hence an iterative process of minuted teleconference and email discussions evolved, between October 2014 and January 2016.

Following review of the HoNOS documentation, a review of HoNOS 65+ was also undertaken through to October 2016. This presented an opportunity to maximise alignment between the two versions of the instrument and yielded a number of additional refinements to both measures.

Results

After working through the issues set out in *Table 1*, and reviewing the HoNOS 65+, the advisory board produced a set of revised HoNOS scales (supplementary Table 1 available at <https://doi.org/10.1192/bjb.2017.17>). Each item’s original wording is also included (in greyed-out boxes) to aid comparison.

Discussion

Overarching HoNOS rating guidelines

Despite the agreed objective of keeping the instrument short and easy to use, based on considerable experience of training and routine clinical use, advisory board members universally agreed that the original rating instructions erred on brevity at the expense of clarity. They also recognised that the frequency, duration and quality of training varies significantly.^{3,14} Therefore, to improve interrater agreement (but not to replace formal training), existing training materials and protocols were reviewed and, in many cases, incorporated.

The first notable augmentation was to legitimise the informal training advice that ratings of 0–1 should be viewed as subclinical, whereas ratings of 2–4 indicate problems of a severity that would normally warrant care/treatment planning and intervention.

Second, the original guidance stipulated that behaviours/problems should be rated regardless of cause (i.e. irrespective of psychiatric disorder) but was silent on the rating of issues deemed normal in an individual's culture/subculture. Issues for which the ratings may be affected by cultural and contextual factors have been previously identified³ and include culturally sanctioned aggression (Scale 1), self-harm associated with religious ceremonies or periods of mourning (Scale 2), paranormal experiences associated with cultural beliefs or events (Scale 6), and the expression of sadness associated with bereavement (Scale 7). None of these are attributable to mental health problems and, if rated, would produce a misleading clinical picture. Therefore, although cultural competence remains a prerequisite to good-quality clinical assessment (and thus accurate ratings), there is now an explicit expectation that an individual's culture should be taken into account. This debate also raised a wider question for the advisory board about how attributable to mental ill health behaviours needed to be before they should be included, an issue that was carried into amendments to several individual scales.

Consideration was given to what terms should be used to describe people who use mental health services, their significant others, and staff. This, in part, reflected moves from the recovery perspective and the mental health consumer movement to minimise the extent to which language used is pathologising and pejorative.¹⁵ Discussion indicated that terminology varied between countries, over time and between groups within countries. Given the lack of consistency, the decision was made to retain the term patient to denote a person who uses mental health services, family for people who are significant others of that person, and staff for people who are paid to provide mental health services.

Scale 1 Overactive or aggressive or disruptive or agitated behaviour

It was recognised that while item 1 has a broader scope than most others, clinicians focus primarily on the aggressive elements of the scale.³ The case for creating a separate item for this aspect alone was judged to be a more fundamental change than the current review's scope could support. Instead, the item description was revised to emphasise the need to consider all four aspects. The issue of culturally sanctioned aggression in the context of ritual was felt to have been addressed in the overarching rating guidance, hence the scale remaining diagnosis-agnostic.

Scale 2 Non-accidental self-injury

Revisions here were intended to provide consistency of examples across the severity ratings (covering risks and thoughts as well as behaviours). Cultural influences (e.g. ritual self-flagellation commonplace in some religions¹⁶) continue to require a culturally competent clinician and reference to the overarching guidance.

Scale 3 Problem drinking or drug-taking

As with Scale 2, changes now provide consistent descriptions of key elements of addictive behaviours, with each level describing aspects of craving, dependency and behaviour that align to contemporary notions of severity (e.g. National Institute for Health and Care Excellence guidance¹⁷). The more subjective aspects of the original scales (e.g. ‘within social norms’ and ‘loss of control’) have been removed, and there is an increased emphasis on the psychological effects of drug and alcohol use. This ensures that, during periods of enforced abstinence (e.g. hospital admissions), the severity of addiction can still be captured.

Finally, the advisory board, while fully acknowledging the harmful effects of tobacco use,¹⁸ agreed to explicitly exclude smoking from this scale – a significant decision that warrants further explanation. First, as per the original text, the physiological consequences of smoking will continue to be captured by Scale 5. Second, the prevalence of smoking in people with mental health conditions is approximately twice the norm,¹⁹ creating a ‘shadowing effect’ that can detract from the scale’s clinical utility. There are, of course, more extreme scenarios where, for example, individuals render themselves vulnerable to exploitation through their attempts to obtain cigarettes. The new guidance therefore excludes dependence on tobacco unless there are severe and adverse consequences above and beyond the known detrimental effects to physical health.

Scale 4 Cognitive problems

Feedback suggested that Scale 4 was too heavily orientated towards dementia and, even then, some of the examples were deemed unhelpful. Revisions were therefore undertaken in two stages. Initially, with reference to other versions of HoNOS,^{8,20} the narrow focus on dementia was broadened to incorporate issues such as formal thought disorder and the ability to learn. Through this process, the reported ‘excessive jump’ between ratings of 2 and 3 was also addressed. Then, in parallel with the HoNOS 65+ review, the descriptions were adjusted further. This led to improved alignment between the HoNOS and HoNOS 65+ cognitive scales, but complete alignment was regarded as too radical a change.

Scale 5 Physical illness or disability problems

No changes to this scale were deemed necessary.

Scale 6 Problems associated with hallucinations and delusions

This scale only required minor linguistic changes.

Scale 7 Problems with depressed mood

The descriptors for ratings 2–4 are now consistent with the scale title (i.e. depressed mood rather than depression), thus removing ambiguity surrounding the inclusion/exclusion of other depressive symptoms. This point has also been reiterated in the scale’s initial bullet points. Training experience has shown that the original descriptors led clinicians to focus heavily on the concept of guilt at the expense of other manifestations of low mood. Consequently, as for Scale 1, a more consistent and balanced description of each severity rating (in this case including loss of interest, guilt and loss of self-esteem) has been created.

Scale 8 Other mental and behavioural problems

The frequency with which anxiety is rated within this scale³·10 has resulted in calls for its promotion to that of a scale in its own right. While this proposal has merit, it was deemed a substantial change and thus out of scope for inclusion in this work. The possibility of rating multiple issues on this scale was also discussed, but would again affect comparability with existing data, contradict the ‘rate the worst’ rule and overly complicate the rating guidance for relatively little benefit. As a result, these two proposals were reserved for a more extensive review should the opportunity arise.

HoNOS trainers reported frequently being asked where elated mood should be rated. There was a suspicion that it was often captured under the ‘other’ option in this scale, or rated by proxy in Scale 1 (although no empirical evidence was available). To improve consistency of rating, it was introduced as a specific option (‘K’) in Scale 8. (N.B. The letter J has not been reused to avoid potential confusion between data-sets collated from the use of the original HoNOS and this revised version).

Based again on training experiences, while options A–I have been retained, each has been supplemented with explanatory text. DSM-521 was the genesis for these additions, but descriptors have been heavily edited to ensure they described presenting needs/problems rather than merely reflecting diagnostic criteria. This clearly challenged the core principle of brevity but was felt to be outweighed by the benefits arising from improved clarity.

Scale 9 Problems with relationships

Changes to this scale were limited to modest rewording of descriptions, again intended to increase clarity.

Scale 10 Problems with activities of daily living

Additional introductory text has been added to reflect common training advice regarding how to ‘manage’ the effects of any existing support the patient is receiving. The considerably more complex and granular approach that might be required to accommodate the occasional problems experienced when rating patients whose complex skills are intact, but whose self-care skills are not, was also considered. The approach used by the tabulated version of the HoNOS 65+22 was suggested as a possible model to accommodate this, but was deemed to represent a substantial change and hence rejected.

Scale 11 Problems with housing and living conditions, and Scale 12 Problems with occupation and activities

The issues and solutions for the final two scales were very similar, and hence their discussion has been combined. First, experience from the field suggested that, without adequate training, Scales 11 and 12 are often used to consider aspects of the patient’s abilities (as in Scale 10) rather than to rate how well their current environment matches their needs in terms of accommodation or occupation and activity. Alternatively, these scales can be misused as global ratings of the quality of accommodation and occupation/activity. Either way, the conceptual complexity causes difficulty in routine use.²³ An additional bullet point now addresses these misconceptions.

Second, in recognition of the rating difficulties that can arise at/around the point of hospital admission and discharge,²⁴ a thorough review of supplementary advice provided in each country was undertaken. The option to vary the 2-week rating period for these scales was considered, but the board was uncomfortable breaching this core rule. Instead, a less radical solution was to highlight that ‘the patient’s usual . . .’ was to be rated and provide clearer guidance about how this should be dealt with in different living situations. Retaining this degree of clinical discretion was deemed both tolerable and more likely to result in clinically meaningful ratings.

Other revisions to these scales were less complex and primarily sought to update some of the terminology used and ensure all terms were acceptable to each participating country.

Other issues

In addition to the changes discussed, the review highlighted further areas for development that may be considered desirable. However, these constitute substantial changes that fall outside the scope of the agreed review. These would require the development of a new instrument but remain an option for future development pending sector agreement, as well as government interest and funding.

Implications

The Council of the Royal College of Psychiatrists considered the proposed changes to the HoNOS set out in this paper at its meeting on the 14 July 2017 and agreed to these recommended changes proposed by the advisory board. In doing so, the Council acknowledged that it is highly desirable that the perceived benefits of the changes be subjected to empirical testing through assessment of interrater reliability and revalidation of the measure in the field. Such testing will require funding and ideally the involvement of those countries that have heavily invested in the HoNOS to date; this is being pursued by members of the advisory board.

It is also acknowledged that there are likely to be issues that will affect the implementation of a revised version in the different jurisdictions involved in the review, as well as in other parts of the mental health community worldwide that have invested in the use of the HoNOS and translations of the original scales. One such effect might be on the programmes of training for clinicians; while the proposed changes are intended to improve the clinician experience of using the scales, they do not obviate the need for training in the use of the scales.

We thank the following members of the advisory board: **Prof. Mike Crawford**, Director of the College Centre for Quality Improvement, Royal College of Psychiatrists; **Adrian Worrell**, Head of Centre for Quality Improvement, Royal College of Psychiatrists; **Dr Clive Bensemam**, Director of the Mental Health & Addictions Healthcare Service Group, Auckland District Health Board, New Zealand; **Dr Arran Culver**, Deputy Director, Mental Health Ministry of Health, New Zealand; **Dr Mark Smith**, Clinical Lead, Te Pou, New Zealand; **Dr Rod McKay**, Chair, National Mental Health Information Development Expert Advisory Panel (NMHIDEAP), Australia; **Mr Tim Coombs**, Australian Mental Health Outcomes and Classification Network (AMHOCN), Australia; **Ms Rosemary Dickson**, AMHOCN and NMHIDEAP Coordinator, Australia; **Allen Morris-Yates**, Director of the Centralised Data Management Service, Australia.

Mick James is the National HoNOS Advisor and MHCT (Mental Health Clustering Tool) Project Manager at the Royal College of Psychiatrists, London, UK; **Jon Painter** is Joint Clinical Lead of the Care Pathways and Packages Project, National Health Service England, and is a Mental Health Nurse Lecturer at Sheffield Hallam University, Sheffield, UK; **Bill Buckingham** is a Consultant and Mental Health Technical Advisor to the Australian Government Department of Health, Canberra, Australia; and **Malcolm W. Stewart** is a Consultant Clinical Psychologist at Thrive Psychology, Auckland, New Zealand.

Abstract

Aims and method

We explored the prevalence and use of constant supportive observations (CSO) in high, medium and low secure in-patient services in a single National Health Service (NHS) mental health trust. From clinical records, we extracted data on the length of time of CSO, the reason for the initiation of CSO and associated adverse incidents for all individuals who were placed on CSO between July 2013 and June 2014.

Results

A small number of individuals accounted for a disproportionately large proportion of CSO hours in each setting. Adverse incident rates were higher on CSO than when not on CSO. There was considerable variation between different settings in terms of CSO use and the reasons for commencing CSO.

Clinical implications

The study describes the prevalence and nature of CSO in secure forensic mental health services and the associated organisational costs. The marked variation in CSO use between settings suggests that mental health services continue to face challenges in balancing risk management with minimising restrictive interventions.

Declaration of interest

A.B. and J.L.I. are both directly employed by the NHS trust in which the study was conducted.

– *Discussion*

Supportive observations involve the increased monitoring of mental health in-patients who are at an increased risk of harming themselves, harming others or absconding.¹ The practice involves clinical staff being assigned to an unsettled patient to engage with them therapeutically² and monitor their well-being.³ The National Institute for Health and Care Excellence (NICE) guidance on the short-term management of violent behaviour in in-patient settings⁴ outlines four distinct levels of observations, with the highest two levels (3 and 4) involving constant observation of the patient. Observations may also vary in terms of the number of staff assigned to conduct them – constant supportive observations (CSO) are commonly conducted on a one-to-one basis, but in more extreme cases multiple staff may be assigned to observations of the same patient (the most recent NICE guideline on the management of aggression has formalised observations involving multiple staff as a distinct category⁵).

Observations are the recommended approach for managing individuals deemed to be at risk,⁶ reflecting the competing demands of a mental health service – the provision of compassionate care while managing risk – but the rationale and efficacy of CSO is debated in the literature.⁷⁻⁹ However, there are no reports of the prevalence of supportive observations in mental health services, and so the extent to which supportive observations are being utilised in mental health services, and in what context, is unclear. This research therefore explored the prevalence and nature of CSO in a single National Health Service (NHS) mental health trust, comparing data from high, medium and low secure forensic mental health services within that trust.

Method

The data were gathered from a single NHS mental health trust in England for the 12-month period between 1 July 2013 and 30 June 2014. The secure division within this trust comprises a high secure service (HSS; 228 male in-patient beds), a medium secure unit (MSU; 58 male in-patient beds and eight female in-patient beds) and a low secure unit (LSU; 32 male in-patient beds). During the period of study, the mean daily occupancy levels were at 84% of capacity for high secure, 88% for male medium secure, 93% for female medium secure and 90% for low secure (not including beds assigned to patients on trial leave).

From clinical records, we identified all individuals who were resident on 1 July 2013 or admitted between 1 July 2013 and 30 June 2014 in each service. The clinical information for each individual was manually searched, and we extracted and collated data on all episodes of level 3 or 4 observations that took place within the review period. For each episode, the data recorded were: the level of observations (level 3 or 4), the start and end time/date of each episode of observation, the number of staff involved in each episode, and the reason for initiation of the episode. An episode of CSO was only recorded when there was a defined start and stop time recorded in clinical notes. Thus, where the CSO arrangement was flexible dependent on circumstances (e.g. level 2 in communal areas but level 3 when in their bedroom) and no start/stop time was recorded in the notes for the changing levels of CSO, it was not possible to record the data for those episodes. Data on all adverse incidents involving the individuals on CSO were collated and manually searched to establish the number of incidents that occurred while that individual was on CSO and not on CSO.

Results

During the review period, 239 individuals were resident in the HSS at different periods and 56 of these were placed on CSO at some stage during the year. In the female MSU ward, nine different individuals were resident during the year and eight of these were placed on CSO. There were 84 individual residents during the year on the male MSU wards, with 31 of these being placed on CSO. Eighteen of the 38 residents in the LSU during the year were placed on CSO. There were only a very small number of episodes of level 4 observations across the data-set (seven episodes in HSS, two episodes in MSU, and four episodes in LSU) and so for the purposes of analysis, these were combined with the level 3 episodes. A summary of the data extracted for each unit is shown in *Table 1*. Table 1

Prevalence of constant observations

Across the secure division, patients were placed on CSO for a total of 85 947 h in the 12-month period of study. *Table 1* shows the prevalence of CSO in the three different units, both in terms of the number of hours that patients spent on CSO and the number of staff hours devoted to CSO. To allow comparison between units, occupied bed days (OBD; the sum of the daily number of occupied beds for the entire period) was used as the common denominator. *Table 1* shows the total number of hours of CSO per 100 OBD in each unit. The HSS recorded the lowest CSO levels (59 h per 100 OBD), while the highest level of CSO was in the female MSU (514 h per 100 OBD). Staff hours devoted to CSO were consistently higher than patient hours, owing to episodes of 2:1 or 3:1 observation, and the magnitude of increase in staff hours varied between 10 and 18% of patient hours (low secure: 10% higher; male medium secure: 18% higher; female medium secure: 17% higher; high secure: 15% higher).

Distribution of CSO hours across patients

CSO was not evenly distributed across the in-patient population; in all units, a small number of individuals accounted for a substantial proportion of staff time on CSO. In the HSS, five out of 56 individuals on CSO accounted for 54% of all CSO hours in the unit (one individual was on CSO for the entire 12-month period). On the female MSU ward, two out of eight individuals on CSO accounted for 57% of the CSO hours, while on the male MSU wards, four out of 31 individuals on CSO accounted for 56% of the CSO hours. Similarly, in the LSU, two out of 18 individuals accounted for 46% of the CSO hours.

¹ OBD, occupied bed days; CSO, constant supportive observations; Env. change, environment change.

² Estimates based on one-third of CSO conducted by staff in band 5, two-thirds conducted by staff in band 3.

Reason for commencing CSO

To aggregate the reasons for commencing CSO, the circumstance of each episode of CSO was extracted from clinical notes and placed in one of five categories. Reasons were categorised as ‘Aggression’ if the individual was placed on CSO because of an act of aggression (including violence) or threats of aggression, including verbal abuse. ‘Self-harm’ included actual self-harm as well as threatened self-harm and requests from the individual for extra support because they feared harming themselves in the near future. CSO was categorised as ‘Deterioration’ when individuals were placed on CSO because of a general agitation or deterioration in mental state that warranted additional support for them. CSO was categorised as ‘Environment Change’ when a specific change in environment preceded CSO and was the main reason for it, e.g. new admission, termination of a period of seclusion, ward change. CSO was categorised as ‘Other’ when there was a specific reason for placing an individual on CSO that did not fit the other categories, e.g. for safeguarding purposes in a situation where there was a high likelihood of exploitation, or for physical health purposes when an individual had recently returned from hospital after an operation and required support.

The proportion of staff hours devoted to CSO in each of the different categories in each unit is shown in *Table 1*, where it can be seen that the reasons for initiation of CSO varied between services. In HSS and the female MSU, self-harm (actual or risk of) was the main reason for CSO, while aggression was not often a reason to initiate CSO. In both the male MSU and the LSU, however, aggression was the predominant reason for initiating CSO. CSO to provide support in self-harm was also a frequent motive in the male MSU, while a large proportion of CSO hours were devoted to a specific other reason in the LSU. Further exploration of the LSU reasons indicated that a single individual was placed on CSO for a 6-month period for safeguarding reasons, leading to the unusually high proportion of CSO hours in the ‘other’ category.

Adverse incidents

To examine the effect of CSO on adverse incidents, we extracted data on the date/time of each incident and the incident category for every incident involving any individual on CSO during the period of study. By examining the date/time and circumstances of the incident, it was possible to categorise each incident as having occurred while the individual was either on CSO or not on CSO. Using data on the number of hours that all individuals spent on CSO within a unit, and also the number of hours for those same individuals during the 12-month period that were not spent on CSO, we computed the incident rates relative to a common denominator (per 100 h on CSO and not on CSO) to enable comparisons between incident rates.

Incidents are categorised in terms of nature and severity into four categories, A–D. Category A incidents are very serious incidents that may involve a death, serious sexual assault or hostage-taking. No individuals on CSO during the period of study were involved in any category A incidents. Examples of category B incidents include attempted hostage-taking, serious assault and attempted suicide; typical category C incidents may involve assault, moderate self-harm and threats; and examples of Category D incidents may include verbal abuse, minor self-harm and property damage. *Table 2* shows the number of adverse incidents (in each category) per 100 h of residence while those individuals were on CSO and not on CSO. *Table 2* Adverse incidents in each category and in total for each unit for patients involved in constant supportive observations (CSO) Incidents while on CSO Incidents while not on CSO

In all units, figures indicate that adverse incidents were more common for individuals on CSO than when those same individuals were not on CSO, with the highest overall incident rate for patients on CSO in the HSS (1.06 incidents per 100 h). Further examination of the records from HSS revealed that one individual was responsible for 251 incidents while on observations; because he was on CSO for the entire 12-month period, there were no instances of incidents while not on observations. When this atypical individual was removed from the incident figures, the incident rate for HSS patients while on CSO reduced to 0.58 incidents per 100 h.

The data in *Table 2* indicate that across all units, individuals were at least twice as likely to engage in an incident while on CSO compared with when they were not on CSO, and, in the case of the female MSU ward, almost four times as likely. Closer examination of the figures revealed that this was driven largely by an increase in category D incidents when on CSO.

Organisational costs of observations

The exact cost to the organisation of conducting CSO depends on the hourly rate of pay for the staff that conduct the observations. The identity of the staff who contributed to conducting each episode of CSO was not available in the clinical notes, and so the true costs could not be calculated. However, we estimated staff costs by using the 2013/2014 hourly rates for NHS band 3 (£16.07) and band 5 (£21.51), based on the informal estimate from hospital managers that one-third of CSO was carried out by clinical staff in band 5 and two-thirds by clinical staff in band 3. On this basis, we estimated the cost of CSO to be £851 636 for the HSS, £631 740 for the MSU and £390 370 for the LSU, noting that the female ward accounted for 47% of the total cost of CSO in the MSU (£294 471 for the female ward). When OBD is used as a common denominator, the relative costs of CSO in each service may be compared; the estimated figures in *Table 1* show that the cost of CSO in the HSS was £1221 per 100 OBD, compared with £10 802 in the female MSU.

Discussion

This paper represents the first published study of the prevalence of supportive observations in a UK mental health trust, reporting data from low, medium and high secure services.

In the literature, the organisational cost of observations is reported to be high. One economic analysis in 2008 estimated the annual cost of observations to the NHS at £80 m¹⁰ with £35 m spent on providing CSO. In the present dataset, our findings estimate that the cost to the organisation of constant observations alone was £1.8 m in 2013–14. Estimates suggest that between 3 and 20% of people admitted into mental health services will be subject to some form of intensive observation, and that up to 20% of the nursing budget for a hospital may be used in the provision of constant observations.⁷ In the current economic climate, where cost, value and effectiveness are increasingly important, it is appropriate to consider the use of finite staffing resources. Although constant observations remain fundamental to mental health nursing care, some researchers question the efficacy of the practice,⁸ particularly against the more contemporary background of reducing restrictive practices in mental healthcare, and clinical decisions on the issue of CSO remain a policy matter for individual mental health trusts.

A small number of individuals in each unit accounted for a disproportionately large amount of the time devoted to conducting CSO and thus a large proportion of the CSO costs to the organisation. In the MSU, for example, two patients out of 93 individuals who were resident on that unit accounted for 27% of the total CSO hours in the whole unit. Similarly, in the HSS, two patients out of the 239 individuals who were resident that year accounted for 31% of the CSO hours in that unit. In secure mental health services, it is not unusual for some patients to have high dependency needs, and assessing the balance between pro-active and defensive approaches to managing risk can be a challenge. As a result, some patients are subjected to constant observations for sustained periods of time; as all mental health trusts are motivated to employ the least restrictive interventions while maintaining safety, this is a difficult balance to strike, with some trusts potentially erring on the side of caution.

¹⁰The Authors own the copyrights to the individual articles.

The finding that patients were involved in adverse incidents more frequently when on observations than when not on observations could reflect closer surveillance of behaviour, but is more likely explained by different baseline presentations in the two contexts. Individuals are more disturbed and unwell when they are on observations than when they are not, and it is unsurprising that individuals engage in more adverse incidents when they are more labile and agitated than when they are stable and settled. What is not known from these data is what specific effect CSO had on adverse incidents; it is probable that had those patients not been on constant observations, the level of adverse incidents in such an unsettled group would have been much higher. One motivation for CSO is to manage risk with patients at risk of harming themselves or others, but assessing the extent to which CSO is successful in doing that can be problematic. One explanation of perpetrators' decisions to engage in aggression involves a calculation of the effect/danger ratio,¹¹ where an individual judges the costs and benefits of using aggression in any given situation, opting to use aggression only when the costs to them in terms of detection and reprimand are limited relative to the potential outcome. As such, less serious forms of challenging behaviour can occur as a result of this cost–benefit analysis, and, for individuals unable to manage their use of challenging behaviour, being on observations could encourage the behaviour least likely to elicit reprimand (e.g. more minor incidents such as verbal abuse and property damage). This may explain why the increase in incidents while on CSO was largely due to an increase in category D incidents, and a rational assumption is that the effect of constant observations may have been to deflect what was a potentially serious situation into a more minor incident.

Across the different units, specific concerns about aggression and self-harm were the reasons for initiating most of the CSO hours, but the balance between these reasons was markedly different in different settings. Aggression was most frequently the reason for constant observations in the male medium and low secure settings, but self-harm was the most prevalent reason for constant observations in the female MSU ward and in the HSS. In fact, nearly all instances of CSO on the female ward were motivated by actual, or risk of, self-harm. The dominance of self-harm as a driver of CSO in this setting may be partly related to diagnosis. The present data-set did not drill down into the specific diagnoses of patients in each unit, but a recent large-scale survey of forensic psychiatric in-patients in The Netherlands¹² found that, while around 75% of both male and female patients were diagnosed with both axis I and axis II disorders, 61% of female patients had a diagnosis of borderline personality disorder (BPD) and a further 21% presented with borderline traits. BPD diagnoses were much less prevalent in the male patients in their sample. A separate and equally valid explanation relates to clinician perception and response. There is recognition in secure psychiatric services that clinicians' responses to aggression frequently differ depending on whether the patient is male or female; aggression by men leads to more discussion by clinicians than aggression by women, and aggression generally is viewed as a male phenomenon in spite of the evidence that women may be equally aggressive.^{13·14} Similarly, the prevalent clinical view is that self-harm is more common in women than men, in spite of more equivocal evidence in the literature.^{15·16} Further exploration of this issue falls outside the scope of the current research, but the present data may support the view that a potential gender bias exists in clinical responses to challenging behaviours.

Although findings from these data should be viewed in the context of a single mental health trust (and a single female ward), they nevertheless present a picture of the prevalence and use of a cornerstone of clinical practice in mental healthcare.

Romi Eden, Leah Greenwood, and Rebecca Ozanne gave invaluable assistance in extracting data from clinical notes.

Contents

- *Profile: André Tomlin*

Julia Bland meets André of the Elves, arch communicator and pretension buster, man with a mission: to get healthcare workers better informed so that they can provide higher quality care to patients

The Mental Elf is a charming woodland creature, smiling, intelligent, sensitive, balanced, with no beard, pointy ears, or a cap with a bell on the top.

In fact, he is André Tomlin, 45, information scientist, health blogger, educator, evidence-based practice guru, businessman with a genuine vision of improving the quality of healthcare, and father of three children under 8 years of age. He has over 50 000 followers of his Twitter account, and claims that the twitter community's outrage at Asda for selling mental patient costumes complete with axe and blood for Halloween, led to the removal of the offending items. He sees himself as embedded into an online community of people trying to make sense of their experience (he also has personal experience of anxiety and depression).

If you haven't heard of the National Elf Service (www.nationalelfservice.net), launched in May 2015, you may need an explanation.

This is an online subscription service that provides digests of the latest research in mental health, tailored to your interests, plus a host of interactive opportunities, like webchats, videos, and continuing professional development certificates, all 'gamified' with levels to achieve and gnomish cartoons dancing about. Actually, much less irritating than you might have expected.

Tomlin explained to me the genesis of the National Elf Service. He and his business partner Douglas Badenoch, worked for years at the digital end of evidence-based medicine, believing in the importance of the translation of research into practice, but were frustrated by the unappealing lumpiness of the website delivery vehicles.

They wanted to develop a user-friendly, highly accessible, but accurate and reliable online resource for the time-constrained front-line mental health worker.

Have they done this? And what else do they do? And how does it work as a business versus a piece of philanthropy?

I went to meet André Tomlin with an open mind, but holding a comment from a colleague with a key question: 'He seems to be dominating the social media side of mental health. Why has he become so successful with this and what are his credentials in dictating the agenda?'

The unique selling point of the Mental Elf is the combination of the serious with the playful. The antithesis of pompous. I was convinced of the underlying seriousness, even idealism, of the intentions: 'Accessibility, Usability, Reliability No bias, no misinformation, no spin', with a view to improving standards of mental health provision with a personalised feed of information to the smartphones of mental health professionals, (especially nurses) and of course, some of his subscribers are patients. His anti-silo, deliberate, democratising intention is to open up the debate around

mental health. He thinks that not only should patients and their families be listened to, but also non-health professionals; for example, schools, in relation to child mental health. Social media in the mental health field has a supportive and welcoming rather than aggressive tone, he claims. For example, when the Daily Mirror outed the Everton footballer Aaron Lennon as having been sectioned, there were over a hundred tweets supporting him and criticising the Daily Mirror.

The benign aspect of the Mental Elf is also illustrated by their work with charities like Rethink, Mind, and the Mental Health Foundation. He sees the work as partly public service, running tweet chats offering peer support on topics like suicide and severe mental illness with ‘twitter buddies’, usually clinical psychologists, who can take distressed individuals aside for a private ‘direct message conversation’, and can suggest appropriate action, for example, contacting the crisis team or going to an Accident & Emergency Department.

Of course, this is also a business, and he freely admits that the line between business and altruism is a ‘blurred boundary’. He and Badenoch, another ‘information scientist’, run Minervation (an evidence-based healthcare consultancy) plus the Elves empire. They conveniently believe in ‘coproduction’. As one expert invited to write for the Mental Elf put it bluntly, ‘We don’t get paid. We do the work, and he gets the money.’ Tomlin is frank: ‘Sometimes I help people, sometimes I push people towards my product, and sometimes I just have to do something to make money.’

Minervation, which ‘spun out of the university’ (i.e. the Oxford Centre for Evidence-Based Mental Health), also provides consultancy to big health players: the National Institute for Health and Care Excellence, Cochrane, and Bupa amongst them. They also specialise in building accessible websites for charities and other public sector organisations.

One of his favourite projects was for the General Medical Council. Five years ago, he developed a programme to help general practitioners provide better care for people with learning difficulties. They included a ‘forum theatre’ approach, where a play scenario is set up: a woman with Down’s syndrome and her sister present at Accident & Emergency. She has stopped eating and drinking. As the play evolves, the audience can challenge and participate, ‘why is the doctor talking to her sister and not to her?’. This can then be digitally broadcast and helps promote Mencap’s priority to improve communication by professionals with people with intellectual disabilities.

The Elves are accessed via subscription, and it’s the institutional subscriptions that are most lucrative (over £1000 for a year for group users v. £60 per year for individuals). He has signed up universities including Oxford and Manchester, and Mental Health Trusts such as University College London, hoping to include Kings and in particular, the Masters course at the Institute of Psychiatry, Psychology and Neuroscience soon. Institutions are provided with regular anonymised reports on how their staff are using the Elf system, such as the most popular blogs, the number of reflective practice entries and the research impact.

Subscribers get access to digests of new research with comments on clinical relevance by expert reviewers, connection to other experts via online discussion and journal clubs, and a personalised ‘gamified’ continuing professional development record.

Minervation also run a digital conference service called Beyond the Room, which prepares for, attends, live streams, blogs, and podcasts from your conference for a fee. They see the slides in advance, speak to the speakers, and then do live tweeting and blogging from the conference floor, putting up podcasts afterwards. All this enables a small number physical conference to reach a far larger potential audience.

They used to offer critical appraisal workshops, but have had greater uptake for workshops teaching psychiatrists and others to use twitter and blogs. He believes all this digital output needs to be researched itself with ‘alt metrics’. He fully accepts that numbers of hits don’t reflect quality: 3 years ago, the most popular blog was about dolphin semen, and he wants to improve the capacity of digital sites in ‘meaningful analytics’, which genuinely measure the effect of published articles.

Another Tomlin initiative is a public discussion with experts, every three months, linking Mental Elf, Lancet Psychiatry and University College London psychiatry. They have covered subjects like dementia, digital mental health, preventable harm and women’s mental health.

They have developed the Social Care Elf, Learning Difficulties Elf, Dental Elf, Lifestyle Elf and the Diabetes Elf, and are hoping to expand into Elder Elf, Public Elf, Economist Elf, Sexual Elf and Stroke Elf.

Tomlin’s background is interesting. His Dutch maternal grandfather, who just escaped being shot by Nazis twice

during the occupation of the Netherlands, took young André round the red light district of Amsterdam as a boy. His parents were active members of the Campaign for Nuclear Disarmament and he ‘hung around Greenham Common’, the extensive antinuclear missile protest site, as a child.

His adult politics remain broadly left of centre but he is no dogmatist.

After philosophy and English at university he became assistant librarian at the Institute of Health Sciences in Oxford in 1993. After a Masters in Information Science at the University of West London, he returned to Oxford to help psychiatrist Professor John Geddes establish the Centre for Evidence-Based Mental Health.

Although remaining an ardent supporter of evidence-based medicine, he describes his growing impatience with the inaccessibility of the main health information websites. He and Badenoch could see how newer technology can deliver much faster and more personalised information. He also sees the speed of blogging reactions as contributing to dispelling misinformation.

The example he gives is after a paper with negative findings, determining whether exercise was useful in the treatment of depression, was taken up by the newspaper headlines as ‘Exercise found to be no help in depression’. Tomlin immediately wrote a blog publishing the actual evidence, correcting the interpretation, pointing out that exercise may still be preventative in depression, alerted the Twittersphere, and the BBC. Later that day the newspaper headlines were changed.

The power of social media operating in the interest of accuracy (for once).

Another mission is in myth busting, with evidence, of potentially harmful treatments; for example, a recent review piece in *Mental Elf* by Edel McGlanaghy on the subject of the potentially harmful effects of psychological treatment, mainly online cognitive-behavioural therapy for anxiety.¹

We discussed the merits and demerits of ‘trans diagnostic’ approaches to mental healthcare, recently written about in relation to Child and Adolescent mental health by Miranda Wolpert and Peter Fonagy.²

They have looked at the limitations of diagnosis and evidence-based research, proposing focusing on the person rather than the diagnosis. They point to the long waits for Child and Adolescent Mental Health Services (CAMHS), and the unsatisfactory outcomes for a significant minority of patients. Wolpert recommends a practical, evidence-based coproduction approach, developing apps for young people to prepare for seeing psychiatrists.

In January 2017, the *Mental Elf* published a systematic review of digital interventions for young people with mental health problems. They concluded that evidence is uncertain for digital interventions and should extend rather than replace offline services, with more interdisciplinary research needed, designed with user input and involving computer scientists, and engineers as well as psychologists and psychiatrists.

This migration on Tomlin’s part from traditional psychiatric research towards the ‘groovy social science side’ is never going overboard, he reassures me. ‘I’ll stop in the safe middle ground’. He feels his education about psychiatry has been extended beyond ICD-103 via twitter contact with patients and nurses, reaching out into the wider waters of social care and psychology. But writing from the user perspective can become flaky, he admits, and although his personal philosophy is transdiagnostic, he fully supports psychiatrists who must treat patients on particular pathways determined by diagnosis.

He is also increasingly sceptical about the evidence-based medicine world, which he sees as ‘quite insular’, and even research more broadly, claiming that about half published research is methodologically unsound, and another half never reaches publication because of the bias against publishing negative findings. In fact, he goes even further in pointing to the gap between evidence-based medicine and ordinary practitioners, and states ‘we would have most impact if we just implemented what we know now.’

So, is he a breath of fresh modernising air that we psychiatrists should breathe in deeply, and are sorely in need of with our rushed lives, or is the *Mental Elf* a bit gimmicky or presumptuous in setting the tone and agenda for public debate?

You will need to visit the *Mental Elf* site (free month’s trial) and decide for yourself.

Abstract

Summary

This paper presents a debate in which the authors participated at the World Psychiatric Association conference in Cape Town, South Africa in November 2016. Professor van Staden acted as chair and here, as at the debate, provides a rationale for debating a topic that many of those involved in mental health believe to be decided. The discussion that ensued demonstrated, however, that while the arguments have moved on they have not ceased. Who won? Well that depends how you look at it. A few in the audience shifted position towards the motion but the majority remained opposed. What do you think?

Declaration of interest

None.

Introduction: Werdie van Staden

‘Preposterous’ or ‘high time’ may be the respective responses of antagonists and protagonists to the claim that the concept of culture has outlived its usefulness for psychiatry. Philosophical rigour, however, requires much more than an exclamation of sentiment. Such rigour is probably demonstrated best by articulating an argument that goes against one’s own sentiment, thereby unpacking and clarifying the issues at stake. This article follows suit, thus not committing our contributors beyond the remit of this article – an article that is about the ‘what’ (i.e. the content) as well as the ‘how’ (i.e. argument).

The topic is patently relevant considering the provisions for culture by the DSM-5,¹ specifically through cultural concepts of distress, the cultural formulation and the cultural formulation interview. In addition, connections between culture and mental health may variously and profoundly be found in the way culture affects the various mental disorders in their expression, experience, interpretation, course and outcome. One may assert that culture influences individual resilience, coping mechanisms and social response, which are all crucial for recovery from mental health problems. Anthropologically, one may assert that mental health practice involves the meeting of at least two cultural worlds: the clinician’s and the patient’s.²

A scholarly debate provides for consideration, if of good logical pedigree, of the differences as well as the similarities shared by both sides of the debate. As an introduction to the arguments of our pairs of protagonists and antagonists, two shared features are highlighted: ‘culture’ necessarily involves *practice* and *values*.

The first protagonist, Mohammed Rashed, raises the issue of the conceptual relation between cultural group identity and culture as a dynamic set of shared practices. Taking the latter rather than the former as constitutive of culture, cultural group identity is shown to be a conceptual derivative of shared practice rather than the (commonly assumed) converse. The premise also underpins the antagonist argument of Abdi Sanati below. Following Wittgenstein’s private language argument, he argues that without culture there cannot be language, and, hence, no psychiatry.

The premise that culture is constituted by shared practice thus features on both sides of the debate, with conceptual implications that are beyond the scope of this article. One example, nonetheless, may serve to enlighten their arguments. This premise unmasks the mistaken assumption that culture is necessarily confined to a geographical location (as does the DSM-5).² Examples of the contrary are found in shared practice: the internet culture, the renaissance culture, a scientific culture, a 21st century culture, a ‘Googling’ culture, etc.

An emphasis on values is shared by the arguments of the protagonist, Norman Poole, and the antagonist, Rachel Bingham. The inevitable cultural origins of values are underscored in Bingham’s argument, whereas Poole is concerned by the alienating and exoticising consequences of ascribing mental disorder to cultural values.

Space here does not allow for rebuttal, but the scene is set, no doubt, for further discussion.

For the motion, Mohammed A. Rashed

I am going to argue for this motion: I believe that the concept of culture has outlived its usefulness for psychiatry. I believe so not because I am a defender of a reductive, biological psychiatry – I am not – but because among the two definitions of culture that are, in my view, of relevance to mental health, the first is so general so as to dissolve into the concept of meaning, and the second is so unjustifiably homogenising as to require that we explore the patient’s beliefs and values without the assumption of a cultural group.

Culture has many definitions; I list four. 1Culture in the sense of activity: the tending of natural growth; to cultivate the land, to breed animals, and to await the growth of bacteria in a Petri dish.³ This meaning of culture is irrelevant to our debate. 2Culture also in the sense of activity, but instead of cultivating vegetables and bacteria, we cultivate our intellectual capacities and create civilisation. This meaning of culture lives today in the ‘culture’ section of newspapers.⁴ This meaning of culture, as well, is not relevant here. 3Culture as a noun, denoting groups of people united by shared beliefs and practices; for example, Maori culture, Muslim culture, and so on.⁵ This meaning of culture is relevant. 4Finally, culture as socially acquired and shared symbols, meanings and significances that structure experience, behaviour, interpretation and social interaction; culture ‘orients people in their ways of feeling, thinking, and being in the world’ (Jenkins & Barrett 2004, p. 5; see Rashed 2013, p. 4). This concept of culture is analytic in the sense that its introduction enables researchers and theoreticians to account for the specific nature of, and the differences among,

various social phenomena and people's subjective reports of their experiences. For example, a prolonged feeling of sadness can be explained by one person as the effect of a neurochemical imbalance, by another as the effect of malevolent spirits, and by another as a test of one's faith: these differences can be accounted for through the concept of culture.

Having identified two meanings of culture that are relevant to this motion, I want to show why we should abandon the term culture. Consider the final definition: culture as socially acquired meanings and significances. Here we are talking about interpretation and giving meaning to our experiences, to the experiences of others, to social events and to behaviour. For example, in many societies, there exists the phenomenon of the evil eye.² This is an innate capacity to do unintentional harm through a direct look when encountering abundance or beauty in situations that evoke genuine admiration and appreciation. It may affect animals, plants, material possessions and human beings. People for whom this notion is relevant regularly explain misfortune – for example, if a tree dies or a well dries – by saying that a person who visited recently had given a 'bad eye'. For other people, however, seeing a friend's new car is an occasion to say something like 'congratulations' and to ask for a drive, without worry that one might have, inadvertently, given the bad eye.

Now, both approaches to such a social encounter involve an interpretation and a related response, and this applies to all social encounters irrespective of where the involved individuals come from. But then what part does the term 'culture' play here? If everything is culture, in the sense that everything is subject to interpretation, then it would seem that we just need to attend to that without having to invoke an overarching thing called 'culture'. It could be objected that the term culture is helpful because it allows us to identify a certain set of interpretations that occur together regularly, and to give that a name. This brings us to the third definition of culture I mentioned earlier: culture as a noun denoting groups. So, for example, the benefit of using the term Maori culture is that we can refer to a set of interpretations and practices that Maoris do: a shorthand to refer to a whole group and ascribe to them certain beliefs and practices. This, however, is problematic. The idea that we can demarcate a group of people that believe this or that and do such and such has been debunked as an anthropological fiction belonging to the European missionaries and adventurers of the first half of the previous century. It downplays individual agency in favour of some homogenous thing called 'those people's culture'.³ Consider, again, the evil eye, a phenomenon which I studied in Egypt. No two people agreed on what it meant, on its importance, on the extent to which it is a genuine problem, or on the situations in which it can be harmful. In fact, the description I gave earlier is quite partial; people appropriated the notion and made it their own, and they had a unique sense of what it is and whether or not it is relevant to them.

The notion of a cultural group may be useful politically, but it's not useful for psychiatry. The clinical encounter must always involve a serious inquiry into the person's beliefs and values, and this has to occur every time irrespective of where the clinician and the patient come from; that is, irrespective of their presumed 'culture'. In fact, to continue to use the term culture to refer to a group can be detrimental in that it may make the clinician think that he or she understands the patient – that the patient is 'Muslim' or 'Maori' or 'Irish' – when that understanding may be no more than a stereotype and hence a further obstacle to engaging with the other person's worldview. To recap, the concept of culture is no longer useful for psychiatry; if we understand culture as meanings and significances, then we need to stay with those notions, the term 'culture' playing no useful part. If we understand culture as referring to bounded groups, we would be holding a discredited view of culture, and a view that may prevent genuine engagement between clinicians and patients.

Against the motion, Rachel Bingham

A central conceptual struggle in psychiatry is the question of how to define mental disorder, and thereby delineate the proper boundaries of psychiatric practice. The concept of culture may arise in various ways; for example, in drawing a distinction between religious experience and psychopathology,⁷ or between social deviance and mental disorder.⁸ Here, I will argue that the concept of culture is more useful than ever. My argument, briefly, is that the boundary between mental health and ill health is defined by values, and values arise from culture; therefore, mental health and psychiatric practice cannot be understood without attention to culture. Developing this, I suggest that not only do values depend on culture, but values and culture overlap, or partly constitute each other. Accordingly, to say something about a person's culture is to say something about her values, and vice versa. If so, the concept of culture should be considered vital to values-based practice.⁹

The concept of culture is used here to refer to socially acquired meanings that shape our experiences, our understandings

of our experiences, the behaviours of others and social events more broadly. These shared meanings may influence not only when I believe myself to be unwell and what response I consider is required, but may also shape my experiences, actually contributing to whether or not I feel unwell or in need of help in the given circumstances.⁷ It is important not to overstate the homogeneity of cultural meanings within a group. I may not endorse all supposedly shared beliefs and values of all contexts I inhabit, and it will be difficult to make predictions about my beliefs and values by surveying the community in which I live. Nevertheless, I will be affected by others' beliefs and values – whether I endorse them, unquestioningly go along with them, or even use my rejection of the beliefs and values of my community as a springboard from which to find my own way.

Values are integral to the concept of mental disorder, just as they are to the concept of culture. Attempts to define mental disorder in purely objective, factual terms have not been successful.¹⁰ Distinctions between mental disorder and mental health are irreducibly normative. Facts alone cannot tell us which statistically extreme deviations, such as genius or avarice, are pathological. Neither can facts alone tell us what is functional or dysfunctional, as functions themselves are relative to some valued outcome or purpose. Even if the neural correlates were described for every item in a list of diagnosable mental disorders, we would rely on values to decide the contents of that list. Otherwise, we would merely have a list of states involving changes in the brain, including, perhaps, love or criminality, with no further directions as to which are the proper business of psychiatry.¹¹

Values, then, are essential to the concept of mental disorder. And values, as discussed, are not only influenced by culture, but contribute to culture, and vice versa. But if so, why not abandon culture altogether, as redundant, and focus only on what people value? Yet, to focus only on values and not their context does not serve psychiatry well. Whether values, meanings and interpretations are shared or not may influence whether a particular experience is interpreted as illness, or as some other unusual or distressing but essentially normal state. For example, whether experiences such as fear or hearing voices are shared and understood contributes to whether an individual is considered to be gifted, possessed, well or unwell. In other words, the values and beliefs of our community may partly constitute our experience of illness. The extent to which these meanings are shared may even determine whether or not a diagnosis is made.

In conclusion, among many uses of the concept of culture, one important feature is to describe something other than scientific facts: something essentially about values. Yet, psychiatry cannot focus only on values, abandoning culture, because part of both the experience and the diagnosis of mental health problems depends on the context – the shared beliefs and meanings – in which values arise and develop. Accordingly we need to see the practice of psychiatry as part of a wider context, as happening in a time and place that influence how it proceeds. We need to see our clients, patients, colleagues and ourselves as coming from contexts that influence not only whether we experience distressing or disabling symptoms, but also whether these symptoms are interpreted as illness. Unless we can say this is really being done well, without the need for further theoretical work, we cannot dispense with the concept of culture.

For the motion, Norman A. Poole

As a neuropsychiatrically inclined psychiatrist, it might be assumed that my reservations stem from a preference for biological explanations in psychiatry. While there is something to be said for the role of neuroimaging and biological investigations in psychiatry – for example, the measurement of hippocampal volume and cerebrospinal fluid beta-amyloid concentration in early stage Alzheimer's disease – they do not satisfactorily address the motion, which, let us recall, is that culture has outlived its usefulness for psychiatry. This is not to argue that the focus on culture has hindered psychiatry. Indeed, the transcultural psychiatrists have, among others, helped us to see that biological reductionism is simplistic and wrong-headed. The diagnosis of mental disorder is at the normative level,¹² just as the culturally orientated psychiatrists claimed. Furthermore, transcultural psychiatry has shown that what is deemed pathological in one culture need not be viewed as such within another. Demon possession is considered abnormal in the West, but this does not generalise to all other situations. What is left to discuss? It appears I am at one with my opponents.

My reservation is that cross-cultural psychiatry prioritises difference at the expense of universality, thereby exoticising mental disorder and potentially alienating patients further. Those with so-called culture-bound syndromes appear in the literature like new species of tropical bird for the reader to gape and wonder at. Worse still is the tendency, familiar to anyone who has worked in areas of diversity, for clinicians with a smattering of mandatory 'cross-cultural training' to dismiss unusual behaviour as 'cultural'. I've heard this applied to new-onset domestic violence and social withdrawal; cases of frontal temporal dementia and schizophrenia, respectively, as it turned out.

Instead, I wish to present the view that what goes awry at the level of norms and values is more universal than the trans-cultural psychiatrists have supposed. Consider Pascal Boyer's notion of a folk psychiatry, which is parasitical on what is called intuitive psychology.¹³ That is, the tendency to understand one's own and others' behaviour through appeal to unobservable mental states such as beliefs, desires and emotions, including their relation to one another. Most of this is done at a level beneath conscious awareness; we become aware only of the outcome. And our intuitive expectations of one another are composed of domain-specific abilities rather than this being a general process. While there are differences in explicit psychological models around the world, the evidence from developmental psychology is that intuitive abilities are universal; the best-known being theory of mind, which occurs in all cultures studied to date.¹⁴ Other tenets of intuitive psychology include: mental states somehow represent or map the world as it is; behaviour is internally generated; memory is a store of past experience; communication follows tacit but constraining programmatic principles, with each party endeavouring to ensure the other's ongoing comprehension; a largely unconscious reading of others' subtle emotional cues; and so on. That these develop in infancy implies they are more universal than local. For instance, babies preferentially attend to objects that appear to interact with one another, such as the Heider and Simmel animation involving an 'aggressive' triangle and 'fearful' circle (<https://www.youtube.com/watch?v=VTNmLt7QX8E>). No one, with the exception of those with autism,¹⁵ has any trouble in attributing internal mental states to these shapes. Indeed, feelings of pity for the circle are frequently evoked.

The idea is that mental disorder is implied when behaviour, including verbal behaviour, contravenes one or more of our tacit expectations. People with schizophrenia exhibit disordered thought and speech that fails to follow the tacit rules of checking, repair, reducing ambiguity and so forth, which are apparent to carers and fill the psychopathology textbooks. It is important to note that this failure to meet the expectations of intuitive psychology are not mere violations of social norms – it is possible to behave in a socially unacceptable manner without there being a corresponding difficulty with its understandability. Repeat offenders are socially sanctioned, but few of us have trouble attributing a motive to their crimes. Intuitive psychology also seems to help sort the classic cross-cultural psychiatric cases, without recourse to culture. The belief that one is possessed by demons does not in the West seem to map or represent the world accurately. There are, however, other accepted means for the acquisition of belief; beliefs can also arise from the testimony of others.¹⁶ The belief that one is possessed by demons is accepted in some cultures, because the belief is acquired from authority, i.e. the rest of the group. This removes culture, because it is a fault with the mechanism of belief acquisition that triggers suspicion of dysfunction rather than the more general notion of a social norm being contravened.¹⁷

To conclude, culture has outlived its usefulness for psychiatry because it has misconceived the level at which things go wrong in mental disorder. Those with mental disorder are not identified merely for social deviancy but because some aspect of their behaviour fails to meet the intuitive and universally held psychological expectations of others. By focusing at this level, we are better able to appreciate what unites us, both in sickness and in health.

Against the motion, Abdi Sanati

In what follows, I aim to show that culture is inseparable from psychiatry, and that, in fact, psychiatry cannot be practised, or conceived of, without culture. One can think of different ways to link psychiatry and culture. One of the most basic ones is through language. First, let us focus on the relationship between language and psychiatry. One of the important, and in my opinion essential, elements of psychiatry and its practice is psychopathology. It provides the framework within which we define signs and symptoms of mental disorders and communicate them to others. And language plays a necessary part in this discipline. From an ontological point of view, I find it hard to imagine the existence of delusions, verbal hallucinations and obsessional thoughts without language. From an epistemological point of view, to say any enquiry about human emotions is impoverished without use of language is an understatement. Even describing purely behavioural signs needs a language.

Now, I shall consider the relationship between language and culture. Culture and society are inseparable. One of the integral elements in every society is communication. Language is one of the most complex means of communication and has enabled human society to achieve immense complexity. The increase in the complexity of language contributed to the increase in the complexity of the culture. The increase in complexities of culture, in turn, feed back to make language more complex. There are many other factors operating in this process; for instance, I cannot deny the impact of technology on both culture and language. However, there is a definite link between culture and language. One can argue that while there is a definite association between culture and language, this association is merely a contingent one and it does not necessarily have to be the case. In the next step, I shall argue that the association is indeed necessary; that

is, without culture we would not have language. Here, I rely on the work of Ludwig Wittgenstein, especially his private language argument. Wittgenstein explores whether there is a possibility of existence of a language which is logically private; that is, it could be understandable only by one person.¹⁸ To clarify, it is not the possibility of a language that someone like me can develop, which can be deciphered, but the possibility of a language by someone who has been separate from others since birth: a born Robinson Crusoe. This is different from development of a new language by someone who already is a language speaker. That person is already in possession of language skills, and the new language would follow accepted rules. The Crusoe-type person in question does not have any awareness of the rules of language and has to develop them from scratch. In other words, this language is developed *de novo* in an individual who has never been part of a community/culture. Wittgenstein concludes that ‘a language in principle unintelligible to anyone but its originating user is impossible. The reason for this is that such a so-called language would, necessarily, be unintelligible to its supposed originator too, for he would be unable to establish meanings for its putative signs’.¹⁹ Why would he be unable to do so? The answer lies in Wittgenstein’s description of language. According to Wittgenstein, to understand a word is not to have a mental process signifying it. It is knowing *how* to use the word. In other words, it is to know how to follow the rules of using the words in different linguistic activities such as questioning, asserting, joking, demanding, etc. Language is a rule-governed activity. And to follow a rule one needs public criteria, i.e. something outside oneself to objectively confirm that the rule is followed. By objective, Wittgenstein does not mean that the rules are in some way independent of our practice, something he asserted in his earlier philosophy, but that what constitutes a rule is our collective use of it. Rule-following is a general practice established by agreement, custom and training.²⁰ He argues that the concept of rule presupposes a custom. It is a cultural phenomenon. It cannot be imagined to happen individually, independent of ‘historical groups of individuals who are bound together into a community by a shared set of complex, language-involving practices’.²¹ There is a vital connection between language and the complex set of practices and activities that binds a community together. Language is interwoven into the activities of the people and is fundamentally cultural in nature. In other words, without culture there cannot be language and, hence, no psychiatry.

2018-4

Contents

- *Management of common mental disorders for psychogeriatric patients in Hong Kong: comparison of two clinics after 1 year of treatment*

We would like to update the findings of our pilot study which compared the enhanced common mental disorder clinic (CMDC)¹ and conventional specialist psychiatric out-patient clinic (SOPC) in the management of common mental disorders (CMDs) for psychogeriatric patients in our hospital in Hong Kong. In our previous letter to the editor, different clinical factors were compared between the two groups 6 months post-treatment. This time, findings for 1 year post-treatment were available.

The CMDC is a 1-year programme with multidisciplinary involvement. There were 30 patients in each group. After 1 year of treatment, only 15 patients (50%) remained in the CMDC, while 23 remained in the SOPC ($P = 0.03$). Ten patients (33.3%) completed the CMDC programme and were successfully discharged from the CMDC. They did not require any medication for their CMDs. One patient refused to attend medical follow-up. One patient was transferred from CMDC to SOPC, as she was found to have dementia. Another patient was transferred to the general out-patient clinic for continuation of treatment for her mixed anxiety and depressive disorder.

Concerning psychological intervention, half of the patients in the CMDC group (50%) were referred to a clinical psychologist, and ten had good adherence to appointments. For the SOPC group, only three patients (10%) were referred to a clinical psychologist ($P < 0.05$).

Concerning antidepressant use, the rate at 1-year follow-up was 11 (36.7%) for CMDC v. 20 (69%) for SOPC patients ($P = 0.02$). Profiles of benzodiazepine and hypnotic use and prescription were similar prior to consultation, after the first consultation, 6 months post-treatment and 1 year post-treatment. Eight patients (26.7%) in each group did not require benzodiazepines or hypnotics after the first consultation. The reduction in benzodiazepines and hypnotics was statistically significant ($P = 0.04$). At 1 year after treatment, ten patients (33.3%) in each group were taking benzodiazepines or hypnotics.

In summary, psychiatrists of both clinics were able to reduce benzodiazepine and hypnotic use after the patients formally presented to the psychiatric clinic. Nearly half of the patients who were given a benzodiazepine or hypnotic did not require it afterwards. Instead, about two-thirds of them were treated with antidepressants. Significantly more patients did not require antidepressants at 1 year post-treatment in the CMDC group. There were also significantly more patients who did not require medical follow-up at 1 year for the CMDC group.

Remission of CMDs is possible for patients who have completed the 1-year CMDC. Its psychological and pharmacological components, as well as timely interventions, have contributed to its success. The treating team and the patients are aware of the time-limited nature of the programme and have expectations that suitable cases can be discharged from the programme upon its completion. This helps to ensure that the clinic is not overwhelmed by continual accumulation of cases. On the contrary, the SOPC does not have a specified duration of treatment and the doctors are less ready to discharge patients from the clinic if they are stable on medical treatment. It is not common to refer back stable cases to primary care. Enhanced collaboration between the SOPC and primary care in the management of CMDs can help to reduce the burden on the SOPC, so that it can have more capacity to deal with complicated and unstable cases.² The acceptability of psychological interventions is expected to be better if they can be more tailored to elderly patients; in fact, many older people expressed a preference for talking therapies.³

1.5.15 Benjamin (Ben) Steinberg, MD FRCPsych

J. Guy Edwards

date

2018-4

Contents

- *Benjamin (Ben) Steinberg, MD FRCPsych*

Formerly Consultant Psychiatrist, Knowle Hospital, Fareham and Royal South Hants Hospital, Southampton, UK

2018/S2056469417000249_inline1.jpg

Ben Steinberg, who died recently at the age of 93 years, was regarded as one of Hampshire's most popular and well-respected psychiatrists. He had an encyclopaedic knowledge of many subjects, including psychiatry, world affairs, history, literature and the theatre, and was a most engaging conversationalist. He could debate controversies in a robust but sensitive way, and was a great listener. He had an unrelenting capacity to care. In his later years, he worked voluntarily for a charity providing emotional, legal and financial support for refugees and asylum seekers in Southampton and Winchester.

He served as chairman of the Medical Committee, was a member of the Management Committee and chairman of the Psychiatric Rehabilitation Committee at Knowle Hospital, was chairman of the Wessex Psychotherapy Society, and was also a member of the Southampton and District Community Health Council and chairman of its Mental Health Group. He taught under- and post-graduate students and assisted in a number of research projects.^{1,2}

He was an active member of the Labour Party and was elected chairman of the Romsey and Southampton North Branch and chairman of the Southampton and District Fabian Society.

Ben was born into a Jewish family in Latvia. In 1925, his family moved to Belfast where his father became an assistant Rabbi. He graduated in medicine from Queen's University, Belfast, in 1946 and obtained his MD in 1957. Following his preregistration training, he served in the Royal Army Medical Corps for 2 years and then undertook his psychiatric training (1949–1956). He was appointed Senior Hospital Medical Officer in Cardiff in 1956 and consultant at Knowle Hospital in 1958. After retiring he worked as clinical assistant in the Rehabilitation and Long-Stay Units at Knowle and Southampton for a further 9 years.

He and his late wife, Phyllis (a nurse from the Republic of Ireland), showered hospitality on his colleagues and many generations of trainees and their partners. Many overseas trainees showed their appreciation decades after returning to their native countries.

Ben remained youthful until near the end. His clinical skills, intellectual prowess, sense of duty, concern for patients and loyalty to friends and colleagues will remain as monuments to his memory. He will be sadly missed by all who knew him, but most of all by his family, to whom he was deeply devoted – his three children (David, Judith and Helen), ten grandchildren and two great grandchildren.

Abstract

In this article I argue that fictional accounts of mental illness should be unethically unobliged. I suggest that art is not generated with conscious ethical intent and provide evidence that art proceeding from an ethical agenda is more likely to be poor art. I also consider ways in which a writer-doctor might need to compromise what they articulate to maintain a professional ethical integrity.

- ‘To know before hand is to freeze and kill’ Commentary on... Should psychiatrists write fiction?

“For only after, can one nail down, examine, explain. To try to know beforehand is to freeze and kill. Self-consciousness is the enemy of all art, be it acting, writing, painting, or living itself, which is the greatest art of all. Ray Bradbury¹”

Beveridge² argued that fiction supports psychiatrists to imaginatively enter other lives to become more ethical and empathetic. The previous article³ changes the slant: psychiatrist/writers should enter the life of readers to encourage them to become more ethical and empathetic regarding mental health. Oyeboade, a poet/psychiatrist, sees literature as lacking conscious ethical intent, but argues that a secondary outcome of fictional investigations of psychiatry is to influence how society sees mental disorder and how politicians will tackle this area.⁴

Will Self has written many pieces of fiction with a recurring psychiatrist character, Zack Busner, who sometimes resembles Ronnie Laing, sometimes Oliver Sachs. For Self, psychiatry has become central to his writing, because: “... psychiatrists stand – whether they acknowledge it themselves [...] at the threshold between happiness and sadness and between sanity and madness [...] I’m thinking [...] in terms of priests who manage the transition from the phenomenal to the numinal.⁵”

In a secular age dominated by scientism, psychiatrists function as meaning-makers. Given this status, shouldn’t psychiatrists who write show an ethical loyalty to the project of psychiatry?

The way in which creativity proceeds and how art and psychiatry interact with each other can be approached using the framework of one of psychiatry’s foundational figures – Karl Jaspers. Jaspers identified two modes of knowing, which should weave together in the work of a psychiatrist: Verstehen and Erklären.⁶ Erklären tries to make explanatory sense of phenomena by finding the laws that govern them. The psychiatrist who engages in Verstehen tries to make empathetic sense of phenomena by looking for the perspective from which the phenomenon appears to be meaningful. Jaspers is describing the art and science of medicine, insisting that scientific explanations are necessary but not sufficient accounts of our patients.

Fiction attempts to subjectively understand the human condition – it is *Verstehen*. At the same time, fiction is not just a right-brained tapping of the unconscious. A writer gains by having authority over the subject matter: to be coherent, to be up-to-date, to teach us, to please us with erudition. We know the difference between well-researched and poorly researched novels. However, writing that is overly occupied by *Erklären* will fall dead from the womb.⁷ A Pulitzer Prize winner writes: “‘*What’s erroneous is the assumption that the thoughtful analysis and willful insertion of that in the work is the creative process [...] it’s the antithesis of the process [...] If you start perverting that with other motives to write, your ability to become an artist is severely hampered, if not destroyed.*’⁸”

In the accompanying piece, the authors simplify and rationalise the writing process, which they depict as ‘*Firstly, the writer gathers information through research. Secondly, a story framework, however loose or rigid that may be, is devised. Thirdly, a coherent narrative is constructed through putting the words onto paper.*’⁹ This strikes me as true when I write professionally or academically. I would suggest that the process of writing fiction is fundamentally different, that the authors misunderstand the writing process by assuming the ego’s fingers have a firm grip of the pen. Numerous writers have described the creative process as passive,^{8,9} for example, Paul Bowles states: “‘*If I am writing fiction, I am being invented. I cannot retain any awareness of identity. The two states of being are antithetical. The author is not at a steering wheel [...]*’⁹”

The creating artist may be caught in an unconscious dream, but Margaret Atwood does not allow so easy an abdication of moral responsibility: “‘*Why do authors wish to pretend they don’t exist? It’s a way of skinning out, of avoiding truth and consequences.*’¹⁰”

Ray Bradbury states: ‘*For only after, can one nail down, examine, explain.*’¹ This feels true to the writing experience: that creation is often unconscious, but the subsequent shaping of the material is conscious and where ethics become relevant. The poet Selima Hill describes the moral editorial step which occurs late in her creative process. She uses the following rubric to guide her: “[...] *the morals of the thing. Is it libellous? Is anyone’s reputation going to suffer? [...] Am I exploiting someone else’s work, or life? Or might it, on the other hand, have a positive (morally ‘good’) effect?*’¹¹”

The power dynamic in psychiatry is so asymmetric and the potential consequences of breaching confidentiality are so severe that when psychiatrists write about psychiatry, our policing needs to be rigorous. How we achieve this is another topic in itself.

Selima Hill concludes that the function of art is not that of *Erklären* but the subversion of *Erklären*. “‘*It is not the place of art to draw conclusions or even to understand. On the contrary, isn’t the whole point that it is non-judgemental? That it undermines the making of value judgements? It is modest, helpless, useless, but at the same time determined, and just. I think of Heaney’s phrase ‘to set the darkness echoing’ – where darkness is what it is, and we can neither flinch nor sink.*’¹¹”

Hill is arguing that art should be ambiguous, should avoid conclusions. Psychiatry is used to shades of grey in its epistemology, nosology and ethics. More than other branches of medicine, we require negative capability – the skill of sitting with uncertainty without irritably reaching after a simplistic explanation.¹² This is *Verstehen* – a different kind of understanding, one that does not make value judgements. To achieve such an end, the artist/psychiatrist will put aside *Erklären* and ethics. An activity that is ‘*modest, helpless, useless but just and determined [...] where [...] we [...] neither flinch nor sink*’ sounds like what most psychiatrists do, the kind of modest psychiatry we can believe in, the psychiatry that we actually practise in shabby clinics and battered wards ‘*where we set the darkness echoing*’.

2018-4

Abstract

This paper looks at the relationship between fiction and psychiatry. Specifically, the idea of psychiatrists as fiction writers is explored, and reference is made to various fictional texts to illustrate the problems of stigma and negative imagery. These two main areas of focus are highlighted as ones that the practice of writing fiction might address, and some potential pitfalls are discussed. The paper suggests how psychiatrists might ameliorate the present problems by incorporating their unique clinical skills and knowledge into fictional narratives.

 - *Correcting the image*
 - *Pitfalls*
 - * *Ethics*
 - * *'Medical' fiction*
 - *Conclusion*

In 2003, Allan Beveridge examined the idea of whether psychiatrists should read fiction.¹ This paper asks the related question of whether psychiatrists should *write* fiction? Chekhov did it, and so did Oliver Sacks, even if he did burn his first efforts. Femi Oyeode² notes the similarity in the tasks of the fiction writer and the psychiatrist, pointing out that they are both trying to make sense of human behaviour. This observation is pertinent to this paper, which will look at the connection between psychiatrists and fiction writing. Certainly, fiction can be powerful, but so can psychiatry. Garcia-Nieto³ says that there used to be a strong connection between literature and psychiatry, a connection that was severed during the 20th century. Psychiatrist/writers can help to restore that link.

Novelists write about the human condition, that much is evident. As Baker *et al*⁴ note, for writers 'madness has long been, and remains, a compelling preoccupation'. Fiction writers often write about psychiatry for dramatic effect, but not always faithfully. The result can produce stereotypical depictions of mental health and of the people who work in that arena. Writers also write about psychiatrists, often with the same result.

Patrick McGrath has done both; he has written about psychiatry and the experience of mental suffering (*Spider*), but he has also written about psychiatrists. In *Trauma*, his character, Charlie Weir, is a psychiatrist struggling to come to terms with his mother's death.

McGrath has also combined the two. In *Asylum*, set in a secure hospital in the late 1950s, McGrath writes about the experience of suffering, and about a young psychiatrist and his family.⁵⁻⁷

Drawing on experience is something that every writer does, but some knowledge of psychiatry is important for such genre writing. I want to suggest that writing fiction, as an avenue open to psychiatrists, presents a great opportunity to provide positive models of mental health. The understanding psychiatrists have for their patients is likely to encourage a more complete illustration of character and setting. So the answer to the question posed by this paper should be yes. The writing process essentially involves three stages. First, the writer gathers information through research. Second, a story framework, however loose or rigid that may be, is devised. Third, a coherent narrative is constructed through putting the words on to paper. When it comes to writing about psychiatry, it is plain that psychiatrists have a head start. Step one, where Sebastian Faulks, for example, spent 5 years researching his epic book about psychiatry, *Human Traces*, can be leap-frogged by psychiatrists. Similarly, the difficulty that Patrick McGrath⁸ talks about in drawing from psychiatry for fiction is largely circumvented by the closeness of psychiatrists to their subject matter and their ability to make sense of human experience.

Before the reader dashes away from the clinic armed with a notebook stuffed with observations and ideas for their new novel, I should introduce something by way of balance. The critics would suggest, for example, that somebody working therapeutically should not write, or that they may end up manipulating patients.⁹ Those in the ‘no they shouldn’t write’ camp might also caution against the danger of clinical narrow-mindedness and an overkill of technical psychiatric jargon. This pitfall will be examined below. For the moment, it should be sufficient to note that the skill of a writer is in creating a world *apart* from real-world experience. Paradoxically, though, this subtle shift from fact to fiction has the aim of *seeming* real. I therefore suggest that, beyond wishing to produce an entertaining product, psychiatrists should have two principal goals in mind when approaching the writing of fiction. These are: •correcting stigma by raising awareness, educating others and promoting good mental health•countering the negative image of psychiatry and the psychiatrist.

Raising awareness

The impact of media representations has major effects on the stigma experienced in mental health. That media portrayals of mental health and mental health professionals influence public perception is a well-documented phenomenon.¹⁰ ¹¹ As Stuart¹² notes, the media has a ‘vast store’ of negative images in relation to mental illness.

As Liam Clarke said, literature’s take on human behaviour ‘surpasses the descriptions of social and psychological sciences’.¹³ The potential power of the combination of fictional narrative and psychiatric insight could offer a potent formula of truth and wisdom resulting in enlightened understanding. The demystification of mental health services through the normalising effect of honest and informed writing cannot be understated. As Oyeboode¹⁴ suggests, these narratives influence ‘how wider society perceives mental illness’. It therefore follows that sensitive portrayals of psychiatry would encourage a more informed and sympathetic view of the work done by psychiatrists. Rightly or wrongly, psychiatry has always endured its critics. Many of these issues are still current, whether they relate to concerns about paternalism,¹⁵ over-reliance on medication,¹⁶ the use of ‘specialist’ knowledge in the maintenance of power,¹⁷ criticisms of biological models,¹⁸ or even debates about the value of diagnostic labels.¹⁹ ²⁰ Psychiatrists might, therefore, wish to respond to such commentary through writing fiction that points to a more eclectic nature in the profession and what they do.

The acknowledgement that psychiatrists can move to a more collaborative relationship with the service user movement²¹ would suggest one area where fiction could develop a stronger image for psychiatrists and patients alike. Such efforts are starting to show potential, as in the recent novel by Monica Starkman, *The End of Miracles*.

The other thing to bear in mind is that although fiction may be the poor relation to the medical textbook,²² fiction is more accessible, and people are more likely to read a fictional account than a research paper or the DSM-5.

Correcting the image

Psychiatry has had its periods of self-doubt. In fact, it would be hard not to see the problem as a perennial identity crisis.²³⁻²⁵ Fiction does little, it seems, to help. In her study of media representations of psychiatrists, Jacqueline Hopson claims that psychiatrists are ‘demonised’ by fiction. She asserts that psychiatrists are regarded with suspicion and fear, and that the portrayals in fiction, which are frequently related to power, are deleterious to the profession. She points to representations such as *The Snake Pit* and Antonia White’s *Beyond the Glass* in support of her thesis.²⁶ Psychiatrists are without doubt in a position of power, and the idea of using psychiatric treatment as a punishment is a popular theme in fiction. If we believe what we read, it is a short step from administering medication to using it to control and punish others. *The Bell Jar*, Sylvia Plath’s classic book, with its references to electroconvulsive therapy (ECT), self-harm and suicide, shows us the confusion depicted in the character of Esther Greenwood, confusion which is epitomised after her first ECT session, when she remarks: ‘*I wonder what terrible thing it was that I had done*’.

In *The Trick is to Keep Breathing*, by Janice Galloway, her character, 27-year-old Joy Stone, has doubts about her psychiatrists. Joy sets out a list of general ‘lessons’ she has learned about them, including her belief that psychiatrists are ‘devious and persistent. They always win in the end’. Such portrayals have significant consequences for those who work in mental health settings, just as they do for sufferers. For psychiatrists, negative imagery can lead to problems with recruitment,²⁷ difficulties with their public image,²⁸ and denigration from their colleagues in other branches of medicine.²⁹

With a more positive mindset, fiction can act as a beacon of truth. Andy Bickle³⁰ urges that we ‘should not underestimate the importance of literary and other media representation in creating the milieu in which we work’. In the same way that social worker Freya Barrington had the aim of raising awareness of her profession in her book, *Known to Social Services*,³¹ psychiatrist Monica Starkman relates her goal of showing psychiatry and psychiatrists as they are, and not as the stereotypes portrayed in books or films.³² So, a prime motivator for psychiatrists might be to adopt the ‘inform and entertain’ ideal in their approach to writing fiction, and tell readers what being a psychiatrist is *really* like. As I have already said, there are plenty of fictional psychiatrists, and they are by no means universally negative, despite what Hopson claims in her paper. In his latest novel, *Where My Heart Used to Beat*, Sebastian Faulks presents Robert Hendricks, a post-war psychiatrist who is a long way from the unpleasant stereotype Hopson bemoans. Nevertheless, there is potentially a different dimension to ‘psychiatrist point-of-view’ novels written *by* psychiatrists.

As well as correcting erroneous imagery, psychiatrists might wish to portray something of the conditions in which they work. The political dimension of psychiatry has been written about before, perhaps most strikingly in *One Flew Over the Cuckoo’s Nest*, but there are other books that use narrative as a form of commentary on the state of mental health or welfare services. *Poppy Shakespeare*, by Clare Allan, is set in a psychiatric day unit. This novel, which raises issues of institutional relationships and of benefits payments, is a notable example of how fiction can highlight current difficulties in service provision.

Pitfalls

Ethics

*The writer is a member of society and therefore has ethical and moral responsibilities. We need to take care in the construction of our own ‘make believe’ worlds.*³³ Ethical considerations are always prevalent in psychiatry. For psychiatrists writing fiction, there are issues of confidentiality and professional sensitivity to consider. There are always those who claim that fiction is simply fiction, but Gandolfo would disagree on the basis that fiction has the power to make a difference to people’s lives. He has argued that writers should ‘rigorously question both themselves and their writing’.³⁴ The fiction produced by psychiatrists might be governed not only by the desire to tell a story, it will also be tempered by the need to provide honest and realistic portrayals of the subject matter. Of course, the ethical dimension can be productive in itself. Beveridge³⁵ points out that writers might want to explore moral quandaries, a subject particularly prevalent in psychiatry. Issues of power, liberty, treatment and the like are fertile topics that do not have to be restricted to textbooks and non-fiction.

'Medical' fiction

Psychiatrist Monica Starkman asks whether psychiatrists write good novels. In attempting to answer her own question, she points out that psychiatrists have access to 'the deepest, most private thoughts and feelings of many people', which might lead one to assume that fiction writing should be easier for a psychiatrist. However, writing should be informed, but it should also be entertaining, and another obstacle for potential 'psychiatrist fiction writers' is technical language. Beveridge³⁶ suggests that writers are attempting to do crudely what modern psychologists do in a sophisticated manner. This is missing the point of fiction, but it is a point he later seems to correct. In 2010, he said that fiction can 'deepen our understanding of people with a mental illness' and divert from the narrow evidence-based approach to psychiatry.³⁷ Potential writers should always think about the reader, so psychiatrist/writers should resist the desire to overdo psychiatric terminology. As Crawford and Baker note,²² it should be remembered that fictional texts are *representations* of illnesses. They also reiterate the fact that fiction is not written for the purposes of diagnosis. To 'diagnose or not' is a consideration psychiatrist fiction writers will face. Oyebode¹⁴ points out that novels are not scientific studies of psychopathology; in a discussion I had with award-winning novelist Nathan Filer (*The Shock of the Fall*), Filer pointed out that, despite the protagonist in the novel having a strong psychotic dislocation, the term 'schizophrenia' was only used twice in his book. There are other writers, Nicola Barker, for instance (*Reversed Forecast*), who similarly convey a sense of suffering without resorting to psychiatric terminology.

Conclusion

Psychiatrists are dealt a rough hand by fiction. Despite more light-hearted depictions such as the satirical archetype produced by Will Self in a number of his novels (Dr Zack Busner appears in a succession of Self's novels and short stories, *The Quantity Theory of Insanity*, *Ward 9*, *Dr Mukti*, *Umbrella*, *The Book of Dave*, *Shark*), the work of the psychiatrist is depicted as mysterious at best and threatening at worst. Such imagery is only likely to have negative results. Not only does this affect the profession, but it filters down to the end-users of mental health services.

Although Bickle³⁰ suggests that fiction deals with the 'wrong type of data' to convey a comprehensive knowledge of mental illness, Bickle³⁰ makes the point that it offers the chance to step back from the world and to explore these issues, thereby helping psychiatrists reflect on their practice. The efforts of psychiatrist/writers in producing fiction presents an opportunity to correct some of these ills. If psychiatrists can avoid the pitfalls, then writing fiction can achieve a number of positive outcomes.

1.5.18 Weekday and seasonal patterns in psychiatric referrals in three major London A&E departments, 2012–2014

James Dove Amit Mistry Nomi Werbeloff David Osborn Nora Turjanski

Correspondence

James Dove (james.dove@nhs.net)

date

2018-2

Abstract

Aims and method

To identify temporal and demographic trends in referrals made to psychiatric liaison services. Routine clinical data from 16 105 individual referrals from three central London accident and emergency (A&E) departments to psychiatric liaison services from 2012 to 2014 were obtained and analysed using the Clinical Record Interactive Search (CRIS).

Results

Referrals from A&E to psychiatric liaison services increased 16% over the 3-year study period. There were fewer referrals to psychiatric liaison services in winter months compared with other seasons. There were fewer referrals to psychiatric liaison services over the weekend compared with weekdays (average 15.4 daily weekday referrals *v.* 13.2 weekend, $z = 5.1$, $P < 0.001$), and weekend referrals were slightly less likely to result in admission to psychiatric hospital (11.3% *v.* 12.8%, respectively, $\chi^2 = 6.33$, $P = 0.01$).

Clinical implications

Psychiatric staffing in A&E and inpatient psychiatric wards requires planning to meet temporal and regional variations in the pattern of demand.

 - * *Trend in referrals year on year*
 - * *Seasonality of referrals*

* *Weekend referrals*

– *Discussion*

* *Limitations*

Accident and emergency (A&E) departments in the UK are getting busier, with an estimated 50% increase in demand over the past 10 years.¹ Approximately 5% of A&E attendances are for treatment of a mental disorder.² An estimated 8% of all A&E attendances are by ‘chronic repeat attenders’; the most common reason for frequent attendance is an untreated mental health problem.¹

The increased demands on A&E and the consequent impact on bed availability in acute trusts have been well studied, and a trend in peak pressures on A&E departments over the winter months has been established.^{3,4} Although it is acknowledged that A&E attendances are generally lower in the winter months, patients are likely to be more unwell, requiring admission that can lead to longer hospital stays and long waiting times in A&E – the ‘winter pressures’.⁵ This phenomenon has attracted injections of short-term funding of staff and resources in an attempt to encourage flow through the system – including to liaison mental health teams.

Public awareness of these pressures has led to a number of developments in recent years. These include the drive towards consultant-delivered care and, more recently, the ‘7-day National Health Service (NHS)’ proposals made by Bruce Keogh initially in 2013.^{6,7} These initiatives are now supported by government policy following suggestions that, further to the pressures on NHS services, there may be a weekend effect in terms of increased morbidity and mortality.⁸

A recent study by Patel *et al*⁹ investigated the mortality relating to *psychiatric* weekend admissions and found no correlation between weekend admission and increased mortality. However, the study identified that those admitted at the weekend had shorter admissions and higher readmission rates, leading to the suggestion that there is a different population who are more likely to be admitted at weekends. There is little or no work looking at the fluctuation in presentation at the gateways to psychiatric admissions – of which A&E attendance is a major source.

Anecdotally, it is said that ‘major’ mental illness, i.e. bipolar affective disorder and schizophreniform disorders, have bimodal peaks in presentation of spring and autumn;^{10,11} it might be assumed, therefore, that these would be peak admission times for psychiatric patients.

Here, we describe a study that analyses 3 years of referral data from three central London A&E departments to their psychiatric liaison teams, looking at seasonal variation and variation in weekday/weekend referrals, as well as some limited analysis of the demographics of those patients referred.

Aims

The aim of this study is to describe referral rates from three central London A&E departments to their respective psychiatric liaison services, to explore whether patterns of referral are similar to trends reported regarding general attendance to A&E, including the weekend and ‘winter pressures’ models reported nationally. The secondary aim was to compare weekend *v.* weekday referral trends, and whether these referrals were more or less likely to result in admission to inpatient services. The tertiary aim was to assess those presenting frequently to A&E services (3 times during the study period), and determine whether these patterns were more pronounced in this group of patients.

Method

Routine clinical data for this study was obtained from Camden & Islington (C&I) NHS Foundation Trust using the Clinical Record Interactive Search (CRIS) tool. CRIS is an application developed to enable routinely collected electronic health records to be used in research, using an explicit deidentification process.¹² C&I is a large mental health provider serving a geographic catchment area of two inner-city London boroughs, and approximately 440 000 residents. The database contains full but anonymised information from over 100 000 mental health patients.¹³ Studies using CRIS received ethical approval from the National Research Ethics Service (NRES) Committee East of England – Cambridge Central (14/EE/0177).

We conducted a retrospective cohort study of all A&E referrals to psychiatric liaison services across three London teaching hospitals (Royal Free Hospital (RFH) and Whittington Hospital (WH) in North London, and University College London Hospital (UCLH) in Central London) over a 3-year period (2012–2014), deriving a complete data set of 16 105 individual psychiatric referrals. These 3 years were chosen since complete electronic record data was available for all three sites.

Data collection on the 16 105 referrals was limited to fields that are well recorded on CRIS and encompassed the following: •day and date of referral from A&E to psychiatric liaison service•demographic details of referee – age, gender, ethnicity•discharge destination of referral, i.e. admission or discharge•admission, i.e. informal or under a section of the Mental Health Act.Data on diagnosis were not used for purposes of this study, as the majority of the patients referred to liaison teams are not allocated a recorded ICD-10 diagnosis, for instance, where no mental disorder is present after assessment.

Discharge destination of liaison referral being admission to psychiatric hospital was used as a ‘proxy of severity’ of presentation, in common with other similar studies.^{14–20}

Number of presentations of individual patients during the time period was also recorded, and those presenting 3 times in the study period were identified as ‘frequent attenders’ and analysed as a separate cohort within the study in an attempt to identify any differences in patterns of referral for this group.

Statistical analysis

Number of referrals per year was expressed as a proportion of referrals from the total population in the C&I catchment area (426 463 according to the 2011 census). Z-tests were used to compare the proportion of referrals between the different study years, seasons and days of the week (weekday *v.* weekend).

Descriptive statistics of all patients referred over the study period were examined.

The chi-square test of independence (²) was used to compare the number of referrals across seasons and days of the week.

Multilevel logistic regressions were used to account for multiple referrals of one patient and to examine the association between patient characteristics (sex, age and ethnicity) and weekend referral.

Finally, frequent attenders were compared to non-frequent attenders using the ² test for categorical variables and independent samples *t*-test for continuous variables.

Results

In the years 2012–2014, there were a total of 16 105 referrals from A&E services to psychiatric liaison teams in the study area (RF: 4575, UCLH: 6440, WH: 5090). These referrals represent a total of 10 049 individual patients referred. The total number of referrals per patient varied from 1 to 49.

Description of cohort

The average age of patients referred was 38.8 years (SD = 15.6); 92.6% were under 65 years of age. 51.2% of the cohort were male. Ethnicity data were missing for 17% of the sample. Of those with complete data, the majority of patients were of White ethnic origin (69.5%).

Frequent attenders (3 referrals over study period, $n = 1108$) did not differ from the rest of the cohort with regard to gender and age distribution, although there was a slightly higher proportion of people of White ethnic origin.

Trend in referrals year on year

As can be seen in *Table 1*, there was an increase of 16% ($z = 7.764$ $P < 0.001$) in total referrals over the 3 years across the three sites (RF +36%, WH +7%, UCLH +12%).

Site	2012	2013	2014	Total % increase 2012–2014
Royal Free Hospital	1229	1679	1667	36%
Whittington Hospital	1606	1769	1715	7%
University College London Hospital	2076	2040	2324	12%
Total	4911	5488	5706	16%

Referrals as proportion of population in catchment area: 1.15% 1.29% 1.34%—

Over the 3 years, 12.4% of referrals led to an inpatient psychiatric admission ($n = 2003$), 33.4% of those ($n = 654$) under a section of the Mental Health Act.

Seasonality of referrals

When the 16 105 referrals across the year were divided by season (defined as: winter, December to February; spring, March to May; Summer, June to August; Autumn, September to November) the only statistically significant finding was that, compared with all other seasons, the winter months saw fewer referrals ($z = 4.8$, $P < 0.001$; see *Table 2* and *Fig. 1*). This matched with the lowest percentage overall of admissions from all seasons. Peak admissions were seen in the spring – 13.1% or 546 admissions over the 3 years – however, the percentage of referrals resulting in admission did not differ significantly by season ($\chi^2 = 3.92$, $P = 0.27$). Similarly, there was no statistically significant difference between the percentage of referrals resulting in admission under the Mental Health Act by season ($\chi^2 = 0.30$, $P = 0.96$).

Season	Total no. of referrals (%)	Admissions from referrals (%)	No. of admissions under section of the Mental Health Act (%)
Winter	3715 (23.1)	474 (12.8)	157 (33.1)
Spring	4160 (25.8)	546 (13.1)	174 (31.8)
Summer	4162 (25.8)	496 (11.9)	165 (33.3)
Autumn	4068 (25.3)	487 (12.0)	158 (32.4)
Total	16 105	2003	654

Proportion of population (%) 0.87% 0.98% 0.98% 0.95%

Weekend referrals

Of the 16 105 referrals, there were fewer referrals to psychiatric liaison services at weekends compared with weekdays (0.48% v. 0.56% of the population; $z = 5.1$ $P < 0.001$).

Fewer weekend referrals resulted in inpatient admissions compared with weekday referrals (11.3% v. 12.8%, respectively, $\chi^2 = 6.33$, $P = 0.01$). Of the weekday referrals that resulted in admissions, 33.3% were under a section of the Mental Health Act. Of the weekend referrals that resulted in admissions, 30.6% were under a section. This difference is not statistically significant ($\chi^2 = 1.20$, $P = 0.27$).

Multilevel logistic regressions suggested that patients referred on weekends were more likely to be female, under the age of 65 and of White ethnic origin (Table 3). Table 3 Comparison of demographic data of all referrals to psychiatric liaison services; weekend v. weekday attenders

Total no. of referrals	Weekend referrals, %	Odds ratio (95% CI), P

Discussion

Referrals to psychiatric liaison services between 2012 and 2014 within three central London A&E departments echoed the national figures for A&E attendances, with increased overall attendance year on year. Our results also showed a seasonal trend similar to the A&E data, with decreased absolute referrals in winter months. However, in contrast to the general hospital population, these referrals appear to be for people with a lower severity of illness in the winter months (using the proxy outcome measure of an admission to inpatient psychiatric services resulting from those referrals). Our data showed increased severity of presentations (increased admissions) occurring outside the winter months, but there was no statistically significant variation in number of patients admitted informally or under the Mental Health Act throughout the year.

Weekdays were slightly busier in terms of average numbers of psychiatric referrals and admissions than weekends, in terms of both numbers of referrals and numbers of admissions to psychiatric inpatient beds (11.3% v. 12.8%, respectively, $\chi^2 = 6.33$, $P = 0.01$).

There is only limited evidence from this data set to support the concept of a defined seasonal variation in psychiatric presentation; despite the academic position that ‘major’ mental illness – bipolar affective disorder and schizophreniform disorders – have bimodal peaks in presentation of spring and autumn.¹ This phenomenon might, however, be able to explain the trend seen in our data of a shift in severity of illness when comparing the psychiatric population with the general acute hospital intake, with a peak of admission rates from winter to spring; however, there were no reliable data in this study on diagnosis.

This study demonstrates an increased presentation of mental health problems to A&E, and increased severity of those presentations, during the week rather than at the weekend.

Key points and implications for A&E and psychiatric liaison services from this study are as follows. •There was a significant increase in number of referrals from A&E to psychiatric liaison services year on year. •Winter was significantly different from the three other seasons (with lower referrals). •There were significantly fewer referrals per day (on average) on weekend v. weekdays, but the absolute difference was only 1–2%.

Limitations

We looked at referrals to mental health liaison services, rather than totals for A&E mental health presentations. It is anticipated that a far higher proportion of patients with a primary psychiatric reason for presentation are managed by A&E staff and discharged without referral to mental health liaison services. It could be argued, therefore, that referral itself could be used as a proxy for severity of presentation.

This study looks at only one route of psychiatric presentation – through A&E – and does not include other routes of presentation, i.e. crisis teams, general practitioner, etc., and it is therefore not a comprehensive picture of fluctuation in need throughout the year.

Diagnosis was not reliably recorded in the data set and therefore not included in this study – a major limitation in discussion around seasonal variations in psychiatric illness presentation.

We have no data on timings of referrals and we are therefore unable to comment on ‘out of hours’ attendance other than weekday/weekend comparisons.

It is highly likely that there is a variety in threshold for referral between sites and at different times of year. For example, higher absolute summer referrals could possibly be accounted for by an influx of new doctors with lower thresholds for referral, resulting in an increase in summer referral rates but lower severity of presentation; however, we have used statistical tests in the data set in an attempt to mitigate the impact of these variables.

Use of psychiatric admission as a proxy for severity is not without its limitations: decisions to admit, particularly informally, may well be linked to bed pressures, abilities of home treatment teams locally, etc. The admissions under a section of the Mental Health Act should be less susceptible to these variables.

Although there are differences in the populations that the three hospitals serve, they are of similar size and location with equally diverse local populations, allowing for a good generalisability of the data. The e-record (RiO) is the only records system used by the psychiatric teams at all three sites and as such is a reliable representation of all patients seen.

Abstract

Aims and method

Structured clinical judgement tools provide scope for the standardisation of forensic service gate-keeping and also allow identification of heuristics in this decision process. The DUNDRUM-1 triage tool was completed retrospectively for 121 first-time referrals to forensic services in South Wales. Fifty were admitted to medium security, 49 to low security and 22 remained in open conditions.

Results

DUNDRUM-1 total scores differed appropriately between different levels of security. However, regression revealed heuristic anchoring on the ‘legal process’ and ‘immediacy of risk due to mental disorder’ items.

Clinical implications

Patient placement was broadly aligned with DUNDRUM-1 recommendations. However, not all triage items informed gatekeeping decisions. It remains to be seen whether decisions anchored in this way are effective.

Declaration of interest

Dr Mark Freestone gave permission for AUC values from Freestone *et al.* (2015) to be presented here for comparison.

Secure mental health services in the United Kingdom are designed to detain individuals who have severe mental ill health and are believed to pose a significant risk of harm to others.¹ Secure services in the UK are configured around three tiers (low, medium and high) in order to accommodate people in different levels of clinical security. The task of allocating individual patients to different security tiers is challenging. First, clinicians are expected to adhere to the principle of the *least restrictive option*,² and yet there are no clearly defined eligibility criteria for different levels of security, and no clear guidelines for their particular roles.³ Furthermore, consideration of a patient's clinical presentation, psychiatric history, diagnosis, comorbidity, developmental history, family history, employment history and ethnic/cultural background,⁴ and the patchy information about outcomes achieved by secure services, complicates and compromises gatekeeping decisions further still. The challenge for forensic gatekeepers in matching patients to appropriate security levels is apparent in the reported heterogeneity of cases admitted by both medium^{5,6} and low⁷ secure services.

The process of deciding who should/should not be admitted to specific levels of security requires consideration of a wide range of characteristics.⁴ Unfortunately, knowledge about associations between patient characteristics and relevant outcomes is currently restricted by a dearth of rigorously controlled outcome studies⁸ and by a range of confounding factors that include, but are not restricted to, diagnostic uncertainty, individualistic risks, individual needs and treatment responsiveness. At present, decisions regarding patient allocation to different levels of security must be extrapolated from an uncertain knowledge base, with inevitable uncertainty regarding likely outcomes. Apart from the weak knowledge base, it is important also to consider the inherent complexity of this form of decision process.

Under complex and uncertain circumstances, human decision-making typically depends upon heuristics. Heuristics describe the normal tendency for people to employ a range of strategies in order to reduce the burden on their finite cognitive resources.⁹ Heuristics are especially prevalent when decision makers are required to accommodate multiple or conflicting sources of information.¹⁰

Heuristic phenomena of particular relevance to forensic practice include representativeness bias, availability heuristics and decision anchoring.¹¹ The anchoring heuristic, which will be the focus here, describes decision processes that are biased toward initially received (or attended to) information.^{12,13} Anchoring describes a process where initially considered features disproportionately influence decisions, while later processed information is neglected and does not influence decision-making.¹⁰

When anchoring is present, decisions that are supposed to be based on a range of characteristics (i.e. should the patient be admitted to secure services?) will instead be based on a limited set of characteristics. Under these circumstances, the structure of assessments and/or the emphasis placed on specific characteristics will be more important than the bulk of the information that is intended to inform decisions. There is a risk, therefore, that patients may be inappropriately placed because of the neglect of information.

One of the objectives of structured clinical judgement tools is to increase the transparency and consistency in decision-making and to make sure that relevant factors consistently inform clinical decisions. Despite the availability and widespread knowledge of structured clinical judgement tools in forensic services, clinical opinion can still be more influential than formally assessed risk status in decisions to detain people in secure conditions.¹⁴

Clinical opinion has been criticised as error prone and too heavily dependent on heuristics.¹⁵ Heuristics have predominantly been associated with misdiagnosis, inappropriate treatment¹⁶ and (notably for forensic services) high-impact failures of case management that have resulted in fatalities.¹⁷ Heuristics are predominantly presented as a source of error; there is a widespread assumption that cognitive short-cuts are necessarily bad, but also a growing realisation that the efficacy of heuristics is open to debate.¹⁸ A counter argument has therefore arisen against the *a priori* assumption that heuristics are necessarily bad. This counter argument is that heuristics may have many practical benefits that counterintuitively can include accuracy, transparency and efficiency.¹⁹ Furthermore, it has been argued that heuristics in practice-based medicine drive the iterative refinement of decision-making and allow clinicians to learn to focus on outcome-relevant features through reflection on the consequences of clinical decisions that they observe directly over time.²⁰ The possibility that heuristics may have some value is particularly interesting to forensic practitioners who have become accustomed to the notion that clinical opinion is less reliable than actuarial or structured clinical judgement tools.²¹ The nature and extent of the use of heuristics in forensic practice, however, remain largely unknown, despite the substantial potential benefits and costs for these forms of decision-making.

Until recently, gatekeeping decisions have relied on clinical experience along with local definitions of security need.

Structured clinical judgement tools with robust psychometric properties are now beginning to influence gatekeeping practice and may be preferred because they promise increased transparency and uniformity in decision-making. Despite widespread knowledge of the DUNDRUM quartet²² among secure service personnel, the extent to which this tool has been adopted and implemented in gatekeeping decision-making is unknown and has only recently become a subject for evaluative investigation.²³

Kennedy²⁴ lists violence, immediacy of risk, specialist forensic need, absconding behaviour and public confidence as the assessment guidelines that should determine security placement of patients. The Dangerousness, Understanding, Recovery and Urgency Manual²² was developed as an aid to clinical decision-making, and includes a scale designed to assist psychiatric triage (DUNDRUM-1). The DUNDRUM-1 is an 11-item risk assessment tool that uses both scores on individual items and the distribution of those scores (a case should score mostly in one category) to inform judgement. The tool is reported to have excellent predictive validity, high internal consistency and good interrater reliability.²⁵ The DUNDRUM-1, therefore, has potential for assisting clinical decision-making regarding patient placement and for evaluating the correspondence between patient characteristics and secure service placement. The DUNDRUM-1 also has the potential to measure the influence of heuristic bias in clinical decision-making.²⁶⁻²⁷ The DUNDRUM quartet is a third-generation risk assessment tool, with items that are anchored in specific definitions of low, medium and high security that do not take account of the contextual factors within individual secure units (patient acuity, patient dynamics, workforce skill, philosophies of care and so on). Nevertheless, the DUNDRUM allows the initial quantification of the specific nature of anchoring that may underpin clinical decision-making in relation to allocating people to levels of security.

Aims and hypotheses

First, the current study was designed to extend examination of the external validity of the DUNDRUM-1 psychiatric triage tool to a sample that was different from the original validation sample,²²⁻²⁵ and also different from the first external demonstration²³ of the DUNDRUM-1 as a useful support for clinical decision-making. Significant alignment between DUNDRUM-1 scores and patient placement would confirm the external validity of the tool. The second objective of the current study was to use the DUNDRUM-1 as a ‘best practice’ framework in which to examine anchoring heuristics in secure service gatekeeping decisions. Anchoring would be apparent if, following regression, one (or a narrow set) of the DUNDRUM-1 items were able to explain a disproportionately large fraction of variance in patient placement.

Method

Sampling

The study was approved by the research ethics committee of Cardiff Metropolitan University’s School of Health Sciences, and as a service evaluation by the relevant local National Health Service (NHS) Health Board Research and Development department. All patient characteristics were extracted from written narrative reports that had been triggered by a referral requesting admission to secure services. In every instance, permission was sought from the original report author; no requests were declined.

Characteristics of the sample were extracted from the All Wales Secure Services database of immediate post ‘referral-to-service’ (gatekeeping) assessment reports between January 2010 and June 2013. This database is used in the management of Welsh secure service patient placements. Cases were selected if they had not previously been referred either for treatment or assessment by secure services. First-time referral was used as an inclusion criterion to control for possible confounding of assessment recommendations by previous placement of patients. The database was interrogated sequentially for cases where a psychiatric report was available and the destination of the patient recorded. A total of 121 assessment reports were present in the database for the sampling period.

Of the 121 cases, 50 patients were admitted to medium security, 49 were admitted to low security and 22 remained in open conditions. Reports included comprehensive details of the index offence, forensic history, Mental Health Act 1983 status, psychiatric history, diagnoses, previous non-criminalised violence and/or self-harm, and the gatekeeping recommendation for security level.

Design

The study used a between-subjects retrospective cohort design.²⁸ All cases involved first-time referrals for secure care to avoid biasing of placement decisions by previous secure referrals. Neither of the raters had any involvement in the referral process for any of the patients included in the current study. Both were also blind to the referral outcomes at the time of completing the assessments.

Materials

The Dangerousness, Understanding, Recovery and Urgency Model²² was used as the method for rating patient characteristics at the time of first referral. DUNDRUM-1 is the triage component of the DUNDRUM Quartet and consists of 11 items that rate patient triage features on a 0–4 scale, where 0 is very low severity and 4 is high severity. Kennedy *et al.*²² suggest that people who mostly score 4 (across the range of the items on the scale) will initially require conditions of high therapeutic security (i.e. Special Hospital). A person who mostly scores 3 is likely to need conditions of medium security, and a person who is mostly rated 2 will be best placed in conditions of psychiatric intensive care (acute low security). A patient rated as 1 on most of the items should be safely treated in an open setting, and a person mostly rated 0 may be cared for in a community setting.

The DUNDRUM-1 was selected on the basis of its psychometric properties. The DUNDRUM-1 has been reported to have acceptable validity and reliability.²⁵ For instance, the scale has been reported to have good internal consistency (Cronbach's α : 0.95) and also good interrater reliability; the kappa statistic could be rated for seven of the 11 items and was greater than 0.85 for each of these.

Procedure

The DUNDRUM-1 was applied to each report by one of 2 raters (D.L. & T.D.). Both raters had successfully completed reliability workshops for the Historical Clinical Risk Management-20 (HCR-20), Sexual Violence Risk-20 (SVR-20) and Psychopathy Checklist – revised (PCL-R); they had achieved high interrater reliability with HCR-20 assessment (kappa for both: 0.9) and were therefore assumed to be reliable in the application of other similar structured clinical judgement tools (DUNDRUM-1). For each case, each item of the DUNDRUM-1 was scored by either D.L. or T.D. in accordance with item score definitions published for DUNDRUM-1.²²

Methods of analysis

All statistical analyses were conducted using SPSS version 22 (IBM). The alpha criterion was set throughout at 0.05, and alpha was adjusted for multiple comparisons using the Holm–Bonferroni method.²⁹

The index of predictive validity reported here is the area under the curve (AUC). In both the current study and the comparison data²³ the AUC was used to determine the ability of the individual DUNDRUM-1 item scores (and total score) to discriminate between cases admitted to security (low or medium secure) versus those who were not admitted to security (open conditions). AUC values can range between 0 and 1 (0 = perfect negative prediction, 0.5 = no predictive validity and 1 = perfect positive prediction). Higher AUC values indicate increased predictive validity, 0.5 acts a reference and 95% confidence intervals are used to determine whether predictive validity is superior to chance; where the lower bounds of the 95% CI were below 0.5, the null hypothesis (predictive validity is no better than chance) was accepted. Similarly, where confidence intervals overlapped, there were no significant differences in predictive validity between DUNDRUM-1 items or samples.

The next set of analyses was designed to determine whether scores for DUNDRUM-1 items differed between patients allocated to each of the three tiers of security (open conditions, low security or medium security) in the current sample. Total DUNDRUM-1 scores and individual DUNDRUM-1 item scores for these three groups were compared using Kruskal–Wallis analyses, *post hoc* contrasts between specific pairs of groups used Mann–Whitney U, and alpha inflation was controlled using the Holm–Bonferroni²⁹ method.

The final set of analyses used multiple ordinal regression to explore the extent to which DUNDRUM-1 items might individually, or in combination, explain patient placement. Analysis used multiple ordinal regression because of the ordinal nature of the independent (DUNDRUM-1) and dependent (patient placement) variables. Models were designed using the enter method in order to explore possible structures in decision processes.

Results

For comparison, the results of the AUC analyses for the current sample and for the Freestone *et al.*²³ sample are presented in *Fig. 1*. Predictive validities of total DUNDRUM-1 scores for both samples were superior to chance, and the AUC values and confidence intervals were remarkably similar between the two samples. The picture for individual DUNDRUM-1 items was more complex and not wholly consistent between the two samples. The two samples yielded similar significant AUC results for the following five items: immediacy of risk, specialist forensic need, absconding and legal process. The two samples were also consistent in finding that neither self-harm nor suicide immediacy predicted secure admissions. The two samples yielded inconsistent AUC results for violence seriousness, preventing access, public/victim sensitivity, complex risk of violence and institutional behaviour. Violence seriousness predicted secure placement in the East London sample but not in the South Wales sample; the same pattern was observed for preventing access, public/victim sensitivity and complex risk of violence. The opposite pattern was apparent for the institutional behaviour item; this item showed significant predictive validity for the South Wales sample but not for the East London sample. The preceding analysis served as a means of assessing the predictive validity of the DUNDRUM-1 for discriminating between patients admitted to secure services versus those not admitted to secure services. The next series of analyses were concerned with whether either DUNDRUM-1 total scores or individual DUNDRUM-1 items differed significantly between three groups of patients in South Wales. *Fig. 1* Comparison of AUC for DUNDRUM-1 total and item scores between East London (Freestone *et al.*²³) and South Wales (current sample). AUCs reflect the validity of DUNDRUM-1 items for discriminating individuals admitted to secure services (low or medium secure) from those not admitted to secure services. Error bars indicate 95% confidence intervals. The hatched reference line at AUC = 0.5 indicates the line of no information.

External validity, total DUNDRUM-1 scores

Fig. 2 presents the mean total DUNDRUM-1 scores separately for the patients who stayed in open conditions and for those who were admitted to either low or medium secure care. The mean scores suggest appropriate alignment between DUNDRUM-1 criteria and clinical gatekeeping decisions; mean scores increased as the levels of therapeutic security increased. This impression of the total DUNDRUM-1 scores was confirmed by the association between patient placement and total DUNDRUM-1 scores, $H(n = 121, d.f. = 2) = 20.737, P < 0.000$. Furthermore, *post hoc* comparisons with Mann–Whitney and alpha adjustment revealed that mean total DUNDRUM-1 scores for each of the groups differed from the other two groups (open *v.* low, mean difference = 3.86, $P < 0.050$; low *v.* medium, mean difference = 5.78, $P < 0.005$; and open *v.* medium, mean difference = 9.64, $P < 0.005$). *Fig. 2* Mean DUNDRUM-1 scores for the patients allocated to open conditions, low and medium security. Error bars show the standard error of the mean (* $P < 0.050$; *** $P < 0.001$).

External validity, individual DUNDRUM-1 items

Fig. 3 presents the mean scores for individual DUNDRUM-1 items for three groups of patients referred to the South Wales Forensic Mental Health Service: those who subsequently remained in open conditions, those admitted to low security and those admitted to medium security. Between-group differences and successive increases in the mean scores for individual items indicated that patient placement had been consistent with DUNDRUM-1 criteria. Inspection of the data in *Fig. 3* suggested that patient placement was not consistently aligned with all of the DUNDRUM-1 items, for example, there was clear separation in mean scores between the groups for the legal process item but poor separation for the self-harm seriousness item. In order to explore this impression of the association between items and patient placement, a series of Kruskal–Wallis tests were conducted, one for each of the 11 items of the DUNDRUM-1. *Fig.*

3 Mean DUNDRUM-1 item scores for patients who stayed in open conditions, and those who were admitted to either low or medium security. Error bars show the standard error of the mean.

The results of the multiple Kruskal–Wallis analyses are presented in *Table 1*. The impression that some DUNDRUM-1 criteria fitted service placement more accurately than others was confirmed. Only seriousness of violence, immediacy of risk, specialist forensic need, legal process and institutional behaviour were significantly associated with patient placement. Placement was not associated with absconding risk, complex violent need, victim sensitivity/public confidence, preventing access, self-harm seriousness or immediacy of suicide risk. It is worth noting, however, that several items (absconding risk, complex violent need and victim sensitivity/public confidence), if tested individually, would have been regarded as statistically significant but were rejected here after alpha adjustment. *Table 1* Kruskal–Wallis analysis of individual DUNDRUM-1 items

DUNDRUM-1 item	Observed P -value	Adjusted alpha	Significance
Legal process	<0.0000	0.005	***
Immediacy of risk	<0.0000	0.005	***
Specialist forensic need	<0.0000	0.005	***
Seriousness of violence	<0.0000	0.006	***
Institutional behaviour	<0.0010	0.007	**
Absconding risk	<0.0500	0.008	ns
Complex violent need	<0.0500	0.010	ns
Victim sensitivity/public confidence	<0.0500	0.013	ns
Preventing access	>0.0500	0.017	ns
Self-harm seriousness	>0.0500	0.025	ns
Immediacy of suicide risk	>0.0500	0.050	ns

The above Kruskal–Wallis analysis was used to select predictor variables for regression modelling of gatekeeper decision-making and identified five significant potential predictor variables. The current sample of 121 cases with five predictor variables therefore exceeded the normal power convention (30) in standard regression analyses (104 + number of predictors = 109).

Analysis of heuristics

With an ordinal dependent variable, an ordinal regression was chosen. The distribution of the dependent variable was skewed towards the higher security levels (see *Fig. 2*), so the complementary log-log function was used.

The predictors for the model were those highlighted in *Table 1* by the Kruskal–Wallis analysis (seriousness of violence, immediacy of risk, specialist forensic needs, legal process and institutional behaviour). The model was a significant predictor of level of security assignment ($\chi^2 = 236.6$, d.f. = 5, $P < 0.001$), with estimates of variance accounted for ranging between 86% (Cox and Snell) and 98% (Nagelkerke). The goodness of fit tests (Pearson and deviance) were both non-significant ($P = 1.000$ for both). The test of parallel lines was also non-significant ($\chi^2 = 0.0$, d.f. = 5, $P = 1.000$). Parameter estimates are shown in *Table 2*. The two significant predictors in this initial model were legal process and immediacy of risk. *Table 2* Parameter estimates of variables predicting assigned level of security (whole model)

Estimates	e	Waldd.f.	P -value	Predictors
Seriousness of violence	0.060	190.111	>0.050	Immediacy of risk
0.360	174.701	<0.050	Specialist forensic needs	
0.240	201.471	>0.050	Legal process	
1.810	2842.221	<0.001	Institutional behaviour	
0.220	150.021	>0.050		

To examine the variance accounted for by different elements of the model, the analysis was repeated with only legal process and immediacy of risk (the elements that were significant in the initial model). Legal processes and immediacy of risk were significantly associated (Kendall's tau = 0.255, $P < 0.010$). The simpler model was a significant predictor of security assignment ($\chi^2 = 166.4$, d.f. = 2, $P < 0.001$); the estimates of variance accounted for were lower than when all five predictors were included in the model, between 75% (Cox and Snell) and 85% (Nagelkerke). The goodness of fit tests were both non-significant (Pearson $P = 0.940$, deviance $P = .530$), see *Table 3*. *Table 3* Parameter estimates of variables predicting assignment to level of security

Estimates	e	Waldd.f.	P -value	Predictors
Immediacy of risk	0.350	137.831	<0.005	Legal process
1.560	2540.731	<0.001		

The remaining three predictors (seriousness of violence, special forensic needs and institutional behaviour) were then considered without legal Process and immediacy of Risk, see *Table 4*. The resulting model was a significant predictor of security assignment ($\chi^2 = 34.9$, d.f. = 3, $P < 0.001$); estimates of variance accounted for ranged between 14% (McFadden) and 28% (Nagelkerke). The goodness of fit tests were both non-significant (Pearson $P = 0.200$, deviance $P = 0.080$). Specialist forensic need was correlated with both institutional behaviour (Kendall's tau = 0.342, $P < 0.001$)

¹ Alpha was adjusted for multiple comparisons using the Holm–Bonferroni method. DUNDRUM-1 items were sorted on the basis of observed P -value (reading down, lowest to highest). *** $P < 0.000$; ** $P < 0.001$; ns, not significant.

² Significant P values are highlighted in bold.

³ Significant P -values are highlighted in bold.

and seriousness of violence (Kendall's tau = 0.258, $P < 0.005$); however, institutional behaviour scores were independent of seriousness of violence (Kendall's tau = 0.025, $P > 0.050$). Table 4 Parameter estimates of variables predicting assigned level of security (initially excluded predictors) Estimates. e. Waldd.f. P-value Predictors Seriousness of violence 0.370.165.011 <0.050 Specialist forensic needs 0.300.135.261 <0.050 Institutional behaviour 0.330.136.261 <0.050⁴

Discussion

External validity of the DUNDRUM-1 triage tool

The weaknesses of unsupported clinical risk assessment have been the subject of debate for more than 30 years, and a growing number of tools have been designed with the intent of maximising consistency and transparency; however, the application of violence risk assessment tools has been extensively criticised.³⁰ The DUNDRUM quartet²² has been designed specifically as a support tool for clinical judgements at important junctures in patient care (admission to hospital, increasing/decreasing therapeutic security and discharge). One potential weakness of the DUNDRUM quartet is that it was developed in a specific service context, and its practical relevance depends heavily upon its generality. Currently, the validity of this tool rests upon work conducted predominantly by its authors; very little is known about how well the contents of the DUNDRUM quartet generalise to decision-making in other services.

Overall, the findings of the current study support the predictive and external validity of the DUNDRUM-1 triage tool as a clinical decision aid for first-time referrals to secure psychiatric services. Total scores on the DUNDRUM-1 differed between all three of our groups of patients (open conditions, low secure and medium secure), and scores increased as levels of security allocation increased. The main measure of predictive validity was the AUC, and our findings, along with those of Freestone *et al.*,²³ indicate acceptable discriminative power for the DUNDRUM-1; total scores on the DUNDRUM-1 yielded AUC values between 0.75 and 0.8, with lower bounds for 95% CIs that were comfortably above chance. It is notable, however, that these AUC values were lower than that reported earlier (AUC = 0.984) when the DUNDRUM-1 was used to discriminate between court cases in which individuals were admitted or not admitted to psychiatric care.²⁵ By contrast, all of the individuals in the samples reported by Freestone *et al.*²³ and here were referred to services, presumably because their offending and/or clinical presentation caused sufficient concern to prompt forensic assessment. It is therefore unsurprising that our AUC values were lower than those reported earlier, because any sample referred to specialist services will have been relatively homogenous compared with a 'randomly' selected and clinically heterogeneous court sample. This finding shows that the predictive validity of the DUNDRUM-1 depends to some extent upon the context in which it is being applied, and its external validity may therefore be constrained.

The pattern of findings for the predictive validity of individual DUNDRUM-1 items was not simple. First, both the current study and Freestone *et al.*²³ found that self-harm and suicide risk were not related to decisions following referral for possible admission to secure conditions. This finding suggests that secure admissions in South Wales and East London were not influenced by the severity of the risk that individuals posed to themselves. It is plausible that differences in service configuration (e.g. the degree of integration between secure and general services) between the UK and Eire could explain the restricted external validity of these two items. Alternatively, this could reflect a difference in emphasis on public protection between services in the UK and in Eire. Further research would have to be conducted in order to determine the source of this important difference.

As well as the differences between the two UK samples and the original validation sample for the DUNDRUM-1, there were also a number of differences between the two UK samples that may indicate local constraints on the validity of some of the tool's items. There was agreement in AUC analysis between the South Wales and East London samples for

six of the 11 DUNDRUM-1 items (including non-significant results for suicide and self-harm). AUC results therefore differed for five items, including seriousness of violence, preventing access, public/victim sensitivity, complex risk of violence and institutional behaviour. Therefore, the influence of these factors on secure admissions decision-making differed between South Wales and East London.

Overall, the above interpretation of the external validity of the DUNDRUM-1 triage tool raises some difficult questions. Are generic clinical judgement tools viable for applications across contexts, where there appear to be so many differences in emphasis between services and in the predictive accuracy of the tool? Might locally defined clinical judgement tools provide an alternative approach that would be more contextually relevant, especially in light of increasing devolution of health service configuration and governance between regions of the UK?

Anchoring heuristics in clinical decision-making

The emphasis in the forensic literature has been on the possible contribution of heuristic decision-making to preventable fatalities; however, only a minority of such events are in fact predictable, even when heuristics could have been minimised by the application of risk assessment tools.³¹ The current work makes a novel contribution, because it focused instead on characterising the nature of heuristics applied by gatekeepers when patients were allocated to different levels of therapeutic security at the point of first referral to secure services.

The information for rating all of the items of the DUNDRUM-1 was readily available in all of the patient referral reports that were analysed in the current study. The gatekeeping clinicians were therefore clearly collating and reporting patient characteristics relevant to all 11 of this tool's items, even though the gatekeepers were not using the DUNDRUM-1 in their decision-making. The DUNDRUM triage tool, therefore, showed excellent face validity with respect to the information gathering practices in secure triage assessment. In the following, we consider whether all of this information actually informed clinical triage decisions to the same extent, or whether gatekeeping decisions instead reflected the operation of heuristic bias.

The second objective of the current study was to use regression analyses of individual DUNDRUM-1 items and gatekeeping decisions to examine the nature of heuristics in the decisions made by clinicians in South Wales. Our analyses revealed the presence of anchoring¹² that was biased in favour of a subset of DUNDRUM-1 items. Two of the 11 (legal process and immediacy of risk due to mental disorder) explained a disproportionately large fraction (between 86% and 98%) of the variance in patient placement. When these two potent predictors were removed from the model, three further variables (seriousness of violence, specialist forensic need and institutional behaviour) were shown to predict security level but explained a more modest proportion (between 14% and 28%) of variance in decision-making. Taken together, the two regression analyses suggest a two-tiered, hierarchical heuristic (see *Fig. 4*) that was primarily anchored by two items, legal process (which reflected the least restrictive option acceptable to all parties) and immediacy of risk due to mental disorder; the secondary tier included consideration of seriousness of violence, specialist forensic need and institutional behaviour. *Fig. 4* Legal process and immediacy of risk served as heuristic anchors that may have acted as a heuristic frame for secondary consideration of seriousness of violence, specialist forensic need and institutional behaviour.

Our heuristic analysis rested on the assumption that each of the items of the DUNDRUM-1 tool should influence decision-making to the same extent. This is a common assumption in the construction of risk assessment tools (PCLR; HCR-20), but it often does not reflect the subjective weighting given to these characteristics by clinicians during assessments. Further application of regression methods with the DUNDRUM-1 and other assessment tools could further elaborate the extent and nature of anchoring heuristics in many aspects of clinical decision-making regarding people with mental illness.

Limitations

Anchoring and framing heuristics are closely interrelated,¹¹ and it is plausible that consideration of two or more of the patient characteristics may have interacted: consideration of some items may have acted as frames for subsequently considered items. Unfortunately, the design of the current study did not allow more detailed exploration of such interactive cognitive processes; the contribution of framing heuristics here must remain unknown.

Examination of the referral reports yielded information on a great many factors that did not form part of the items included in the DUNDRUM-1. Gatekeepers were therefore routinely collecting and assessing information beyond the scope of the DUNDRUM-1. Our analysis depended on applying the DUNDRUM-1 as a best practice framework, and it could not capture the possible contribution of these other factors to triage assessment decisions. We conclude that the heuristic in triage decisions was anchored on only two factors. It is possible that selection of the DUNDRUM-1 as the best practice framework for the current analysis may have artificially constrained the resulting heuristic and clinicians may have been basing their decisions on a wider set of factors.

The current study does not inform about any relationships between triage decisions and either health or forensic outcomes. Individual progress monitoring and aggregated data on outcomes for patients placed in secure mental health care (cf. Centre for Mental Health, 2011) remains underdeveloped in the UK.

1.5.20 Against the stream: Antidepressants are not antidepressants – an alternative approach to drug action and implications for the use of antidepressants

2018-2

Abstract

Although antidepressants are regarded as effective and specific treatments, they are barely superior to placebo in randomised trials, and differences are unlikely to be clinically relevant. The conventional disease-centred understanding of drug action regards antidepressants as targeting an underlying brain process, but an alternative ‘drug-centred’ view suggests they are psychoactive substances that modify normal mental states and behaviour. These alterations, such as numbing of emotions, may reduce feelings of depression, and also create amplified placebo effects in randomised trials. Patients should be informed that there is no evidence that antidepressants work by correcting a chemical imbalance, that antidepressants have mind-altering effects, and that evidence suggests they produce no noticeable benefit compared with placebo.

Declaration of interest

The author is co-chairperson of the Critical Psychiatry Network.

 - *Antidepressant effects and the drug-centred model of drug action*
 - *Adverse effects*
 - *Conclusions*

Antidepressants are by far the most commonly prescribed class of drug for mental disorders, and their use continues to rise.¹ Huge marketing campaigns have persuaded the general public that depression is a ‘chemical imbalance’ that antidepressants can help reverse. Professional organisations claim that antidepressants are an effective and specific treatment for depression, and that they are considerably more effective than placebo. The Royal College of Psychiatrists’ current information leaflet suggests that 50–65% of people who are given an antidepressant will show ‘much improvement’ within 3 months, compared with only 25–30% on placebo.²

The evidence base

Overall, randomised controlled trials show that depression ratings decrease slightly more with antidepressants than placebo. Studies are inconsistent, however, and differences are small, especially when unpublished trials are included. Reviews of the literature on tricyclic and older antidepressants concluded that ‘in well-designed studies, the differences between antidepressants and placebo are not impressive’.³ Meta-analyses of trials of selective serotonin reuptake inhibitors (SSRIs) and other modern antidepressants that include unpublished trials have found mean differences between antidepressants and placebo ranging from 1.80 to 2.55 points on the widely used Hamilton Rating Scale for Depression.^{4–6}

The clinical significance of such small differences is doubtful. The Hamilton scale has a total score of 54 points. A recent analysis comparing scores on the Hamilton scale with scores on the observer-rated Clinical Global Impression (CGI) scale suggests that a difference of three points on the Hamilton scale is equivalent to a rating of ‘no difference’ on the CGI scale, while a difference of eight points is required to obtain CGI scale ratings of ‘mild improvement’.^{7,8} Antidepressant/placebo differences therefore appear to fall well below levels required to make a noticeable difference in someone’s condition.

Antidepressant effects and severity

It is often suggested that antidepressants are more effective, or perhaps only effective, in severe depression, and that this can explain their poor performance relative to placebo in trials with mixed populations. Some meta-analyses have found a gradient between the size of the antidepressant/placebo difference and the severity of initial depression across trials,^{5,9} although differences in people with the most severe depression still fall well below those equating to ‘mild improvement’ on the CGI. Other meta-analyses have not identified a severity gradient.^{10,11}

Older evidence suggests that antidepressants are not particularly helpful for inpatients with depression. A Medical Research Council trial, for example, found little difference between imipramine, phenelzine and placebo.¹² Trials of antidepressants for the treatment of depression in people with bipolar disorder have also found no differences between antidepressants and placebo.¹³

Antidepressant effects and the drug-centred model of drug action

The accepted view of drug action in psychiatry is that psychiatric drugs work by targeting a putative underlying brain abnormality. I have called this the ‘disease-centred’ model of drug action. An alternative explanation is the ‘drug-centred’ model, which suggests that psychiatric drugs influence symptoms of mental disorder and distress through their psychoactive effects. ‘Psychoactive’ drugs, sometimes referred to as ‘mind-altering drugs’, include recreational drugs, drugs prescribed for mental health problems and some other medical drugs (e.g. steroids, anticholinergics). They modify normal thoughts, emotions and behaviours in characteristic ways. According to the drug-centred model of drug action, for example, antipsychotics reduce the symptoms of psychosis through their ability to produce a state of mental slowing and emotional restriction, a state they produce in animals and humans, regardless of the presence of psychiatric or behavioural problems. Anxiolytics reduce symptoms of anxiety through their well-known sedative and relaxant effects, which occur independently of any psychiatric disorder.

Elsewhere, I have outlined the lack of evidence for the disease-centred view of drug action for any class of psychiatric medication.¹⁴ The serotonin and noradrenaline theories of depression, which appear to explain the action of antidepressants in a disease-centred manner, are not supported by evidence or expert opinion.¹⁵¹⁶ Moreover, numerous randomised trials have shown that drugs that are not considered as antidepressants, and have actions on other neurotransmitter systems, including benzodiazepines, opiates, stimulants and antipsychotics, are as effective as recognised antidepressants in people with depression.¹⁵

The drug-centred model suggests that the mental and physical alterations produced by antidepressants account for the differences between antidepressants and placebo in randomised trials. The psychoactive effects of individual antidepressants vary in strength and character, depending on chemical class and composition. Tricyclic drugs are strongly sedating and impair psychological test performance.¹⁷ SSRIs have weaker and more subtle effects, but can induce a state of emotional numbing or restriction, lethargy, reduced libido and sexual impairment. They also occasionally produce a state of agitation and tension, especially in young people.¹⁸ Antidepressant-induced emotional numbness may directly reduce the intensity of people’s feelings, but mental and physical alterations may also produce an amplified placebo effect, by revealing to people participating in randomised trials that they are taking an active drug. The fact that drug/placebo differences are so small, however, suggests that antidepressant-induced alterations are not clinically useful, whether they act through pharmacological or psychological means.

Adverse effects

By emphasising that psychiatric drugs change the normal state of the brain and body, the drug-centred model highlights the likelihood of adverse effects. Although modern antidepressants are usually well-tolerated, there is mounting evidence of less common but serious effects, including increased suicidal thoughts,¹⁹ fetal malformations,²⁰ bleeding, a prolonged and severe withdrawal syndrome,²¹ and persistent sexual dysfunction after discontinuation.²² The widespread use of antidepressants may also produce nocebo effects by undermining people’s sense of self-efficacy, potentially setting them up for a lifetime of chronicity and dependence on services.

Conclusions

The public have been led to believe that depression is caused by a chemical imbalance that antidepressants help to rectify; however, there is no current evidence that any sort of drug specifically targets an underlying biological abnormality, and whether there is an underlying brain state or states specific to the experience of depression has not been demonstrated. Amplified placebo effects and the subtle emotional alterations produced by antidepressants may account for the small differences between antidepressants and placebo found in some randomised controlled trials, but these small differences are unlikely to translate into a clinically meaningful effect. Doctors need to share this evidence with patients who are considering taking an antidepressant. Doctors should also help people to consider the pros and cons of using a mind-altering drug, such as an antidepressant, in relation to each individual’s particular situation. This should include discussion of alternative ways of achieving desired outcomes, using strategies that do not carry the inherent risks of drug treatment.

Although the discovery of a specific antidepressant agent in the future cannot be ruled out, it is possible that we misunderstand the nature of depression, and that regarding it as a discrete and universal disorder may have raised false hopes about the chance of a generally applicable ‘cure’ or treatment. The alternative view of depression as part of the spectrum of meaningful human responses to the world suggests that drugs will only dull the experience. In the end, the situation that provoked the negative emotion needs to be addressed. Depression is a signal that change is needed in some aspect of life.

1.5.21 Sharing quality and safety improvement work in the field of mental health

Amar Shah

date

2018-2

Contents

- *Sharing quality and safety improvement work in the field of mental health*

I welcome the findings of D’Lima, Crawford, Darzi and Archer¹ on the relative scarcity of publications related to mental health quality and safety improvement within reputable quality and safety journals.

I agree with the authors’ proposition that there is increasing interest in the application of improvement science within the mental health field. A large number of providers of mental health services in the UK and beyond are now starting to apply quality improvement methods at scale. The Royal College of Psychiatrists has established a quality improvement committee over the past year, and has recently appointed its first quality improvement lead. There is also an organically growing global mental health improvement network (#MHimprove), which meets twice a year and has begun to present and share knowledge at large international conferences.

As both the College quality improvement lead and the lead for quality at East London NHS Foundation Trust (ELFT), with perhaps one of the largest improvement programmes in the world within mental health services, my experience agrees with the conclusion of the authors that publishing mental health improvement work within reputable quality and safety journals is a struggle. Our efforts to share real-world improvement work have largely been unsuccessful in the high-quality journals within this field. My theory, both as a submitting author and a reader of these journals, is that the journals are still focusing more on the research and evaluation end of the spectrum, as opposed to real-world, messy improvement work in mental health services.

As an example, the use of Shewhart (control) charts to demonstrate improvement over time, which is seen as best practice by improvers across the globe, is still frowned upon by journals (both subject-matter specialist journals and quality and safety journals), who prefer enumerative statistics in the form of pre- and post-comparison of averages. This jars with the real world of applied science, where there is no pre- and post-state, but a gradual and iterative transition, fuelled by multiple tests of change with increasing degree of belief and reliability in the change package.

Despite these challenges, ELFT has published approximately 15 peer-reviewed articles over the past 4 years and has 3–4 articles continuously in the process of submission. All published papers are made available transparently to everyone through the ELFT quality improvement website (<https://qi.elft.nhs.uk>), which has now had over half a million hits in the past 3.5 years. Going even further, ELFT aims to share learning from all completed projects on its website, in acknowledgement of the fact that practising improvers and clinicians will always struggle to find time to publish all completed improvement work in peer-reviewed journals.

This brings me to the question: are journals still relevant in a world of fast-paced knowledge-sharing and acquisition, and with increasingly digital and connected networks? More than 500 leaders and clinicians from more than 50 different provider organisations have now been to visit ELFT to find out more first-hand about the quality improvement work taking place. At ELFT, we are also using the web and social media to share knowledge in real time and transparently with everyone, as we recognise our responsibility in helping to grow the field of knowledge within mental health improvement, and also to foster confidence in the use of quality improvement.

So, while my personal experience leads me to agree with the authors that publishing mental health improvement in journals remains challenging and often puts people off from even submitting, I would also suggest that there is much more active improvement work taking place and being shared by mental health services globally than might be apparent from looking at high-quality peer-reviewed journals alone.

1.5.22 A lost cause

Anuradha Menon

date

2018-2

Contents

- *A lost cause*

On reading Dr Moorey’s earnest response to Dr Gipps’ views, I was struck by his description of the ‘depressive mode’.¹ This marvel of development, 100 years on from Freud’s classic paper,² is – in Dr Moorey’s view – a ‘complex neural network, including multiple relevant brain regions that are activated or deactivated during depression’. This, he argues, is the target of therapeutic practice in cognitive–behavioural therapy (CBT), where unconscious schemas are automatic, not repressed. It seems to the reader that in this dehumanised framework, grief and loss are merely ‘problems’ that face humankind, which need to be put on the CBT table to be sorted out openly between therapist and patient. The tools? Good old-fashioned common sense, an indefatigably optimistic therapist and well-positioned intelligence. As for the measures: specially designed scales that measure the very structure which they helped create.

I am writing this piece to explore how both Dr Moorey and Dr Gipps warily circle around a point which is never highlighted in its own right.

Freud’s theory of melancholia² posits an unconscious basis for the depressed patient’s dilemma. This theory holds true: the proof is in the analytic setting, and all contemporary psychoanalytic approaches which describe the transference find their roots in this classic paper.³ Freud writes about an identification of the ego with the abandoned object, saying

‘thus the shadow of the object fell upon the ego’. This is still pre-object relations. American psychoanalysis, which was evolving at the time, is well known to have been profoundly influenced by Freud.

In the 1950s, psychoanalysts around the world were working on extending early theories, and the Americans actively participated in this worldwide development. So, with respect, Dr Moorey’s point about Beck’s ‘perfectly acceptable masochism hypothesis’ is a bit like Lamarck chasing after amputated tails while Darwin was thinking about evolution!

The crux of the matter is that Beck moved into what is essentially the conscious realm when he developed his theory. Today, anyone who manages patients with depression will know that the latter is the easier and, dare we say, cheaper option. It’s all backed up by robust evidence, and supported by what is essentially an Orwellian⁴ environment. I hardly need wonder why patients are rarely asked what they prefer: an analyst who is interested in undiscovered aspects of their loss and is willing to explore themselves in the process, or one bent on pinning down the patient’s experience in prosaic terms.

This is why I take exception to the statement in Dr Moorey’s final paragraph, which is unreferenced and states that CBT ‘has given psychoanalysts methodologies they now use to evaluate their own theories’. This is outrageous, as no self-respecting psychoanalyst would turn to a two-dimensional construct to tell them whether they are tuned into their patient’s inner world. I think this is another example of the kind of empiricism that undermines a patient’s personal struggle with loss, ignores the depth in a poorly understood psychoanalytic theory and exposes a flawed theoretical argument. Why would psychoanalysis have any real use for a methodology that doesn’t even address its basic theoretical stance? Dr Moorey’s thesis is, unfortunately, a lost cause. So, to quote from the excellent choice of title for this debate:

‘I give you the mausoleum of all hope and desire [...] I give it to you not that you may remember time, but that you might forget it now and then for a moment and not spend all of your breath trying to conquer it. Because no battle is ever won he said. They are not even fought. The field only reveals to man his own folly and despair, and victory is an illusion of philosophers and fools’. (William Faulkner, *The Sound and the Fury*⁵)

1.5.23 Completed audit cycle to explore the use of the STOPP/START toolkit to optimise medication in psychiatric in-patients with dementia

Victor M. Aziz Natalie Hill Sugandha Kumar

Correspondence

Dr V. M. Aziz

(victoraziz@doctors.org.uk)

date

2018-2

Abstract

Aims and method

To explore the use of the STOPP/START toolkit in older psychiatric in-patients with dementia. Clinical records and current drug charts were reviewed against STOPP/START criteria for all in-patients ($n = 86$) on six specialist dementia wards.

Results

Benzodiazepines, antipsychotics and opiates were most commonly prescribed inappropriately. The most common unprescribed medication groups were statins, calcium supplements and vitamin D supplements. There was an overall reduction of 7% in comorbidities and 8% in the number of prescriptions. t -test showed a significant drop in average comorbidities between both audits, $t(1) = 23.920$, $P = 0.027$, and in average prescriptions per patient, $t(1) = 28.808$, $P = 0.022$. There was no difference in the number of patients receiving polypharmacy, $t(1) = 7.500$, $P = 0.084$, or receiving medication with a high risk of adverse drug reactions, $t(1) = 6.857$, $P = 0.092$.

Clinical implications

The STOPP/START toolkit highlighted the importance of collaborative working between doctors, clinical pharmacists and nursing staff, and could provide old age psychiatrists with a structured tool to identify inappropriate prescribing of non-psychiatric medications.

Declaration of interests

None.

Contents

- *Completed audit cycle to explore the use of the STOPP/START toolkit to optimise medication in psychiatric in-patients with dementia*
 - *Methodology*
 - * *Agreed action plan following the first audit*
 - *Results*
 - *Discussion*
 - *Conclusion*

There are 10 million people in the UK over the age of 65. The latest projections suggest there will be an additional 5.5 million older people by 2036, and that the current number will have nearly doubled to around 19 million by 2050. Older people have a high prevalence of chronic and multiple illnesses and are likely to be prescribed multiple medications. Potentially inappropriate prescribing (PIP) is reported to be highly prevalent in this age group, and has been associated with adverse drug events (ADEs) leading to admission to hospital and death.¹ Inappropriate prescribing occurs when the risks associated with prescribing a medication outweigh the potential benefits of the medication in a particular patient. PIP may also occur when a patient does not receive a medication indicated for the treatment or prevention of a disease or condition.² Pharmacokinetics and pharmacodynamics may be altered by ageing or disease. This puts older people at a high risk of adverse drug reactions (ADRs), ADEs and drug–drug interactions.

Some of the drugs that are considered a high risk with respect to hospital admissions include: non-steroidal anti-inflammatory drugs (NSAIDs, including aspirin), diuretics, warfarin, angiotensin-converting enzyme inhibitors

(ACEIs)/angiotensin-II receptor antagonists (A2RAs), antidepressants, lithium, beta-blockers, opiates, digoxin, prednisolone and clopidogrel.³

The National Service Framework (NSF) for older people recommends that an older patient should have medication reviews to reduce medicine-related problems. Studies in general practices and care homes have demonstrated that pharmacists undertaking medication reviews can improve the quality of care, optimise the use of medicines and produce cost-effective savings.^{4,5}

The aim of the audit was to review all prescribed medication in psychiatric in-patients over the age of 65 with a diagnosis of dementia in the Cwm Taf University Health Board (UHB) area covering a population of 300,000, to determine the degree of inappropriate prescribing and to optimise medication.

Methodology

Cwm Taf UHB is responsible for providing healthcare services (hospital- and community-based services) to the population of Merthyr Tydfil and Rhondda Cynon Taf, estimated to be around 289 400 people. The Health Board is divided geographically into four sectors.

The audit included all mental health patients with a diagnosis of dementia who were in-patients on 1 December 2015. All psychiatric assessment wards (for those over the age of 65) and specialist dementia wards in Cwm Taf UHB were audited. We identified 47 patients in December 2015 and 39 patients in the re-audit in May 2016. A thorough past medical history and current medication history were established for each patient using the clinical records. All diagnoses were made using internationally agreed standard criteria, such as the National Institute of Neurological and Communicative Disorders and Stroke and the Alzheimer's Disease and Related Disorders Association criteria, by the consultant psychiatrist and their teams in either the community or in-patient settings. The dementia ranged from moderate to severe for all specialist dementia wards. For the purpose of this audit, polypharmacy was defined as more than five medications. The audit used the second version of the toolkit;⁶ the tool itself takes about 30 min to complete.

Some tools have been developed to identify older people at risk from adverse effects and to reduce the risk of initiating drugs likely to cause adverse events. These include the screening tool of older persons' potentially inappropriate prescriptions (STOPP) and the screening tool to alert doctors to the right treatment (START). The toolkit was not designed for mental health patients. However, the STOPP-START tool has been validated in patients aged 65 and over by a consensus panel of 18 experts in geriatric pharmacotherapy in Ireland and the UK.^{7,8,9} The panel included experts in geriatric medicine, clinical pharmacology, old age psychiatry, clinical pharmacy and primary care medicine. Interrater reliability of the STOPP ($K = 0.75$) and START ($K = 0.68$) criteria was tested in six different European countries.⁸ A further study¹⁰ found higher interrater reliability of STOPP ($K = 0.97$) and START ($K = 0.92$).

All prescribed medication was checked against the STOPP/START criteria. In the STOPP/START tool, STOPP comprises 65 clinically significant criteria for PIP in older people. Each criterion is accompanied by a concise explanation as to why the prescribing practice is potentially inappropriate. It emphasises potential adverse drug-drug interactions and duplicate drug class prescriptions. An example is the advice to stop NSAIDs in patients with a history of peptic ulcer disease or gastrointestinal bleeding because of the risk of peptic ulcer relapse. In addition, NSAIDs should be stopped with moderate to severe hypertension (moderate: 160/100–179/109 mmHg; severe: 180/110 mmHg) because of the risk of exacerbation of hypertension.

START consists of 22 evidence-based criteria and identifies potential prescribing omissions (PPOs), e.g. start levodopa in idiopathic Parkinson's disease with definite functional impairment and resultant disability.

A *t*-test was conducted to compare the means between the initial audit and the re-audit. Following the initial data analysis, the audit was presented to all involved teams and action plans were introduced.

Agreed action plan following the first audit

It was agreed that all teams would regularly review the medication charts along with the clinical pharmacist to optimise prescribing. Small pocket-sized smartcards/leaflets showing the drugs commonly meeting the STOPP/START criteria were also produced. Smartcards were placed alongside all medication charts on the wards. Training regarding the use of the STOPP/START toolkit was also incorporated into team inductions for junior doctors and nursing staff. A re-audit was completed on 1 May 2016 to determine the impact of these changes.

Results

Table 1 shows a summary of the demographics across both audit cycles. There was no significant difference in age between the two audits. According to the Mann–Whitney U test, the distribution of the female gender was the same across both audits, $P = 1.000$. There was no significant difference in the proportion of patients on specialist dementia wards in the two audits. There was no reduction of medications prescribed in the community for patients on the acute wards before those patients came into hospital. Table 1

Demographic	First audit	Re-audit
Number of patients	584	47
Age, years (mean \pm s.d.)	78.33 \pm 2.74	78.72 \pm 3.11
Female gender (%)	31 (53.5)	29 (63)

2 Average comorbidities per patient (mean \pm s.d.) 6.23 \pm 1.52 5.73 \pm 1.02 $t(1) = 23.920$, $P = 0.027$ 95% CI = 2.803–9.157

Average number of prescriptions per patient (mean \pm s.d.) 10.88 \pm 1.27 10.15 \pm 0.58 $t(1) = 28.808$, $P = 0.022$ 95% CI = 5.877–15.153

Number of patients receiving polypharmacy (%) 51 (88) 39 (85) $t(1) = 7.500$, $P = 0.084$ 95% CI = 31.237–121.237

Number of patients receiving medication with high risk of adverse drug reactions (%) 55 (95) 41 (89) $t(1) = 6.857$, $P = 0.092$ 95% CI = 40.943–136.943

Number of patients on specialist dementia wards (%) 48 (83) 39 (83) $t(1) = 9.667$, $P = 0.066$ 95% CI = 13.678–100.678

There was an overall 7% reduction in the number of comorbidities and an 8% reduction in the number of prescriptions. The t -test showed a significant drop in the average number of comorbidities between the two audits, $t(1) = 23.920$, $P = 0.027$, and a drop in the average number of prescriptions per patient, $t(1) = 28.808$, $P = 0.022$. The overall improvement in prescribing contributed to a 19% reduction in bed occupancy for specialist dementia beds.

However, there was no difference in the number of patients receiving polypharmacy, $t(1) = 7.500$, $P = 0.084$, or the

number of patients receiving medication with a high risk of ADRs, $t(1) = 6.857$, $P = 0.092$. There was also no significant difference in the number of patients in specialist dementia wards, $t(1) = 9.667$, $P = 0.066$.

Fig. 1 represents the STOPP part of the toolkit, while *Fig. 2* represents the START component. *Fig. 1* Inappropriate drugs prescribed according to STOPP. *Fig. 2* Drugs that should have been prescribed according to START.

According to the STOPP toolkit, 164 drugs were prescribed; of those, 118 (72%) drugs were prescribed for longer than a year. Forty-one (25%) drugs were considered to have been inappropriately prescribed and could be stopped according to STOPP (*Fig. 1*). The four main types of inappropriateness were long-term use, lack of clear indication, symptoms no longer present, and lack of clear documentation. The most common drugs inappropriately prescribed were benzodiazepines, antipsychotics and opiates.

According to the START toolkit, 145 drugs were prescribed; of those, 129 (89%) drugs were prescribed for longer than a year. Twenty-six drugs should have been prescribed according to the toolkit but were not (*Fig. 2*).

Discussion

When reviewing all geographical sectors, an improvement in the prescribing pattern was found between the audits. All teams were more conscious of inappropriate prescribing in older people. In some of the cases, we had little information on who prescribed the medications, why they were prescribed and when they were reviewed. Nevertheless, it is important to remember that the STOPP/START criteria were designed to highlight inappropriate prescriptions and prevent ADEs, especially those involving medications with a high risk of ADRs.

The audit showed an observed overall 24% reduction in polypharmacy and a 25% reduction in prescribing of medications with a high risk of ADRs. However, the difference between the audits was not statistically significant. The non-significance may be related to the reduction in number of patients from 58 to 47, or the reduction in drugs per patient may have been due to them having fewer illnesses.

According to the STOPP Toolkit, 164 drugs were prescribed in the 2016 audit. *This was a 25% reduction in prescribing since the first audit.* Seventy-five central nervous system (CNS) drugs were prescribed according to STOPP, a 40% reduction in prescribing since the first audit. According to the START toolkit, 145 drugs were prescribed at the time of the re-audit. *This was an 8% reduction in prescribing since the first audit.* There was no change in the total number of CNS drugs prescribed, according to the START toolkit. However, *there was less antidepressant prescribing across all sectors.* These results are also a proxy measure for improving care by optimising medicines in the elderly, i.e. reduced exposure to polypharmacy improves care and quality of life.

According to the toolkit, our CNS drugs will be mainly inappropriately prescribed because of long-term use (longer than a month). However, the nature of mental disorder and its associated behavioural and psychological symptoms will mean that it is appropriate for our patient groups to be on longer-term medication. The multiple comorbidities will also add to the complexity of those patients and their management.

Another important observation is that adequate documentation is very much needed to clarify the target symptoms and the rationale for prescribing. It is important for all the teams to review medications and their appropriateness as part of the weekly ward round and monthly clinical pharmacist input. It is important to continue to raise awareness of the STOPP/START tool and to encourage its use by doctors and pharmacists, in order to promote safe prescribing among older patients.

Prescribers should not feel overwhelmed when reviewing multiple medications prescribed for older people. The STOPP/START tool has been proven to be a useful framework.

The audit has provided the foundations of a good multidisciplinary relationship between medical, nursing and pharmacy staff, which has not only benefited the in-patients but also demonstrated how a multidisciplinary team can stop inappropriate prescribing in older patients. It is clear that we can improve the care and safety of such patients by optimising their medicines. This will also have a secondary economic impact by producing an annual cost saving. The additional cost benefits in preventing adverse effects and associated medical treatment should be included in any basic financial evaluation. These additional benefits are likely to be substantial in economic and human terms. The benefits of the medical and pharmaceutical perspectives working together as a team were both additive and synergistic.

The audit also highlighted the need to facilitate greater collaboration with a clinical pharmacist and the older person's physician/general practitioner to provide better care for older psychiatric patients. As the toolkit looked at the prescribing pattern, it does not include the patients' views or their families' opinion about drugs. However, shared decision-making should be always a priority for clinical teams. As the audit reflects a cross-section of old age psychiatry, we believe that the results are generalisable. It will be useful in the future for a well-designed research study to be conducted in old age psychiatry covering multiple areas or larger community and in-patient settings to test that assumption.

The small pocket-sized smartcards/leaflets showing the drugs commonly meeting the STOPP/START criteria proved useful on all wards. Introducing the toolkit at junior doctor induction has also been beneficial.

Conclusion

Inappropriate prescribing occurs when the risks associated with prescribing a medication outweigh the potential benefits of the medication in a particular patient. PIP may also occur when a patient does not receive a medication indicated for the treatment or prevention of a disease or condition. The STOPP/START criteria have been used to review the medication profiles in various settings worldwide. STOPP/START criteria are validated, reliable systems-based criteria for PIP. The STOPP criteria significantly predict ADEs, and the application of the STOPP/START toolkit improves medication appropriateness and probably reduces/prevents adverse events. The STOPP/START criteria are *not* the complete answer to preventing medication errors, but they help to optimise pharmacotherapy at the point of initiation and at routine medication review. The use of the STOPP/START toolkit can also have a positive impact by reducing prescribing errors. Sustaining these changes will require continued efforts to maintain prescriber awareness of the STOPP/START toolkit.

Abstract

Aims and method

Psychiatric disorders are common in neurological in-patients, but they are under-recognised and undertreated. We investigated the frequency of detection of mental disorder and referral to psychiatric services in a regional neuroscience centre. The results were compared with the expected prevalence. All in-patient referrals received in 2014 from the in-patient wards of the regional neuroscience centre and acute neurological unit were reviewed.

Results

A total of 129 ward referrals were identified; of these, 78 were from the regional in-patient neurological unit, which comprised 11.4% of the total of 679 admissions to that unit.

Clinical implications

A spectrum of neuropsychiatric conditions were recognised by neurologists, but overall rates of recognition were low. To address the problem of under-recognition, routine screening with validated assessment tools can represent a cost-effective and acceptable method to detect psychiatric disorders in an in-patient neurological setting.

 - *Discussion*

Liaison neuropsychiatry is an important element of psychiatric care in neurological in-patients, given the severity and complexity of the cases involved.¹ Yet there is a dearth of information about consultation rates, presentation, diagnoses, and interventions that would improve access to services, facilitate evidence-based practice, and articulate the relationship between neurological and psychiatric disorders.²⁻⁴

Previous estimates of psychiatric comorbidity in neurological settings have revealed high prevalence rates. For example, the overall rate of psychiatric disorder in neurological out-patient clinics has been reported as 55.1%,⁵ the most frequent diagnoses being somatoform disorders, which represented 33.8% of the sample. Similarly, the prevalence in an acute in-patient neurological unit was 51.3%.⁶ It appears, therefore, that psychiatric comorbidity is high in neurological settings. This is to be expected, given the elevated rates of psychiatric comorbidity in neurological disorders. Patients with cerebrovascular and Parkinson's disease have prevalence of depression that ranges between 20 and 40%.⁷⁻⁸ Functional neurological symptoms are also common in neuroscience settings; it has been reported that 14% of consecutive neurological admissions had no so-called 'organic' bases for their symptoms, while another 24% had symptoms not fully accounted for by the underlying pathology.⁹

Neuropsychiatric conditions in neurological in-patients, if undetected or not adequately managed, are associated with poor quality of life, greater morbidity, mortality and poor psychosocial outcomes.¹⁰ Moreover, there are specific neuropsychiatric presentations associated with common neurological conditions that pose diagnostic, nosological and management challenges, which require the unique clinical skills of neuropsychiatrists. These conditions may include

schizophrenia-like psychosis of epilepsy, forced normalisation,¹¹ organic personality changes or organic mood disorders,¹² to name a few. This highlights the need for the development and implementation of structured care pathways for the neuropsychiatric comorbidities associated with neurological conditions.¹³

Despite these high rates of psychiatric comorbidity, surveys investigating referrals from neurology wards to neuropsychiatric liaison services have demonstrated unexpectedly low rates of referral. Fitzgerald *et al* and Jonge *et al* found that only 6% and 2.4% of neurology in-patients, respectively, were referred to liaison neuropsychiatry.^{14,15} The present study sought to investigate the rates of referral to an established neuropsychiatry service in a tertiary neurosciences centre, in order to better understand referral patterns and rates of recognition of mental disorder in neurological in-patients.

Method

This study was conducted at the Atkinson Morley Regional Neurosciences Centre at St George's Hospital, London, covering a population of 3 million residents of South West London and Surrey. All referrals made to the neuropsychiatry service at St George's Hospital over a 12-month period in 2014 were included.

We reviewed the referral forms and electronic patient records to extract information on demographics, reasons for referral, diagnoses, treatment plan, and number of contacts made. We identified the reasons for referral from the free text provided by the referrers. This requested information gives specific details about reasons for referral, presenting symptomology, referrers' suspected diagnoses, previous psychiatric history and interventions, and management difficulties. Reasons for referral were grouped into categories, and more than one reason for each patient was allowed. The patient electronic records system used to record every contact with patients was also searched to retrieve the primary ICD-10 diagnoses for each patient. These results were then compared against those available in the published literature on neuropsychiatry and adult liaison psychiatry services referral patterns.

Those referred to the neuropsychiatry service from the acute neurology ward were compared against admission data for that ward to establish rates of referral. This was then contrasted with results from previous studies of this ward investigating the prevalence and rate of detection of mental disorder by neurologists. All clinicians involved in this study work within the clinical team and had access to patients' records as part of their role. Anonymised data were analysed and compared with previously published data.

Results

A total of 129 referrals were identified in the year 2014. They were evenly dispersed across age groups, with a small peak in the age group 50–59. The female:male ratio for referral was 1.35:1 ($P = 0.09$). Almost 50% of the sample had a past psychiatric history. In terms of face-to-face contacts made, 32% received initial assessment only, 27% were seen twice, 15% were seen three times, and 10% were seen four times. The remaining 16% had four or more face-to-face contacts. The cumulative sum of all face-to-face contacts (first assessment and follow-up) was 311. Usually, the first assessments lasted 45–75 minutes and 90% were seen within 2 working days of the date of referral. The highest rates of referral were during the months March, June, October and December.

Sixty per cent of referrals came from the regional in-patient neurology ward, 15% from neurosurgical wards, 9% from the stroke units, and 4% from the neuro-intensive care unit (NICU). The remainder were referred from other wards. Only 7% were made as urgent referrals. It was documented on 75% of forms that the referrer had discussed referral with the patient.

The most frequent cited reasons for referral were depression (50%), functional neurological symptoms or functional overlay (27%), anxiety (22%), cognitive decline or confusion (17%), agitation/aggression (13%), suicidal ideation or behaviour (12%), and psychotic symptoms (12%). Often, more than one reason for referral was provided; hence, the percentages do not total 100%. As a reason for referral, 'agitation' was associated most with organic disorders, 'suicidal' with adjustment disorder and organic mood disorder, and 'depression' with mood disorders, adjustment disorder and 'no diagnosis'. Functional symptoms/overlay were invariably associated with a psychiatric diagnosis of dissociative/conversion disorders. Almost all (91%) of the referred patients met the criteria for a psychiatric disorder according to ICD-10. The most common primary psychiatric diagnoses were: mood disorder (22%); dissociative

disorder (18%); adjustment disorder (9%); delirium (5%); organic disorders (24%), including organic mood disorder (8.5%); and organic personality disorder (5%). In 9% of those referred, no mental disorder was established (*Fig. 1*). *Fig. 1* Distribution of patients per diagnostic categories.

Seventy-eight of the referrals were sent from the regional in-patient neurological unit, comprising 11% of the total of 679 admissions to that unit. The age of referred patients was distributed evenly across the decades of life, with a small peak in the 20–29 age group. The female:male ratio was 1.4:1. Initial assessment only was completed for 31%, while 27% were seen twice, 14% three times, and the remainder four times or more. Urgent referrals constituted 10% of all referrals from this ward, and 83% of referral forms had documented a discussion with the patient. Collectively, depression, anxiety and adjustment disorders represented the most frequent diagnoses (32%), followed by ‘organic’ disorders (31%) and then somatoform disorders (21%). Most of those referred (81%) had a past history of psychiatric disorder. The majority of those patients diagnosed with dissociative disorders (70%) attended out-patient follow-up with our service following discharge.

Discussion

This is a retrospective study of referrals from a regional neurology unit, which can come with its own limitations. Such a unit would generally have more complex neurological in-patients with a higher rate of neuropsychiatric comorbidity. However, the results of the present study and previously published papers are broadly comparable, suggesting no specific biases associated with our study population. The total number of referrals was small, despite the expected prevalence of psychiatric illnesses in neurological settings. This is in keeping with the low rates of identification of psychiatric comorbidity found in earlier prevalence studies. It may also suggest that neurology colleagues have a high threshold for referral to the psychiatric services. However, this implies that patients suspected to have psychiatric disorder were not referred to specialist services.

Our results show that patients referred to the team presented with a wide range of neuropsychiatric disorders (*Fig. 1*). The rates of mental disorder in our sample did not match those in community¹⁶ or general hospital¹⁷ settings, demonstrating the distinctive nature of neuropsychiatric samples. The most common categories in our population were mood disorders, organic disorders and dissociative disorders, while the most common reasons for referrals were ‘depression’ and ‘functional neurological symptoms’. Rates of disorder in our sample were close to those reported in previous studies,^{14, 15} with a few differences.¹⁷ One difference is that depressive disorder accounted for 40% of referrals reported by Guthrie *et al* to their general liaison service that serves a large teaching hospital, but only 20% of our referrals received this diagnosis. Nevertheless, as for Guthrie *et al*, ‘depression’ was the leading reason for referral to our service and the most common diagnosis in our sample. Schizophrenia and bipolar disorders constituted a small portion of our workload, while they comprised one-third for Guthrie *et al*. Other significant differences were found in the rates of somatoform disorders (18.6 v. 2.6), organic disorders (24 v. 1.7), substance use disorders (4.8 v. 1.55) and personality disorders (0.7 v. 3.8), as shown in *Table 1*. Not unexpectedly, perhaps, our neuropsychiatry team was referred a higher proportion of organic disorders compared with the general hospital liaison service of Guthrie *et al*. It might be that neurologists perceive neuropsychiatrists as more willing and/or able to manage patients with organic psychiatric disorders than a liaison psychiatric service, such as that of Fitzgerald *et al*. Alternatively, because the Atkinson Morley Centre is a tertiary unit which admits complex neurological cases, there may be a higher percentage of organic psychiatric disorder in the population we serve. Another difference was the higher rate of dissociative disorders compared with liaison psychiatry teams, which again likely reflects that a tertiary neurology centre admits the most complex functional cases for thorough investigation and intervention – especially as there is a dearth of neuropsychiatry services outside the London area. The unexpectedly low rate of substances misuse and personality disorders identified in our sample could reflect a reluctance to discuss these issues or an oddity of our population. Either way, this finding merits further evaluation. These variations will differentially influence the clinical expertise and practice of neuropsychiatrists and their colleagues in liaison psychiatry. *Table 1* Comparison of psychiatric diagnoses as a proportion of total number of referrals (%)

Regarding the acute in-patient neurological unit, our results demonstrated a referral rate of only 11.16%, although previous studies on the same ward have demonstrated substantially higher prevalence rates. Utilising a battery of screening questionnaires followed by psychiatric interview Jeffries *et al*⁶ identified a DSM-IV-defined mental disorder in 51.3% of 265 consecutive admissions during a period of 6 months. Of these, 18.7% fulfilled the criteria for two diagnoses, and 5.1% were diagnosed with three or more. Earls *et al*¹⁸ investigated rates of detection of psychiatric symptoms by neurologists on this same ward 3 months pre and post Jeffries *et al*'s screening period. This showed that neurologists recognised and documented symptoms of mental illnesses in 23.7% of all admissions, but referred fewer than half of these (10.4%), echoing our more recent findings (11.6%). Taken together, this demonstrates that 70–80% of neurological patients with a comorbid psychiatric disorder are not being referred to specialist services. Given the known impact of neuropsychiatric comorbidity on quality of life, duration of hospital stay, mortality, and cost of care, this may have a deleterious effect on those unable to access timely and effective psychiatric intervention.¹⁹ Of those who were referred, analysis of the reason(s) for referral indicated strong correlation with the eventual confirmed diagnosis. The small number of patients who did not receive any diagnosis points to a low rate of false positives. Thus, it appears that neurology referrers were specific but not sensitive to identification of cases. *Table 2* suggests that few patients with anxiety, adjustment disorders, personality disorders, and substance misuse disorders were referred, while referral was made for only a minority of those with depression and cognitive disorders. Appropriately, all those with psychotic disorders were referred, as were half the patients with somatoform disorders. Regarding patients with cognitive impairment, it may be that neurologists consider themselves capable of managing this patient group, as agitation was given as the main reason for the referral in all cases involving that problem. *Table 2* Comparison of psychiatric diagnoses/symptoms as a proportion of total admissions in the specific neurological in-patient unit (%)

Diagnostic categories	Jeffries <i>et al</i> , 2007	Earl <i>et al</i> , 2011	Dawood <i>et al</i> , 2016
Prevalence of psychiatric diagnoses DSM-IV	51.3	23.7	11.6

Eating disorders	0.50	Other organic disorders	1.1
No diagnosis	0.58	Total ^a	51.123.711.16 ¹

It is unclear how this under-referral affects the well-being of patients and the efficiency of neurological departments. Similarly, Jonge *et al* found that neurologists throughout Europe refer only a small proportion of the psychiatric patients on their wards. Possibly, their recognition of mental disorder is poor, or these comorbidities are considered irrelevant to their neurological care. Jonge suggested a referral procedure consisting of a short questionnaire to facilitate detection of caseness.¹⁵ Likewise, Jeffries *et al* concluded that psychiatric screening questionnaires have a high sensitivity and specificity, thereby representing a cost-effective and acceptable method for improving identification of psychiatric morbidity and comorbidity.⁶ The intervening years have not lessened the arguments for this approach. There is now a pressing need for strategic planning to develop neuropsychiatric provision, both nationally and internationally.^{20–22} Provision of prospective screening on neurological units and the impact of neuropsychiatric input would require prospective evaluation to evaluate their utility and efficacy.

1

a. Percentages add up to more than total because some cases had two or more comorbid psychiatric diagnoses.

2018-2

Abstract

Aims and method

To assess the benefits of the introduction of routine vitamin D serum sampling for all patients admitted to a secure in-patient hospital in the North of England providing medium security, low security and rehabilitation services for offenders with intellectual and developmental disability. The vitamin D levels of 100 patients were analysed at baseline. Those with insufficient or deficient levels were offered treatment and retested after 1 year. Vitamin D levels were analysed in the context of level of security, seasonality of test and co-prescription of psychotropic medications.

Results

Eighty-three per cent of patients had suboptimal vitamin D levels at initial test (41% deficient and 42% insufficient). This was seen among established patients and new admissions. Regression analysis of baseline vitamin D levels revealed no differences for levels of security, seasonality, whether patients were taking antipsychotic or anticonvulsant medication, or length of stay. Patients with deficiency or insufficiency were all offered supplementation. Those who opted in had significantly higher vitamin D levels at follow-up, compared with those who declined treatment.

Clinical implications

Established and newly admitted patients in our secure mental health services had substantial levels of vitamin D insufficiency. In the light of the morbidities that are associated with deficient vitamin D levels, routine screening and the offer of supplementation is advisable.

Declaration of interest

None.

Background

Suboptimal levels of plasma 25-hydroxy vitamin D (25OHD) have been implicated in a number of morbidities, including musculoskeletal and cardiorespiratory diseases, diabetes and depression.^{1,2} A substantial proportion of vitamin D is obtained from ultraviolet-B light acting on the skin¹, although the relative amounts obtained from solar and food sources vary from study to study.³ There is, therefore, a greater potential for impaired vitamin D levels during the autumn and winter months.⁴ Public Health England currently advise a minimum of 10 µg of vitamin D per day for the general population, but give no separate advice for those at risk of minimal sunlight exposure, such as institutionalised individuals.⁵

It is estimated that approximately 50% of the population of Northern England have insufficient or deficient vitamin D levels.⁶ Based on National Health Service guidelines, in January 2013, a decision was made by the clinicians at Northgate Hospital, Northumberland, UK, to routinely screen for vitamin D deficiency and treat as necessary.⁷ Northgate Hospital has a range of levels of secure care facilities for people with intellectual and developmental disabilities (IDD) who offend, as well as providing specialised services for people with severe autism spectrum disorders.

This paper describes an evaluation of the results of screening for 25OHD at Northgate Hospital. It was hypothesised that patients in secure services would have suboptimal levels of 25OHD due to less exposure to sunlight, and as a possible consequence of medications prescribed for mental disorders. We were also interested in the effect of season of testing, and whether the decision to routinely screen for and treat 25OHD deficiency would lead to improvement in any such deficiencies.

Aims

1 To describe vitamin D levels in an ‘at risk’ population of offenders with IDD in secure care, across a range of levels of security; 2 To assess the effectiveness of screening for and treating any vitamin D deficiencies.

Method

Cohort 1

Between January 2013 and February 2014, all patients at Northgate Hospital were screened for vitamin D deficiency. These existing patients, who were having blood tests taken as part of their annual health checks over the year, had a serum vitamin D level added to the standard biochemistry request form with no additional venepuncture over and above routine testing.

Cohort 2

While existing patients were having their vitamin D levels checked as part of annual health checks, new admissions to the secure services were also being screened. Because we judged that there may be differences between the established patient group and new admissions (higher levels of sun exposure, dietary intake differences), new admissions from January 2013 onwards were considered as a separate cohort for the purpose of assessing baseline vitamin D levels.

Data were collected for the first 100 patients screened, from both cohorts. The results were classified according to standard biochemical reference ranges for total 25OHD (the sum of 25OHD₂ and 25OHD₃): •deficient (<25 nmol/L) •insufficient (25–49 nmol/L) •sufficient (50–75 nmol/L) •optimal (>75 nmol/L) vitamin D levels. Each result was stored with anonymised data about the patient’s age, length of stay prior to the initial test, co-prescribed psychotropic medications, level of in-patient security and the season the test was performed.

Following the initial test, all patients were offered appropriate treatment by the hospital’s physical health service if required, although not all patients accepted it. At Northgate Hospital, the supplementation protocol for vitamin D is based on guidance provided by the National Health Service Specialist Pharmacy Service.⁸ Those patients found to be deficient were treated with 20 000 units of oral colecalciferol twice weekly for 8 weeks and then maintained on 800 units daily. Those found to have insufficient levels were treated with a maintenance dose of 800–1600 units of oral colecalciferol daily. Patients’ 25OHD levels were then re-tested a year later as part of the next year’s annual health checks.

Data analysis

Baseline 25OHD data

Mean baseline 25OHD levels were analysed using a single multiple regression analysis. The regression model assessed the effects of the following categorical predictors on baseline 25OHD levels: season of testing, levels of security, prescription of antipsychotic or anticonvulsant medication, and the cohort tested. Data that were not normally distributed were transformed appropriately (using a log₁₀ transformation for 25OHD values).

Effect of treatment

Patient records were scrutinised to ascertain whether, following baseline testing, treatment to correct any deficiency was offered and/or taken. Follow-up testing data were collected, and the McNemar test of marginal homogeneity was applied to the pairs of non-adjusted 25OHD levels to assess differences in patients' 25OHD levels between baseline and follow-up.

Data were analysed using SPSS version 22.9 This service evaluation was registered with the Research and Development department of Northumberland, Tyne and Wear National Health Service Foundation Trust, in November 2013 (Registration number SER-13-018).

Results

Study population

Seventy-three established patents at Northgate Hospital had baseline 25OHD screening between January 2013 and February 2014 (cohort 1). Between January 2013 and July 2016, a further 27 patients had been admitted to the hospital and received baseline 25OHD screening on admission (cohort 2). The two cohorts are described in *Tables 1* and *2*. As expected, the median length of stay at baseline test was significantly greater in cohort 1 than in cohort 2 (36 months vs. 1 month; Mann–Whitney U: 34.5, $P < 0.001$) as new patients were tested soon after admission. There were no patients of Black and minority ethnic (BAME) origin among the patient group. Table 1 Description of cohort 1

Baseline vitamin D levels

The mean 25OHD level of the whole study population was 35.1 nmol/L (s.d. 28.1), and the median was 27.0 nmol/L, representing positively skewed values (Shapiro–Wilk: 0.699, $P < 0.001$). The regression analysis was therefore conducted using \log_{10} -transformed values. The statuses of 100 patients at baseline are represented in *Fig 1*, showing that the vast majority had either deficient or insufficient 25OHD levels. Fig. 1 Vitamin D status of 100 patients at baseline testing.

The regression analysis demonstrated no effect of season or level of security on the vitamin D status of the patient at baseline (*Table 3*). Furthermore, there were no differences between the two cohorts, or between those prescribed antipsychotic or anticonvulsant medication. There was a trend for lower 25OHD levels among patients already prescribed antipsychotic medication, and marginally higher levels in those on anticonvulsant medication, although four of the 29 patients in the latter group had already been prescribed vitamin D supplements. Furthermore, 25OHD levels were statistically non-significantly higher in the

summer compared with winter (median 25OHD 33 nmol/L vs. 20 nmol/L), and in the rehabilitation service compared with the medium secure wards (median 25OHD 33.5 nmol/L vs. 27.5 nmol/L).

Follow-up and treatment effects

Follow-up data were available for 89 patients who were retested around 12 months after baseline screening. The mean 25OHD level was 66.3 nmol/L (s.d. 33.6) and the median was 62.0 nmol/L, which represented a less extreme but still significant positive skew (Shapiro-Wilk: 0.914, $P = 0.035$). The numbers of patients with sufficient and optimal 25OHD had improved substantially (see Fig 2). Fig. 2 Vitamin D status of 89 patients at follow-up.

Not all patients who received baseline 25OHD screening and/or treatment were tested a second time. Some patients were discharged from hospital in the interim, or their 25OHD level was not requested by the physical treatment service. A flowchart of all 100 patients is provided in Fig 3. Fig. 3 Flowchart of 100 patients who underwent baseline screening. Mean (s.d.) 25OHD levels are reported.

The regression analysis was repeated for \log_{10} -transformed 25OHD levels at follow-up testing. As in the baseline data, there were no effects for seasonality, security level, or the prescription of antipsychotic or anticonvulsant medication.

Discussion

This is the first study to report data from a specialist hospital for patients with IDD who offend, and those with severe autism spectrum disorders, with a number of levels of secure and non-secure wards and units. This paper describes routinely collected data on serum 25OHD levels obtained at baseline prior to clinical decisions to treat any vitamin D deficiency, along with follow-up serum levels after a year. The rationale for the implementation of this protocol was based on concerns that low levels of sun exposure, the secure environment and the prescription of psychotropic medication put in-patients in a 'high risk' category, with potentially serious long-term health sequelae.⁷

The data suggest considerable vitamin deficiency among this patient group. Furthermore, there were no clear differences in 25OHD levels between patients already in hospital when baseline screening took place and newly admitted patients. This might be attributed to deficiencies in the community, but, in a tertiary service, new admissions frequently transfer from other in-patient services. Limitations in the data available mean that further scrutiny is outside the scope of this paper. There appeared to be a trend for marginally lower 25OHD levels in secure wards compared with rehabilitation services, but there was no statistically significant variation.

Although no significant differences were found between patients taking psychotropic medication and those who were not, these factors remain of clinical concern with respect to bone health. A recent small-scale prospective study found that antipsychotics may inhibit vitamin D-metabolising enzymes, thereby causing a reduction in both calcium and 25OHD levels.¹⁰ This association is of particular concern given the known link between antipsychotics and osteoporosis risk via raised prolactin levels.¹¹

Patients with normal 25OHD levels at baseline who were already on supplements all opted to continue with treatment. Those with normal levels at baseline who were not already receiving treatment were advised by their general practitioner based on the clinical scenario. Neither the supplemented nor the non-supplemented group had significant changes in their 25OHD status at follow-up, but numbers here were small.

Patients with suboptimal 25OHD levels were all offered supplementation using a standard protocol. Those who opted for supplementation had significantly higher 25OHD levels at follow-up, whereas those who opted out experienced non-significant changes. As the data here reported are routinely collected, it is not possible to make any systematic inference as to what lay behind a patient's decision to accept or decline supplementation.

Although vitamin D deficiency was widespread among this group, it was not present among all patients. There is some evidence from genome-wide association studies that genetic factors also have a significant role in identifying those at increased risk, but this is beyond the scope of this evaluation.¹²

Our data are commensurate with a study of psychiatric in-patients in a Scottish high-secure hospital at a similar geographical latitude to Northgate Hospital. That study concluded that all patients in secure settings should be screened

and offered supplementation based on ‘significant and serious’ deficiency of 25OHD associated with bone demineralisation.¹³ Furthermore, such deficiencies do not appear to be limited to secure care. One study of people with IDD in institutionalised nursing care in Finland demonstrated significant 25OHD insufficiency, which was addressed by oral or intramuscular supplementation.¹⁴

The data in this study were routinely collected and not prospectively planned, leading to limitations in their interpretation. Serum parathyroid hormone and calcium levels were not routinely collected, nor were any bone mineralisation tests performed. No data on the content or vitamin D qualities of patients’ diets were collected. It is also not possible to comment on the longer-term health risks such as fractures without a larger, more specialised study. The patient group at Northgate is not ethnically diverse; all patients in this cohort were of white ethnicity. One study of a long-stay psychiatric in-patient facility found an association between low vitamin D levels and being of a BAME background, with improvements in 25OHD levels after treatment.¹⁵ Another recent study in Tier 4 adolescent psychiatric services showed similar numbers of white and BAME patients with 25OHD deficiency (46 vs. 53%).¹⁶

This raises the question as to whether all patients who are ‘high risk’ should be offered treatment. The long stays of patients within secure services, along with concomitant medication, would put these patients within this category. Current guidance by Public Health England recommends a minimum of 10 µg per day for the general population aged four and above, where diet alone is insufficient.⁵ However, the choice between simple supplementation or a deficiency protocol for patients such as these has not been fully established. Furthermore, it has not been established whether supplementation should be offered without suitable baseline screening. It should also be considered that the more general effects of vitamin D supplementation are far from certain. A meta-analysis of 18 randomised controlled trials (RCTs) suggested that there was a modest reduction in overall mortality for people taking standard doses of 25OHD supplementation,¹⁷ but a more recent umbrella review of systematic reviews and meta-analyses of observational studies and RCTs found little convincing evidence of a clear role for vitamin D in health outcomes.¹⁸

Nevertheless, this study has shown that in-patients with IDD appear to have deficiencies in vitamin D and that these are amenable to correction by oral supplementation in many cases. We recommend further research in this area, including prospective studies of the longer-term health sequelae.

Thanks to Dr Andreas Finkelmeyer, Institute of Neuroscience, Newcastle University, who assisted with the statistical analysis.

- *Joan Bicknell*

Dorothy Joan Bicknell, psychiatrist, born 10 April 1939; died 12 June 2017

Brilliant clinician who was appointed professor of psychiatry of learning disability at St George's, University of London.

In 1980, Joan Bicknell, who has died aged 78 of cancer, was appointed professor of psychiatry of learning disability – the first British female professor of psychiatry – at what is now St George's, University of London. A brilliant clinician, she put the disabled person and their family at the centre of each consultation.

She was in constant demand to speak to trainees, parent groups and learning disability services about her vision of what could be done, and published dozens of papers for both clinicians and families. An article drawn from her inaugural lecture as a professor in 1981, *The Psychopathology of Handicap*, was published in the journal *Psychological Medicine*, and remains inspirational today.

In it, she described the emotional effect on parents and siblings of the diagnosis of learning disability in the family and also explored what it is like for children and adults living with a learning disability in terms of their own emotional inner world, their expectations for adulthood and the extent to which they were included or excluded from participating in daily life in the community. At the time, most people with learning disabilities lived at home with their families – unless the family could no longer support the person – and the alternative was usually a hospital admission.

Joan demonstrated that with specialist advice, community services could provide families with more support to care for longer, and the growing number of community homes and hostels could be supported to provide family-style care. This was unpopular with many medical superintendents of “mental handicap” hospitals, and she was never accepted by the medical establishment.

In 1978, a public inquiry into a scandal at Normansfield hospital in Teddington, south-west London, found the medical leadership seriously at fault. The nurses at Normansfield had gone on strike two years earlier complaining about how dysfunctional the organisation was, and the appalling conditions in which people with learning disabilities were living. The South West Thames regional health authority accepted the inquiry recommendations and appointed Joan to lead a taskforce to transform the care provided. It brought staff and relatives together to create an improvement plan, a new multidisciplinary management structure was put in place and money was provided to build more accommodation to reduce overcrowding.

It was against this background that Joan became professor, heading a new NHS-funded academic department to launch the specialty of psychiatry of learning disability at St George's, covering south-west London, Surrey, Sussex and Hampshire. St George's remains a leader in teaching medical students how to communicate effectively with people with learning disabilities, work that began in 1982, when Joan started involving her patients and their families in face-to-face teaching.

During her working day she met patients and families in the clinic or at home, supervised trainees, advised NHS and social service managers and fielded phone calls from people seeking advice. In the evenings and at weekends she would be booked as a speaker or for consultations all over Britain. She took early retirement in 1990 at the age of 50, having suffered from mental illness and severe asthma for the final three years of her career.

Perhaps the hardest thing for her to deal with had been the failure of NHS managers and of politicians to respond with meaningful action when she spoke up for the human rights of people with learning disabilities. She wrote in the Personal View column for the *British Medical Journal* about the men in a locked ward who were not allowed access to the kitchen or to drinking water and resorted to filling their shoes with water from the lavatory pan. Eventually a

water fountain was installed in the living room, only for it to be blocked up by staff using it to dispose of their cigarette ash. Confronting cruelty in such hospitals was yet another of the ways she contributed to the advance of enlightened disability psychotherapy and psychiatry.

Born in Isleworth, south-west London, Joan lived in the capital for most of the second world war with her mother, Dorothy (nee Smith), a solicitor's secretary and later a foster parent, and her older brother, Edward, who went on to become a teacher in Swaziland, where he later died. Her father, Albert Bicknell, a foreman bricklayer in peacetime, served with the Royal Engineers in bomb disposal.

From Twickenham County school for girls Joan went to Birmingham University, graduating in medicine in 1962. A Methodist missionary society needed a paediatrician urgently at the Ilesha Wesley Guild hospital in Oyo, Nigeria, so Joan interrupted her paediatric training to test her new medical skills in a very different setting. When the Biafran war began in 1967, Joan was rounded up with others at bayonet point and put on a plane to Sierra Leone. There she worked on the flying doctor service before returning home.

She took a post at Queen Mary's hospital, Carshalton, in Surrey, where her concern about the poor care given to severely disabled children was strengthened by her own family experience, when her mother fostered two brothers with learning disabilities. This was the new challenge she needed and five more years of clinical training followed.

Joan obtained the diploma in psychological medicine in 1969, and in 1971 completed an MD on the causes and prevalence of lead poisoning in institutionalised children. She was soon active in campaigning about the restricted and poorly supported lives that people experienced in long-stay hospitals.

In 1972 Joan became a consultant psychiatrist in mental handicap at Botley's Park hospital, Chertsey, where she later met Diane Worsley, a social worker. Their friendship and partnership stood the test of time, and after Joan retired they moved to Holnest, Dorset, and ran a farm, welcoming disabled children to work with the animals. Joan and Diane also built up the Longburton Methodist chapel, where they were worship leaders. In 2016 they sold the farm and moved to nearby Stalbridge.

The community team base at Springfield University hospital in Tooting, south-west London, where Joan did much of her pioneering clinical work, was named after her when she left. The Royal College of Psychiatrists instituted an annual essay prize in her honour.

She is survived by Diane.

1.5.27 Psychiatry, not mental health

Richard Braithwaite

date

2018-2

Contents

- | |
|--|
| <ul style="list-style-type: none">• <i>Psychiatry, not mental health</i> |
|--|

Timms begins his article on solid ground, highlighting the serious problem of psychiatric jargon.¹ Sadly, it descends into a light-hearted list, focused on the gulf between manager and clinician in the British health service. Most importantly, he omits four gravely misused jargon terms prevalent in psychiatry.

First, the noun ‘depression’ and its adjective ‘depressed’. The noun has half a dozen dictionary definitions unrelated to medicine² and, as a word on its own, it is not a recognised diagnosis in either psychiatric classification.^{3,4} Yet it is used by the lay public, patients and healthcare professionals alike to refer to a medical diagnosis, a single symptom or a normal emotion. It is invariably unclear which meaning is intended by the speaker. This confusion contributes to massive over-prescription of an unfortunately named class of drugs;⁵ anecdotally, it is not uncommon even for senior psychiatrists to justify antidepressant treatment, having cast aside clear diagnostic criteria,^{3,4} with comments such as: ‘Well, there’s definitely a bit of depression there’ or ‘She says she feels depressed’.

In a similar vein, ‘paranoia’ and ‘paranoid’ are often used by clinicians in their lay meaning of ‘intense suspicion’,² when the true psychiatric definition is ‘delusional’;⁶ such ideation might involve purely grandiose or somatic themes. Despite this, one often sees ‘paranoid’ and ‘persecutory’ used synonymously. The subjective complaint of ‘paranoia’ is common in patients with neurotic presentations and personality disorders, and its inappropriate use in case notes without careful use of inverted commas, to signify a verbatim quote, risks inappropriate labelling of patients as psychotic and overtreatment with antipsychotics.

Next, the term ‘psychosis’ is increasingly used as a diagnosis – as if it were a singular disease for which specific treatments were indicated⁷ – rather than the syndrome that it is. It can occur in organic, substance-induced or affective disorders, yet I contend that ‘psychosis’ is often used, lazily, as a euphemism for schizophrenia, by psychiatrists either ignorant of established diagnostic criteria^{3,4} or wary of stigmatising their patients (as if one would happily tell guests at a dinner party that one was ‘psychotic’).

Most concerning, though, is the jargon that Timms includes in his own title: ‘mental health’.¹ The assumption that ‘mental health’ and the oxymoronic ‘mental health disorder’ are synonymous with psychiatry and its diseases is quite erroneous. Psychiatry, as practised by psychiatric nurses and psychiatrists, was once charged with the management of patients with psychiatric diseases. But our colleagues are now mental health nurses and our departments mental health services. Far from relating to recognised diseases, the doublespeak ‘mental health’ has become synonymous with a vague and unattainable concept of complete emotional well-being. Consequently, an increasing fraction of our population, even a majority according to some reports,⁸ young and old, are reported to have ‘mental health problems’. The jargon underlying this explosion has set us and our entire healthcare system up to fail, through unrealistic public expectations and ever unmet need.

Let us be psychiatrists and psychiatric nurses once more; let us work in psychiatric services. Let us diagnose schizophrenia and depressive episodes using recognised criteria and be judicious in our use of potentially hazardous and costly treatments; most of all, let us avoid terms steeped in ambiguity.

Stigma remains pervasive in mental healthcare, despite efforts to challenge and quell it. Stigma begets more stigma, and a combination of discrimination, prejudice, misunderstanding and stereotyping can ensnare people with mental illnesses in a cycle of self-stigma.

Through a series of discursive essays derived from conversations with her partner, Jo McFarlane reflects on her decades-long experience of mental illness and the way in which she has been treated by clinicians and by society. She uses a ghetto as a harrowing metaphor for the isolation, vulnerability and feelings of entrapment which stigma has enforced upon her. As the metaphor suggests, her journey towards recovery and self-fulfilment is rife with challenges. However, patient-centred therapeutic relationships, the opportunity to volunteer, informal peer support, and the creation and

dissemination of art have all been instrumental in allowing her to achieve her full potential as an individual and as a member of society. She rightly throws shade on the patriarchal role psychiatry has historically had, in which her sexuality and social choices were pathologised rather than embraced, reminding us of the importance of a holistic and open-minded approach to care.

What I found most engaging about the book was the way in which creative endeavour was presented by the author not simply as catharsis but as a fulcrum for self-discovery, allowing her to shift her identity 'from patient to poet' and rise above the stigma which once shackled her. Furthermore, she uses her writing to give a voice to others, the oppressed 'ghettoised' masses, thus showing the role of art in activism and advocacy.

This book serves as a reminder of the importance of recognising and tackling stigma, particularly self-stigma, which I intend to continue to reflect upon as I embark on a career in psychiatry myself. It is an accessible, thought-provoking and stimulating read with occasional space for humour, and I believe it would be a worthwhile read not only for those working in the field of psychiatry, but also for those using mental health services.

1.5.28 Antidepressants in paediatric depression: do not look back in anger but around in awareness

David A. Brent Robert D. Gibbons Paul Wilkinson Bernadka Dubicka

Correspondence

David A. Brent (brentda@upmc.edu)

date

2018-2

Abstract**Summary**

In this paper, we summarise and critique a network meta-analysis (NMA) of antidepressant efficacy and tolerability for paediatric depression and an accompanying editorial. Although we agree that many of the extant studies are flawed, this meta-analysis showed clear efficacy of fluoxetine in the NMA, and for sertraline and escitalopram in pairwise analyses. Consequently, these papers underestimate the benefits of antidepressants for paediatric depression, and provide support for current practice guideline, which recommends the use of an antidepressant if the patient does not respond to psychotherapy. In these circumstances, fluoxetine should be the first choice, with escitalopram and sertraline as alternatives.

- *Antidepressants in paediatric depression: do not look back in anger but around in awareness*

In this article, we review a network meta-analysis (NMA) that examines the relative efficacy and tolerability of antidepressants for paediatric depression, and the accompanying editorial that appeared in the *Lancet*. The meta-analysis provides useful information for researchers and practitioners, but undervalues the benefits of antidepressants and overweights the risks.¹ The accompanying editorial takes this bias as its point of departure, fuelled by righteous indignation about the deceptive reporting and publication practices of some industry-led studies.² While this anger is justified, we believe that it should not preclude the reporting of benefits from the use of antidepressants in depressed youth, when supported by data.

Cipriani and colleagues have contributed a carefully and transparently conducted NMA of the comparative efficacy and tolerability (defined as discontinuation of the drug) of antidepressants for paediatric major depression.¹ This meta-analysis examined 34 randomised clinical trials (RCTs) that encompassed 5260 participants and tested 14 different antidepressants. In the overall NMA, fluoxetine was the only agent found to be significantly more effective than placebo in reducing depressive symptoms ($d = 0.51$, 95% CI 0.99 to 0.03). Fluoxetine was no different from placebo with respect to tolerability and suicidal events, and was better tolerated than duloxetine or imipramine. Furthermore, imipramine, venlafaxine and duloxetine had more discontinuations than placebo. The quality of evidence was rated as ‘very low’ for most comparisons. The authors concluded that antidepressants do not appear to offer a clear advantage for children and adolescents, but if a pharmacological intervention is indicated, fluoxetine is ‘probably the best option’.

Pairwise meta-analyses found that three agents, fluoxetine, sertraline and escitalopram, showed superiority to placebo for both continuous and dichotomous outcomes. Venlafaxine was reported to have a higher incidence of suicidal events (OR = 0.13, 95% CI 0.00–0.55) than placebo and several other antidepressants, whereas none of the other agents studied had a higher rate of suicidal events than placebo.

The authors are to be commended for their careful attention to methodological quality, use of NMA and elegant presentation of results. We agree with the authors about the limitations imposed by low study quality, possible industry bias, incomplete assessment of suicidal events and overall small number of studies. This leads us to a different conclusion, which is that more studies that are conducted more rigorously are needed. Moreover, we found the interpretation of the findings to be inconsistent in three ways – with the data itself, across findings and compared with previous reports by some of the authors.

For example, the meta-analysis found that fluoxetine, compared with placebo, resulted in a medium effect size, yet because the confidence interval upper limit was close to zero (0.99 to 0.03), the authors raise the question of ‘whether this estimate is robust enough to inform clinical practice’. Many statisticians would agree that after passing the muster of NMA, this effect is robust enough. The authors do not offer a bar above which these data are expected to pass. Moreover, the authors support the use of evidence-based psychotherapy for the treatment of paediatric depression, although it has a much smaller effect on paediatric depression than does fluoxetine ($d = 0.29$).³

The authors raised appropriate suspicion about studies conducted by industry, yet, in the case of fluoxetine, they raise the reverse concern that most of the fluoxetine trials were done *without* industry sponsorship and were of smaller sample size, ‘which might result in an exaggerated treatment effect’. These concerns are not grounded in facts. First, the National Institute of Mental Health (NIMH)-sponsored Treatment of Adolescent Depression Study (TADS) was one of the largest placebo-controlled paediatric depression trials, involving 423 young people.⁴ Second, since both published

and unpublished studies with small samples were included, findings are just as likely to yield a Type II error as to result in a spurious positive finding. Third, other studies of paediatric and adult depression have found that the effect size is lower, and the placebo effect higher, when a greater number of sites is involved, as is more common in industry-sponsored studies.^{5–7} In fact, a paper co-authored by the lead author examining trends in clinical trials of antipsychotics observed that ‘effect sizes were reduced by industry sponsorship and increasing placebo response, not decreasing drug response’, and recommended that ‘drug development may benefit from *smaller samples but better-selected patients*’ (italics ours).⁸ We would argue that ‘smaller samples’ of ‘better-selected patients’ would be considered to be a positive design feature in antidepressant RCTs for paediatric depression as well. Finally, re-analyses of the fluoxetine trials for paediatric depression using patient-level data have found efficacy in the reduction of depression comparable to that reported in adults.⁹

The authors found that both sertraline and escitalopram had significant effects on the reduction in depressive symptoms on pairwise meta-analyses that apparently did not survive NMA. Given the reported high degree of homogeneity in these studies, and the fact that there were no indirect comparisons that would contribute extra studies, NMA may be inappropriately stringent. In the case of low heterogeneity, fixed effects meta-analysis, with narrow confidence intervals, may be more appropriate than the random effects used in NMA. Moreover, it may be justified to report also on the effects of *antidepressant drug classes* such as selective serotonin reuptake inhibitors (SSRIs), serotonin–noradrenaline reuptake inhibitors (SNRIs) and tricyclic antidepressants (TCAs). Inspection of the data suggests that SSRIs would show a more favourable effect on depressive symptoms and better tolerance compared with TCAs, which is a message found in previous meta-analyses, but worth repeating.¹⁰

The authors state that the risk–benefit profile is not favourable for antidepressants. Part of this argument is based on wide confidence intervals for efficacy. It seems inconsistent then to not put similar emphasis on the equally wide confidence intervals for discontinuation and suicidality, especially as the antidepressants with the best evidence for efficacy (i.e., fluoxetine, sertraline and escitalopram) are not significantly different from placebo for discontinuation or suicidality. With respect to suicidality, the rates of suicidal events ranged from 0 to 13% in those assigned to the drug, and 0 to 14% for those assigned to placebo. The authors report on a strong association between venlafaxine and suicidal events (OR = 0.13, 95% CI 0.00–0.55). While the rate of suicidal events in those assigned to venlafaxine (4%) was statistically higher than in those assigned to placebo (0%), the absence of events in the placebo group makes it difficult to obtain an accurate estimate of the odds of suicidal events associated with this agent.

The authors correctly point out limitations in the design and conduct of these clinical trials, but there are other limitations that greater access to data cannot remedy. First, the assessment of suicidal events in the majority of these studies was based on spontaneous report, rather than systematic assessment. One study that compared the rate of events by spontaneous reporting and systematic assessment found that spontaneous reporting of suicidal events underestimated the rate of events by a factor of 2.5.¹¹ Moreover, patients on medication, perhaps owing to side-effects, might be more likely to report suicidal events, thus biasing conclusions based on these methods. In one of the few placebo-controlled trials that utilised systematic assessment of suicidal events, no difference was found between duloxetine, fluoxetine and placebo in the frequency of suicidal events.¹² Second, there are inherent limitations in clinical trials, since those patients most likely to be treated with an antidepressant are least likely to be enrolled into an RCT. For example, a recent suicide attempt is an exclusion for almost all paediatric depression pharmacotherapy RCTs. In a study of the relationship between a suicide attempt and initiation of antidepressant treatment in one large healthcare system, a suicide attempt was a common precipitant for *starting* an antidepressant in adolescents and in adults.¹³ Moreover, in these youth, the rate of suicide attempts was highest *prior* to the initiation of treatment, suggesting that antidepressants are protective against suicidal behaviour, even in young people. Although causal inferences cannot be firmly drawn from observational studies, such studies have the advantage of larger size, representativeness, longer duration of treatment, and ability to link treatment to suicide, not just to suicidal events. While not incontrovertible, there are many observational studies showing strong inverse associations between prescription and sales rates of SSRIs and suicide, including suicide in adolescents.^{14–16} Conversely, after the Black Box Warning, there has been at least a temporary decline in antidepressant prescriptions in the United States, Canada and The Netherlands, accompanied by an uptick in adolescent suicides.^{17–18} If antidepressants were strongly associated with suicide, one would expect that a decline in antidepressant prescriptions would be accompanied by a corresponding decline in suicide, rather than the exact opposite.

This carefully conducted meta-analysis was accompanied by an editorial that was a polemic against the use of antidepressants, entitled ‘Antidepressants fail, but no cause for therapeutic gloom’.² The editorialist asserted that the extant

literature greatly exaggerates the benefits of antidepressants and downplays their risks, owing to the poor data quality and selective reporting of results. He recommended that clinicians reading the literature assume that the benefits of a drug are inflated, and that the occurrence of harmful events is more serious and frequent than reported. This editorial asserted that the reported association between fluoxetine treatment and improvement in symptoms and functional outcomes is not necessarily causative, and that fluoxetine is likely to be more dangerous, and less effective than presented in the extant literature. This editorial further opined that fluoxetine has never been compared with a supportive relationship, which the editorialist considered was likely to be more helpful and less harmful than antidepressant medication for depressed youth. The editorial concluded that industry-sponsored research should provide transparency and access to all data and procedures.

It is only with the last statement in this editorial that we can proffer agreement. We wholeheartedly endorse the need for data transparency in all clinical trials, including those conducted by industry, and acknowledge the damage to the credibility of all studies caused by failure to publish and disclose data. However, the largest single clinical trial of antidepressants in paediatric depression, TADS, was not sponsored by industry, but by NIMH. This study showed a higher rate of response and better functioning in those assigned to fluoxetine versus those assigned to placebo.^{4,19} While the editorialist raised the question of whether association implies causality, a blinded placebo-controlled trial has long been considered the gold standard for causal inferences. The editorialist also suggests that supportive therapy is likely to be more effective, and less harmful, than fluoxetine. However, the placebo condition in TADS involved supportive management, and resulted in a response rate of only 35% v. 61% for those treated with fluoxetine.⁴ Although there were more spontaneously reported suicidal events (which includes thoughts without acts) in those treated with fluoxetine than in those treated with placebo, the response rate after 12 weeks of treatment was much higher in those treated with fluoxetine, and absolute risk differences were several-fold higher for efficacy than for suicidal events.²⁰⁻²¹ Moreover, a comparison of another version of cognitive-behavioural therapy (CBT) with supportive treatment found that CBT was much more efficacious.²² Therefore, results of the TADS trial and other published data completely refute the editorialist's assertions that industry sponsorship of some studies automatically dilutes the efficacy reports of medication, including fluoxetine, that causality cannot be inferred from an RCT, and that supportive care would be superior to treatment with fluoxetine.

What is a clinician to make of this meta-analysis and editorial? We believe that the findings from the meta-analysis support current clinical guidelines. In the UK, National Institute for Health and Care Excellence (NICE) guidelines advise the first-line use of an evidence-based psychotherapy such as interpersonal therapy or CBT, and, if the patient does not respond, to then consider adding pharmacotherapy, namely, fluoxetine.²³ We continue to support this approach. Also, as per NICE guidelines, in cases of severe, chronic or treatment-resistant depression, there is evidence to support starting with a combination of psychotherapy and pharmacotherapy, which has been shown to be superior to medication monotherapy for treatment-resistant depression.²³⁻²⁵ Despite the 0% rate of suicidal events in the placebo cells for venlafaxine studies, we agree that caution is indicated in the use of this agent, insofar as SSRIs are just as effective for treatment-resistant depression as venlafaxine, but their use results in fewer side-effects, and lower levels of suicidal ideation and events.^{11,26} Moreover, these meta-analyses are consistent with the view that other antidepressants, such as sertraline and escitalopram, are reasonable and effective alternatives should patients have a history of not responding to an adequate trial of fluoxetine. The risk-benefit ratio for use of antidepressants in paediatric depression is relatively favourable, with about 11 times more young people responding to an antidepressant than developing suicidal events.⁵ Moreover, the shadow cast by the Black Box Warning should not discourage the clinician from using antidepressants for the treatment of anxiety and obsessive-compulsive disorders, as treatment of these conditions with SSRIs is more likely to result in a clinical response, and less likely to result in a suicidal event, compared with antidepressant treatment of paediatric depression.^{5,27}

Our job as responsible scientists and clinicians is to inform patients and families about the risks and benefits of each intervention, with appropriate confidence intervals and without bias, and to use this information to collaborate with families in making clinically appropriate treatment decisions. It is justifiable to be angry about scientific obfuscation and deception, but we should not paint all studies and findings with the same broad brush. Instead, let us consider the wise words of the blind, but insightful, author James Thurber, who advised us to 'not look back in anger, or forward in fear, but around in awareness'.²⁸

1.5.29 Liaison psychiatry for older adults in the general hospital: service activity, development and outcomes

Fedza Mujic Ruth Cairns Vivienne Mak Clare Squire Andrew Wells Ahmed Al-Harrasi Martin Prince

Correspondence

Fedza Mujic (fedza.mujic@slam.nhs.uk)

date

2018-2

Abstract**Aims and method**

This study used data collected to describe the activity, case-load characteristics and outcome measures for all patients seen during a 6-year period.

Results

The service reviewed 2153 patients over 6 years with referral rates and case-load characteristics comparable to those described in a previous study period. The team saw 82% of patients on the day they were referred. Data and outcome measures collected showed significant complexity in the cases seen and statistically significant improvement in Health of the Nation Outcome Scales (HoNOS) scores following service input.

Clinical implications

The outcome measures used were limited, but the study supports the need for specialist liaison psychiatry for older adults (LPOA) services in the general hospital. The Framework of Outcome Measures – Liaison Psychiatry has now been introduced, but it remains unclear how valid this is in LPOA. It is of note that cost-effectiveness secondary to service input and training activities are not adequately monitored.

Declaration of interest

None.

Around two-thirds of National Health Service (NHS) in-patient beds are occupied by older people, with up to 60% having an existing mental disorder or developing one during their admission.¹ Medical in-patients are three to four times more likely to develop a mental illness than the healthy population, with high prevalence rates of depression in patients with diabetes and coronary heart disease.² High rates of dementia, delirium and depression have been reported in older in-patients.³ It is important to identify and treat these conditions, as mental illness has been shown to increase the risk of poor health outcomes, including loss of independence, reduced life expectancy and increased mortality.³⁻⁵

Early studies showed that around 30% of all liaison psychiatry referrals were for people over the age of 65.⁶ Despite an ageing population and strong arguments for specialist liaison old age psychiatry input in general hospitals, a report in 2003 showed that 73% of UK services were provided through a traditional sector-based model,⁷ and it is not clear to what extent this has changed. Recently, the rapid assessment and integrated discharge (RAID) liaison psychiatry service led to significant savings by reducing readmissions and length of stay.⁸ Notably, elderly people represented about a third of the sample but accounted for around 90% of savings through reduced bed use.

The aim of this study was to provide an in-depth analysis of a well-established liaison psychiatry for older adults (LPOA) service, regarding its activity, case-load characteristics and use of outcome measures.

Method

Setting and team development

King's College Hospital is a 950-bed London teaching hospital covering a large inner-city catchment area. The LPOA service was restructured in 2000, moving from an *ad hoc* off-site service to a dedicated specialist service with staff based in the hospital. Also, the old consultation model of service delivery was changed to a true liaison model in December 2000 as previously described,⁹ but has been focused on in-patients over the age of 65 years. No older adult specialist cover had been provided to the emergency department until early 2016, owing to the small team size and insufficient resources.

The staffing level of the service had been unchanged for around 10 years from 2000 to 2010, with limited (approximately two sessions) honorary consultant psychiatrist input, a full-time staff grade/associate specialist doctor, a full-time junior doctor, and no or very poor administrative support. Attempts to improve the staff skill mix of this strongly doctor-led service failed for a long time, owing to resource issues and cuts within the mental health trust. However, with the help of the acute trust providing funding for 18 months initially, the service employed a clinical nurse specialist (CNS) in late 2010. This post has continued and is now funded by the mental health trust. Funding was also secured for a half-time administrator in 2015 and, as the team has expanded, the CNS role has been extended and now also operates as the team manager.

Between October 2013 and September 2015, consultant cover for the service was provided by the substantive consultant from another older adult liaison service within the trust. Funding for a half-time substantive consultant psychiatrist was finally agreed and commenced in September 2015. Since then, and owing to increased demands on the service, there have been further developments to the team skill mix, including fixed-term funding (now made recurrent) for a band 6 psychiatric liaison nurse (PLN) to cover in-patients and Core-24 NHS England (NHSE) funding (<https://www.england.nhs.uk/mental-health/adults/crisis-and-acute-care/transformation-funding/>) for a CNS to provide specialist old age psychiatry input to the emergency department, and a part-time trainee psychologist has joined the team. The most recent developments are further NHSE Core-24 funding for a clinical psychologist and occupational therapist within the liaison psychiatry department; both posts will work across the general adult and older adult teams. The team has now become much more integrated with the general adult psychiatry team, with a single point of access and closer collaboration.

Service activity

The activity of the service has been monitored extensively since its inception in December 2000. This has included descriptive data about the source of and reason for referrals, characteristics of the case-load, outcome of the team's assessment, outcomes and follow-up arrangements. The rationale for this has been to gather information to support further service development and to identify any problems that needed addressing. The data collection has been anonymised throughout, with no patient identifiers recorded on the electronic database used for further analysis.

Sample and data collection

The study included all patients seen by the King's College Hospital LPOA service between January 2010 and December 2015.

A two-page form was filled in by the assessing clinician for each patient, containing demographics, reason for referral, response time, outcome of the psychiatric assessment, discharge destination and follow-up arrangements. Data about mental capacity assessment were also collected, and Mini-Mental State Examination (MMSE) scores¹⁰ were recorded where possible. The main performance and outcome data collected included response time (and whether target times were met) and Health of the Nation Outcome Scales for Elderly People (HoNOS 65+) © Royal College of Psychiatrists 1999.¹¹ The response time standards set for the service were assessment of all urgent referrals within 24 h, medium-urgency referrals within 3 days, and low-urgency referrals within 5 days. A second HoNOS 65+ rating was completed for patients under the care of the service for 2 weeks or longer. A record was also kept of new diagnoses of dementia

and antipsychotic medication reviews in patients with dementia. The information from each form was anonymised and transferred on to the electronic database by F.M.

Statistical analysis

Data were analysed using SPSS version 21.0. Descriptive statistics were used to analyse the main demographic characteristics of the case-load (age, gender, ethnicity), clinical characteristics, cognitive status (MMSE score) and outcome data of the patients in the sample. We also used paired *t*-tests to test the difference between paired HoNOS 65+ ratings.

Results

Case-load

The service reviewed 2153 patients during the studied period, amounting to approximately 360 patients seen on an annual basis. This did not include referred patients where the liaison service provided advice and information only, or where the referral was deemed more appropriate for another team.

The majority of patients were admitted from their homes ($n = 1940$; 90.1%), while only a minority were either admitted from care homes or transferred from another hospital. Apart from medical and surgical issues, 435 (20.2%) patients in this sample were admitted to hospital owing to falls, with 124 (28.5%) of these sustaining various fractures. Suicide attempts, overdose or other self-harm incidents were the reason for admission for 68 (3.1%) patients. The main characteristics of patients and referrals are outlined in *Table 1*. *Table 1* Main characteristics of the referral-

Age, mean years (s.d.) 78.6 (7.93); min 60, max 106
 Gender Female 1141 (53%) Male 1011 (47%)
 Ethnicity White European 1603 (74.5%) Caribbean 313 (14.5%) African 99 (4.6%) Asian 68 (3.2%) White other 46 (2.1%) Other 24 (1.1%)
 Referred by Geriatrics 598 (27.5%) Acute medicine 564 (26.2%) Acute medical unit 378 (17.6%) Orthopaedics 94 (4.4%) Other surgeons 152 (7.1%) Other 367 (17.0%)
 Referral urgency High 758 (35.2%) Medium 1292 (60.0%) Low 103 (4.8%)

Referral requests and assessment

The vast majority of referrals were for advice on issues affecting the patient's stay in the hospital, including mental health diagnosis (82.5%) and management (90.5%). Advice on mental capacity assessment was requested in 8.5% of the referrals, which is lower than when the service was first established and before the Mental Capacity Act 2005 was introduced.¹² Other requests were mainly related to patients' discharge arrangements and made a smaller contribution to the total number of referrals, e.g. advice on placement (1%) and mental health follow-up (5.1%).

The main presenting problems that triggered referral were low mood (65.8%), impaired cognition and confusion (36.2%), behavioural disturbance (21.7%), and abnormal beliefs and experiences (15.4%). The most specific referral questions asked were related to mental state (92.5%) and medication (52%), while other questions included issues with cognition (8.2%) and suicidality (11%).

The majority of patients were diagnosed with one or more psychiatric disorders. Only a small number of patients did not have any psychiatric diagnosis following the assessment (4.3%). The diagnoses are outlined in *Table 2*. *Table 2* Case-load

Diagnosis Main ($n = 2153$) Second ($n = 559$) Overall frequency of diagnosis ($n = 2016$)
 Delirium 473 (22.0%) 187 (33.5%) 660 (32.7%)
 Dementia 438 (20.3%) 113 (20.2%) 551 (27.3%)
 Adjustment disorder 483 (22.4%) 46 (8.2%) 529 (26.2%)
 Depression 307 (14.3%) 57 (10.2%) 364 (18.1%)
 Psychotic illness 125 (5.8%) 29 (5.2%) 154 (7.6%)
 Alcohol 135 (6.3%) 26 (4.7%) 61 (3.0%)
 Bipolar affective disorder 17 (0.8%) 8 (1.4%) 25 (1.2%)
 Other 183 (8.6%) 93 (16.6%) 276 (13.7%)
 No diagnosis 92 (4.3%) n/an/a

Interventions and outcomes

In most cases, the referring team received advice on the patient's ongoing management and medication (*Fig. 1a*). No further intervention was provided in 546 (25.4%) of cases, while others received some further interventions from the service. These included transfers to a mental health unit ($n = 98$, 4.6%); referral for community mental health team (CMHT) follow-up ($n = 249$, 11.6%); referral to the Mental Health for Older Adults home treatment team (HTT; $n = 45$, 2.1%); and referral for psychological intervention or assessment ($n = 21$, 1.0%). Mental capacity was assessed in a total of 12.2% of patients (as the main intervention in 7% and as an additional intervention in the remaining 5.2% of cases). *Fig. 1* The main interventions and discharge arrangements. (a) Main intervention. (b) Discharge arrangements.

Following discharge from hospital, most patients returned to their homes (62.3%) and were followed up by their general practitioner (GP; 48.7%) (*Fig. 1b*). Of the total number of patients, 112 (5.2%) were discharged into an EMI (elderly mentally infirm) care home.

Service activity and outcome measures

As shown in *Table 3*, the service was highly responsive, particularly for urgent referrals, for which almost all patients were seen on the same day and many within 4 h. The achievement was lower for medium-urgency referrals (95.2% seen within 3 days) and low-urgency referrals (93.2% seen within 5 days). *Table 3* Service responsiveness, contacts and HoNOS rating Referrals ($n = 2153$) Seen within 1 day Seen within 4 h High 754 (99.5%) 754 (99.5%) Medium 969 (75.1%) 493 (38.3%) Low 36 (35.0%) 19 (18.4%) All referrals 1759 (81.7%) 1097 (50.9%) Contacts All patients ($n = 2153$) Single assessment 1141 (53.0%) Mean time under care (days) 9.7 (s.d. 15.23) Average number of contacts 2.6 (s.d. 3.269) Mean time spent with patient 152.3 min. (s.d. 170.894) Follow-up patients ($n = 1012$) Mean time under care (days) 17.06 (s.d. 19.550) Mean number of contacts 4.4 (s.d. 4.070) Mean time spent with patient 228.84 min (s.d. 221.971) HoNOS 65+ rating Mean initial HoNOS 65+ rating ($N = 1081$) 12.53 (s.d. 4.125); min 1, max 32 Mean paired HoNOS 65+ ratings ($N = 230$) Initial 14.65 (s.d. 3.919) On discharge 11.80 (s.d. 4.599) Difference – paired t -test: 10.035 (d.f. 229); $P < 0.001$ Difference – 95% CI 2.296–3.418

Table 3 shows that for those patients who were seen on more than one occasion, the service had a substantial number of contacts, and significant time was spent on their mental healthcare during their stays in the hospital.

The HoNOS 65+ rating scale was introduced in January 2013 as one of the outcome measures for the service. Analysis of this data (*Table 3*) indicates a significant degree of complexity of the cases seen by the service and a statistically significant improvement in HoNOS scores following input from the service.

Good clinical practice

New diagnoses of dementia made by the service were included in data collection from January 2013, and a record of antipsychotic reviews in people with dementia started in May 2013. Between January 2013 and December 2015, 273 patients with no existing dementia diagnosis (21.6% of all referrals) were identified with probable dementia that needed further assessment, and 51 patients (4.0% of all referrals) were diagnosed with a new diagnosis of dementia by the liaison service. Of 50 patients with dementia who were on antipsychotic medication at the time of referral, only one patient (2%) did not have his medication reviewed by the service.

Discussion

The results of this study indicate that the LPOA service at King's College Hospital, London, has continued to play an important part in mental health provision to adults aged 65 and over admitted to general hospital beds since its initial description.⁹ The total numbers of patients seen per year, their demographic characteristics and case mix have all remained comparable to those described in 2000/2001. The service has also maintained a good responsiveness, particularly for urgent referrals which, although not described in this data set, the service has extended into the emergency department and clinical decisions unit during this study period.

There are two significant points that have changed in service activity since the last review. First, there has been a marked increase in the number of patients with delirium seen by the service; second, there has been a significant decrease in the number of referrals for assessment of mental capacity. The first point is likely to be explained by new developments within the general hospital and the close relationship of the liaison service with the King's delirium and dementia team that was established in January 2013. This may have led to better recognition of delirium and targeted involvement of liaison psychiatry in management of complex cases for which there is diagnostic uncertainty requiring expertise in recognition, or where pharmacological management is required owing to risks to patients and others. The second point is likely to reflect increased awareness and improved skills of medical and surgical teams in assessing mental capacity following the introduction of the Mental Capacity Act 2005 and the increased training that followed this legislation. Our service has retained an important role in providing a second opinion in complex capacity assessments.

The results presented suggest that the service has played a part in discharge facilitation, with the majority of patients returning home and being followed up by their GP. Relatively small numbers of patients required referral to the CMHT, and for those already under CMHT care there was good liaison between respective mental health services. Only a small percentage of patients required transfer to psychiatric units, but this may have also been influenced by the development of an older adults' HTT in the last 3 years of the study period.

The National Dementia Strategy has included good quality of care within general hospitals as one of its key objectives for patients with dementia.¹³ Around 27.3% of patients seen had a diagnosis of dementia during the study period. This is in line with previous estimates that, at any time, up to a quarter of older patients in general acute hospitals will have dementia.¹⁴ Fifty-one patients were diagnosed with a new diagnosis of definitive dementia from January 2013 and included in the total number of cases. A further 20% of patients seen during the 3-year study period were suspected to suffer from dementia, with a discharge recommendation for further assessment. These data, and the fact that all but one patient with dementia and on antipsychotic medication had this reviewed by the service, suggest that the service engaged in important local and national initiatives for dementia diagnosis and care.

Until the recent introduction of the Framework for Routine Outcome Measurement in Liaison Psychiatry (FROM-LP), there had been no consensus on how to best capture the diverse activities, outcomes and performance of liaison psychiatry services.¹⁵ In addition, as was the case with this team, teams have often had small numbers of staff and limited administrative support, also limiting their capacity for routine outcome measure collection. Despite this, we have recognised the importance of monitoring activity in relation to further team development and during the study period have recorded referral response times and clinician-rated HoNOS 65+ outcome scores for all patients seen. Average HoNOS 65+ scores indicated that the patients seen had conditions of moderate severity and complexity, and a statistically significant improvement was seen in the patients for whom paired ratings were done. Although these are positive data, the extent to which the physical health domains and improvements contributed to positive outcomes is unclear, and this itself does not fully reflect all aspects of the service's activities and roles within the general hospital.

A recent review suggested that the FROM-LP is a very useful tool to measure service quality and clinical effectiveness, and represents a significant step towards developing nationally unified outcome measures.¹⁶ There is also an increasing expectation that outcome measures are available to secure funding and support liaison psychiatry service growth. In response to this, we have been collecting outcome measures as suggested by FROM-LP,¹⁷ as well as HoNOS 65+, since January 2016. However, from the outcome data collected so far, we have some concerns about the validity of the measures and also that they do not measure the aspects of LPOA services that have previously been shown to make them cost-effective. Economic analysis of the Birmingham RAID service suggested that elderly people in their sample accounted for around 90% of total savings with reduced bed usage. We therefore suggest that this is of particular importance for older adult liaison services, and that there is a strong economic case for targeting increased resources for this patient group. This would also support the case for developing specialist LPOA teams as a part of the national

strategy for improved liaison psychiatry services within the general hospital.

Strengths and limitations of the study

The strength of this study is that it provides a large data-set and reflects the everyday practice of a busy inner-city LPOA service. There is very little missing data, as collection was overseen and coordinated by a single practitioner who ensured that data were collected for all patients seen. As such, the study included a large number of patients, ensuring an adequate statistical power. It also gives a clear indication of the need for specific older adults' liaison teams, and indicates the scope for further development and analysis of outcome measures to support this and the cost-effectiveness of services.

This is a descriptive study and does not intend to compare the King's College liaison service for older people with other liaison service provision models for older adults. It is possible that an awareness of service monitoring by team members who were also responsible for data collection might have had an impact on the care provided, but arguably this is less likely as data collection is now a routine part of clinical practice within the team, and there is increasing emphasis on outcome measures and quality improvement activities. Another possible limitation is that the activities and outcomes of the team described in this paper may not be generalisable to other LPOA teams in the UK where the team structure or patient demographics differ.

Clinical implications

The results of this study support the need for specialist LPOA services for older people admitted to general hospitals. However, finding easily measurable outcomes of liaison psychiatry services remains a challenge if we are to find valid measures that also support the services in terms of identifying necessary developments and growth. The King's College Hospital LPOA team is now using the FROM-LP and will pilot the use of these outcome measures. However, we suggest that there are other aspects of service activity in older adult liaison that are not adequately monitored or audited using this framework. For this reason, we continue to use HoNOS 65+, as we feel that this provides a measure of complexity and also indicates improvement over time with paired scores. In terms of further development of outcome indicators for LPOA, we feel it is important to consider whether length of time from admission to referral to liaison affects overall length of stay, as this could help to provide information about cost-effectiveness of older adult liaison services. Similarly, we feel it will be important to measure the impact of training activities for general hospital staff in terms of raised awareness and timely referrals to the service.

1.5.30 Unlocking an acute psychiatric ward: open doors, absent patients?

Damian Smith MacDara McCauley

date

2018-6

Contents

- *Unlocking an acute psychiatric ward: open doors, absent patients?*

In their recent paper, Beaglehole and colleagues¹ reported on the effects of unlocking an acute psychiatric ward. Despite a 58% increase in unauthorised absences and an 8% increase in violent incidents, they concluded that a less restrictive environment had some positive effects, most notably a reduction in the total hours of seclusion per month.

Our service has recently undertaken a similar transition from a locked acute ward opened (and locked) in the 1930s, to an unlocked newly built unit opened in 2016. When comparing the 6 months before and after this transition, we too found that the rate of unauthorised absences increased by 100% from a mean of 4 to 8 per month. Unlike Beaglehole, however, we observed a decrease in rates of violent incidents by 27.4% (from a mean of 31.7 to 23 per month), and an increase in the total hours of seclusion per month by 213.4% (from a mean of 28.21 to 88.42 hours per month). Of note, admission rates increased from a mean of 20 to 23 per month during the same time period.

Although a reduction in the rate of violent incidents (and, in the case of Beaglehole, reduced levels of seclusion) strengthens the case for provision of care in unlocked settings, should we be concerned about the increased rate of unauthorised absences found in both studies?

The largest available study on this topic² would suggest not. In their 15-year observational study involving 145,738 German in-patients, Huber *et al* concluded that locked doors do not prevent suicides, or indeed unauthorised absences.

Although a rare event, suicide is undoubtedly one of the most feared outcomes when any patient absconds. Preventing harm to self or others is often the main rationale for in-patient admission. It is also a ubiquitous criterion for involuntary admission. Consequently, preventing harm is one of the main motives for locking psychiatric units.

In our study, 86% of unauthorised absences over the 1-year study period were by involuntarily admitted patients. In opening our doors, are we doing these individuals a disservice by giving them the opportunity to leave hospital at a time when they are most unwell?

Previous studies have reported on the negative consequences of absconding for patients (interrupted treatment, suicide), staff (anxiety), family members (loss of trust in the service), and emergency services (expended resources).³ It could be argued that a reduction in the number of violent incidents (and, in Beaglehole's case, seclusion) is worth the risk of these adverse outcomes. In our view, however, a modern purpose-built environment coupled with increased staffing levels better explains these findings. Increased numbers of nursing staff result in improved relational security, an important element of therapeutic security provided by higher staff-to-patient ratios.⁴

Our study and that of Beaglehole and colleagues indicate that unlocking acute psychiatric wards leads to an upsurge in unauthorised absences. The majority of patients who absconded were admitted involuntarily. We suggest that acute mental health services give careful consideration to all the risks associated with unauthorised absences before opening their doors. This is of particular relevance given that rates of involuntary admission are on the rise.⁵

1.5.31 Against the Stream: religion and mental health – the case for the inclusion of religion and spirituality into psychiatric care

Simon Dein

Correspondence

Simon Dein (s.dein@qmul.ac.uk)

date

2018-6

Abstract

This paper argues for the inclusion of religion and spirituality in psychiatric care. After discussing the antagonism of psychiatrists and psychologists to religion, I present a critical overview of studies examining the relationships between spirituality, religion and diverse aspects of mental health: depression, suicide, anxiety, delinquency, drug abuse and schizophrenia. The need to assess the impact of religion in different faith groups is discussed. Measures of religious coping, both positive and negative, may provide a more accurate portrayal as to how individuals deploy religion in their lives than global measures such as belief and attendance. I highlight the fact that there is a dearth of research on ritual, prayer and other aspects of religious experience. While many studies demonstrate positive effects of religion on mental health, others find detrimental effects. Finally I examine the clinical implications of these findings.

- *Against the Stream: religion and mental health – the case for the inclusion of religion and spirituality into psychiatric care*
 - *Recent findings*
 - *Criticisms*
 - *Clinical implications*
 - *Conclusion*

Psychiatry and religion have traditionally had a difficult relationship. The views of Freud and others such as Albert Ellis have negatively affected the attitudes of mental health professionals pertaining to the mental health effects of religion. Religious beliefs and practices are widely seen to be ‘primitive’, dependency forming, guilt inducing, non-empirical and necessarily bad for mental health. However, compared with psychologists and psychiatrists, the patients consulting them have been found to have higher levels of religiosity – there is a so called ‘religiosity gap’ between mental health professionals and those they treat.¹ For many people, religion is not only important in their lives but the central aspect of coping with life stresses. There is, moreover, evidence that psychiatrists tend to ignore religion; it is rarely part of standard psychiatric assessment and treatment. As Rosmarin *et al* state²: “[R]eligious beliefs are often ignored in the context of treatment as mental health professionals are often ill-trained in the assessment of these factors in clinical settings. This deficit creates a reticence to broach this topic in psychiatric research and practice, which in turn perpetuates assumptions throughout the field that these facets are tangential to human functioning and a side issue

in treatment. Protocols for assessment seem to ignore religious beliefs and there seem to be few interventions that take account of religious and spiritual beliefs.”

Here I argue against the assumption that religious beliefs are largely irrelevant to clinical psychiatric practice.

Recent findings

In the past 20 years, there has been escalating research focusing on the relationships between various dimensions of religiosity and mental health. To date, several thousand studies demonstrate positive associations between the two.³⁻⁴ Results indicate that those who are more religious generally fare better in terms of mental health.

The presence of religious faith is associated with greater hope, increased sense of meaning in life, higher self-esteem, optimism and life satisfaction. In terms of depression, Koenig (2012) reports that of 70 prospective cohort studies, 39 (56%) indicated that greater religion/spirituality (R/S) predicted lower levels of depression or faster remission of depression, seven (10%) predicted worse future depression and seven (10%) reported mixed results (both significant positive and negative associations depending on R/S characteristics).⁵ Higher religiosity has also been associated with lower rates of suicide,⁶ reduced prevalence of drug and alcohol misuse,⁷ and reduced delinquency.⁸ Findings in relation to anxiety are rather mixed. Although some studies demonstrate reduced anxiety rates, others indicate that anxiety levels are increased in the more religious.⁹ There are few studies relating schizophrenia to R/S. Recent studies from Switzerland suggest that religious individuals with psychotic illnesses frequently pray and read the Bible to facilitate coping with their voices, and that higher levels of religiosity may increase medication adherence.¹⁰ Little work has been conducted on explanatory models, treatment-seeking and outcomes in this condition.

Although the focus of the existing literature on religion and mental health predominantly relates to Christianity, there has been recent work on Islam,¹¹ Judaism¹² and Hinduism,¹³ similarly suggesting that those who are religious have better indices of mental health. Furthermore, these studies suggest that religious beliefs have different effects on mental health depending upon the faith group of subjects.

Global measures of religion such as belief may reflect dispositional religiousness rather than how people actually deploy religion during crises. As Pargament and colleagues¹⁴ (p. 521) state, ‘It is not enough to know that the individual prays, attends church, or watches religious television. Measures of religious coping should specify how the individual is making use of religion to understand and deal with stressors.’ There is evidence that some forms of religious coping are protective in the wake of adverse life events, while others may be maladaptive. This author contends that there are two sorts of coping: positive religious coping and negative religious coping.¹⁵ The former (e.g. benevolent religious appraisals, religious forgiveness) reflects a secure relationship with God and generally results in improved mental health. By contrast, the latter (e.g. reappraisals of God’s powers, feeling abandoned or punished by God) reflects a weak relationship with God and is associated with worse mental health indices. There is some recent discussion of the psychological implications of theodicy – the defence of God’s goodness and omnipotence in view of the existence of evil.¹⁶

There is a dearth of research examining the mental health effects of ritual, prayer and other aspects of religious experience. Although popularised in William James’ classic *The Varieties of Religious Experience*,¹⁷ religious experience has attracted less research than attendance, beliefs and coping, possibly because of its subjective nature and lack of clarity in definition. The focus has been on three main areas: mysticism, conversion and religious hallucinations. Religious conversion has generally been found to enhance mental health. There are phenomenological parallels between mystical and psychotic states (including visions, voices, loss of sense of self) although the outcomes are different. While mystical experiences typically affect mental health positively, psychosis is generally a negative experience.¹⁸ There has been some phenomenological research on hearing God’s voice among Pentecostal Christians in London. Among this group, hearing his voice is normative and many reported its utility in resolving distress.¹⁹ Finally, one study examined the differences between prophecy and loss of agency and thought insertion in schizophrenia. In contrast to schizophrenia, in prophetic experiences agency is preserved.²⁰

However, religion may also have a negative effect on health through inducing guilt and dependency, and in extreme cases may precipitate suicide (e.g. in extreme cultic groups).²¹ Of great contemporary interest, the wider social impact of mental health on radicalisation remains to be investigated. Bhui has provided initial data suggesting that among

Pakistani and Bangladeshi Muslims, those endorsing the most sympathy for violent protest and terrorism were more likely to report depression.²²

Criticisms

There have been a number of criticisms of the above findings.²³ First, there may be selection biases in recruiting subjects. Second, more work needs to be conducted on the non-religious and their mental health associations, including atheism and agnosticism.²⁴ Third, the vast majority of these studies have focused on religious attendance and beliefs among North American Christians, and findings cannot be generalised to other religious groups. Fourth, some people are spiritual – connected to a higher power from which they derive meaning – although not belonging to and participating in institutionalised religion. The similarities and differences between religion and spirituality warrant further research, as do the associations of spirituality with mental health. Finally, measurement scales need to be more culturally and theologically sensitive.²⁵

Clinical implications

Given the above findings, what are the clinical implications? It is clear that the assessment of religious belief should be included routinely in psychiatric assessment. It may be that the incorporation of religious activities such as prayer, Bible reading and ritual into cognitive-behavioural therapy (CBT) could enhance its effectiveness. Evidence suggests that Christian-based CBT is more effective among Christian patients with depression and anxiety than traditional non-religious CBT.²⁶ Future work in this area should concentrate on which therapies are efficacious, for which patients, and which therapists should be conducting them. Pargament provides a number of illustrative examples of how spirituality can be incorporated into psychotherapy.²⁷

Conclusion

There is now a voluminous literature examining the relationship between religion and mental health. On balance, it appears that being religious enhances mental health. Future work in this area needs to explore the clinical implications of these findings, and how working with patients' theological constructs such as guilt, sin and forgiveness helps to promote recovery. Most importantly, both clinical work and research need to be more sensitive to cultural and theological issues.²⁸ The Royal College of Psychiatrists²⁹ and the WPA³⁰ have published two Position Statements on spirituality, religion and clinical care.

1.5.32 Prevalence of vitamin D deficiency in adult patients admitted to a psychiatric hospital

date

2018-6

Abstract

Aims and method

Vitamin D deficiency is increasing in the general population, and is linked with physical and mental illness. However, evidence on its prevalence in people with mental illness is limited. This study investigated vitamin D deficiency in 104 adult patients admitted to a psychiatric hospital in the UK.

Results

Forty-nine per cent were vitamin D deficient (serum 25(OH)D <30 nmol/L), and a further 42.3% were vitamin D insufficient (<50 nmol/L). On admission, 8.7% of patients were vitamin D sufficient (>50 nmol/L). There were no statistically significant differences in mean serum vitamin D between different subgroups of mental illness.

Clinical implications

Vitamin D deficiency is highly prevalent among individuals with severe mental illness admitted to hospital. Assessment and treatment of vitamin D deficiency should be considered in in-patients to protect musculoskeletal health. Further epidemiological and intervention studies are needed to investigate the role of vitamin D in the pathophysiology of mental disorders.

Declaration of interest

- *Prevalence of vitamin D deficiency in adult patients admitted to a psychiatric hospital*
 - *Method*
 - *Results*
 - *Discussion*

It has been known for many years that severe vitamin D deficiency increases the risk of metabolic bone disease, particularly rickets and osteomalacia, and that moderate vitamin D deficiency leads to an increased risk of osteoporosis and fractures.¹ More recently, observational studies have provided growing evidence of an association between vitamin D deficiency and an increased risk for many chronic diseases, including autoimmune diseases, some cancers, cardiovascular disease, infectious disease and type 2 diabetes.² The serum level of 25-hydroxyvitamin D (25(OH)D) is the most accurate reflection of an individual's vitamin D status. The National Osteoporosis Society's guidelines define serum

25(OH)D levels <30 nmol/L as deficient, 30–50 nmol/L as inadequate in some people, and >50 nmol/L as sufficient for almost the whole population.³ Vitamin D receptors are found in nearly all tissues of the body, including both neuronal and glial cells in the central nervous system and multiple areas of the human brain, including the prefrontal cortex, hippocampus, cingulate gyrus, thalamus, hypothalamus and substantia nigra, many of which have been implicated in the pathophysiology of mental illnesses such as depression and psychosis.⁴ At a molecular level, vitamin D is known to have numerous roles in nervous system health and disease. Animal models have increased our knowledge and understanding of the mechanisms by which vitamin D deficiency affects brain development and its subsequent influence on adult psychiatric and neurological disease. There is evidence that vitamin D has important roles in neurodevelopment, neuroprotection and neuroplasticity, not only by exerting its biological function directly, but also by influencing the expression of genes at a cellular level.⁵ Evidence on its prevalence in people with mental illness, in the UK, is limited. This study investigated the prevalence of vitamin D deficiency among adult patients being admitted to a psychiatric hospital in the UK, to ascertain how widespread and severe it is among our patients, and to further assess whether there are stronger associations with certain subgroups of illness such as depressive or psychotic disorders.

Method

This was a cross-sectional study, designed as a pilot, to estimate the prevalence of vitamin D deficiency in patients admitted to a psychiatric hospital, and to ascertain any associations between severity of vitamin D deficiency and severity and subclass of mental illness, in addition to environmental and social demographic factors.

Ethical approval was gained from the National Health Service (NHS) Health Research Authority via the Edgbaston Research Ethics Committee, reference 15/WM/0434. Management permission was sought and gained from the host research and development department at Leicestershire Partnership NHS Trust.

A total of 153 patients were admitted to the general adult wards of the unit, between 17 February 2016 and 23 April 2016, and were eligible for inclusion in the study. One hundred and thirty seven individuals had capacity to consent, of which 104 provided informed written consent. Vitamin D levels were requested alongside standard admission blood tests on serum samples collected by venepuncture. Plasma vitamin D levels of serum samples were analysed in the local pathology laboratory, using Siemens Centaur XP analysers with acridinium ester chemiluminescence technology.

Vitamin D deficiency was defined as a serum 25(OH)D level of below 30 nmol/L, insufficiency was defined as a serum 25(OH)D level of 30 nmol/L or above but less than 50 nmol/L, and vitamin D sufficiency was defined as a serum 25(OH)D level of 50 nmol/L or above.

Primary clinical diagnosis using ICD-10 criteria, ethnicity, gender, age and length of stay were subsequently obtained from participants' electronic in-patient medical records.

Data were initially input and analysed using Microsoft Excel, and further descriptive analysis was conducted on IBM SPSS version 20. The Mann–Whitney U test was used to compare means between different samples.

Results

A total of 104 participants were included in the study; 51% ($N = 53$) were male and 49% ($N = 51$) were female. As shown in *Table 1*, the mean age of the cohort was 40.6 years, and the median age was 39.5 with a range from 18 to 79. In terms of ethnicity, 76% ($N = 79$) of participants were White British, 11.5% ($N = 12$) were British Asian, 5.8% ($n = 6$) were Black British, 3.8% ($N = 4$) were of any other White background and 2.9% ($N = 3$) were of other Asian background. *Table 1* Demographic and clinical characteristics of the population sample

Demographic and clinical characteristics of population sample ($N = 104$)	Age, years	Mean	40.6	Median	39.5	Range	61	Minimum	18	Maximum	79	Gender	Frequency	%	Female	51	49	Male	53	51	Total	104	100	Ethnicity	Frequency	%						
White British	79	76	British Asian	12	11.5	Black British	6	5.8	Any other White Background	4	3.8	Other Asian Background	3	2.9	Total	104	100	Primary diagnosis	Frequency	%												
Depressive episode	29	27.9	Bipolar affective disorder	18	17.3	Schizophrenia	18	17.3	Personality disorder	14	13.5	Acute or unspecified psychotic disorder	7	6.7	Psychoactive substance-related disorders	7	6.7	Schizoaffective disorder	5	4.8	Anxiety disorder	3	2.9	Delusional disorder	2	1.9	Eating disorder	1	1	Total	104	100

In the sample studied, mean serum 25(OH)D was 31.9 nmol/L, and median serum 25(OH)D was 32.0 nmol/L, with a range from <15 nmol/L to 81 nmol/L.

There were no statistically significant differences noted in mean serum 25(OH)D associated with gender, age or primary diagnosis. As shown in *Table 2*, individuals with a primary diagnosis of schizophrenia were noted to have the lowest mean serum 25(OH)D of 29.5 nmol/L, while those with bipolar affective disorder had the highest mean serum 25(OH)D level of 33.8 nmol/L. Mean serum 25(OH)D was higher in participants of White British ethnicity compared with those of other ethnic backgrounds. *Table 2* Mean vitamin D in subgroups Serum vitamin D, nmol/L (N, s.d.)

Whole sample	Mean	31.9	104	13.5	Median	32	Minimum	15	Maximum	81
Gender	Female	32.15	114	14.1	Male	31.75	133	13.2	Primary diagnosis	
	Bipolar affective disorder	33.81	181	7.2	Personality disorder	33.51	141	15.8		
Depressive episode	31.42	99	9.4	Schizophrenia	29.51	181	10.3			
	Ethnicity	White British	33.27		91	13.7	British Asian	28.51	121	13.9
		Black British	28.86		14	Any other White background	23.54	62	Other Asian background	28

As shown in *Fig. 1*, 49% ($N = 51$) of participants were vitamin D deficient (serum 25(OH)D <30 nmol/L), and a further 42% ($N = 44$) were vitamin D insufficient (<50 nmol/L); 8.7% ($N = 9$) of participants were vitamin D sufficient (>50 nmol/L). *Fig. 1* Percentage of participants found to be vitamin D deficient, insufficient and sufficient ($n = 104$).

Although not statistically significant, mean length of stay in participants with vitamin D deficiency (<30 nmol/L) was 45.4 days, 8 days longer than those without deficiency ($P = 0.23$).

Discussion

To our knowledge, this is the first study to assess prevalence of vitamin D deficiency in patients admitted to a general adult psychiatry unit in the UK. We found a very high prevalence of vitamin D deficiency in patients with mental illness being admitted to psychiatric hospital, with a total of 49% being deficient and a further 42% being insufficient in vitamin D.

The reported prevalence in our study was greater than that found in psychiatric in-patient samples in Australia (58% less than 50 nmol/L),⁶ New Zealand (74% less than 50 nmol/L)⁷ and North America (52.3% less than 50 nmol/L),⁸ and in an out-patient sample in Northern Europe (56% less than 50 nmol/L).⁹

The prevalence of vitamin D deficiency in our study was higher, and the mean serum vitamin D considerably lower, than in the general population in the UK. Results from the National Diet and Nutrition Survey reported a mean serum 25(OH)D of 34.8 nmol/L and a 39.3% rate of deficiency (<25 nmol/L) in 19–64 year olds between the months of January and March, while individuals 65 years and older had a mean serum 25(OH)D of 40.5 nmol/L and a 29.3% rate of deficiency.¹⁰

In this study, although the differences were not statistically significant, of the four most common diagnostic groups, we found that participants in our sample with a primary diagnosis of schizophrenia had the lowest mean serum vitamin D of 29.5 nmol/L. This finding has been replicated in other studies. A trend towards lower vitamin D levels in individuals with schizophrenia has been reported in a study of psychiatric out-patients,¹¹ while a mini meta-analysis of seven studies found that individuals with schizophrenia had a medium effect size for lower vitamin D compared with healthy controls, and also a trend for lower vitamin D levels in comparison with other psychoses.¹²

The UK has an insufficient intensity of ultraviolet sunlight to enable cutaneous synthesis of vitamin D over the winter months, between October and April, thus resulting in the vitamin D status of the UK population peaking in September but then falling continually until the start of the following summer in May, when levels begin to rise again.¹³ Historically, vitamin D deficiency has been linked to metabolic bone disease, specifically serum concentrations of <20 nmol/L being associated with clinical osteomalacia in adults and rickets in children.¹⁴

It is unclear why the prevalence of vitamin D deficiency found in this study was higher compared with the general population. In addition to cutaneous synthesis during the summer months, vitamin D can be obtained from the diet, but only a few foods such as fatty fish are good sources of vitamin D.¹ Although institutionalisation in this case would not be a contributing factor, as the participants were newly admitted, it could be hypothesised that people with mental illness are less likely to be spending time outdoors in sunshine and thus produce less endogenous vitamin D over the summer months.

National Institute for Health and Care Excellence and Department of Health guidance identifies the need for vitamin D supplements to be taken by certain at-risk groups, namely all pregnant and breastfeeding women, particularly teenagers and young women; infants and children under 5 years old and people over 65 years old; people who have low or no exposure to the sun, i.e. housebound individuals; and people who have darker skin, for example, people of African, African–Caribbean and South Asian origin.

In a change to previous advice, Public Health England revised its guidelines in 2016, based on a report by the Scientific Advisory Committee on Nutrition. The report recognised the growing prevalence of vitamin D deficiency and is now recommending a reference nutrient intake for vitamin D of 10 g/day (400 IU/day) throughout the year, for everyone in the general UK population aged 4 years and above, to ensure that the majority of the UK population has enough vitamin D to protect musculoskeletal health year-round.¹⁵

Our study has some limitations in terms of its generalisability to the wider population. A total of 104 participants were included, representing a relatively small sample size. Of 153 potential participants, informed consent was obtained from 104 individuals, which could have affected results. As the study was cross-sectional in design, no firm conclusions can be made regarding vitamin D deficiency, mental illness and the direction of causality if present. Our study was also limited to participants being admitted to a single unit. Finally, the study was conducted during the winter months; thus, the reported prevalence of vitamin D deficiency would be affected by sun exposure if the study was conducted towards the end of summer.

Based on this study, in which almost half of the participants admitted to psychiatric hospital were found to be deficient in vitamin D, assessment and treatment of vitamin D deficiency by oral supplementation should be considered to protect musculoskeletal health, alongside other physical health interventions, in patients with mental illness admitted to psychiatric wards.

The NHS Five Year Forward View for mental health has recognised the importance of preventable physical health problems in people with severe mental illness,¹⁶ and thus musculoskeletal health should be optimised where possible.

At the current time, there is insufficient evidence to draw any firm conclusions regarding an association between vitamin D deficiency and non-musculoskeletal health outcomes, including mental illness. More research in the form of larger epidemiological and intervention studies are needed to investigate the association between vitamin D and mental health outcomes; indeed, randomised controlled trials are planned that will hopefully shed more light on this intriguing area in the future.

We would like to thank Dr David Clarke, Operational Lead (Research and Development), Leicestershire Partnership NHS Trust, for his invaluable support and guidance.

Abstract

Aims and method

Caring for patients with personality disorder is one of the biggest challenges in psychiatric work. We investigated whether mentalisation-based treatment skills (MBT-S) teaching improves clinicians' understanding of mentalising and attitudes towards personality disorder. Self-report questionnaires (Knowledge and Application of MBT (KAMQ) and Attitudes to Personality Disorder (APDQ)) were completed at baseline and after a 2-day MBT-S workshop.

Results

Ninety-two healthcare professionals completed questionnaires before and after training. The mean within-participant increase in scores from baseline to end-of-programme was 11.6 points (95% CI 10.0–13.3) for the KAMQ and 4.0 points (1.8–6.2) for the APDQ.

Clinical implications

MBT-S is a short intervention that is effective in improving clinicians' knowledge of personality disorder and mentalisation. That attitudes to personality disorder improved overall is encouraging in relation to the possibility of deeper learning in staff and, ultimately, improved care for patients with personality disorder.

Declaration of interest

Personality disorder is of major clinical importance: a third of psychiatric out-patients and over half of in-patients are estimated to fulfil the criteria for personality disorder.¹ Borderline personality disorder (BPD) is the most prevalent personality disorder in the non-forensic setting^{2,3} and is associated with intensive use of psychiatric services and frequent admissions.^{4,5} Caring for patients with BPD can be experienced as emotionally challenging,^{6,7} and these patients are perceived by some clinicians to be manipulative, attention-seeking or threatening,⁸ making it hard to maintain a therapeutic stance towards them. In turn, patients may experience staff as prejudicial and unhelpful.¹ Negative staff attitudes towards personality disorder are associated with poorer therapeutic relationships, reduced standards of care and overall poorer outcomes.^{7,9}

Mentalisation-based treatment

A central component of BPD is that of a hypersensitive attachment system.¹⁰ At times of stress, patients will more readily seek proximity with a caregiver. Yet the behaviours that sometimes accompany this proximity-seeking, such as self-harm or suicidal acts, can seem irrational and frustrating to the caregiver, who might then lose their own ability to mentalise, for example, through the development of a judgemental attitude towards the patient or a belief that they are undeserving of care.

Mentalising in the context of generic mental health services

A mentalising stance involves having an inquisitive, empathic, open-minded and ‘not-knowing’ approach to mental states, and an ability to consider alternative perspectives. Mentalisation-based treatment (MBT) provides a framework to help healthcare staff understand their attitudes and feelings, and teaches ways to restore mentalising in both the professional and the patient. Bateman suggests that effective MBT skills can be gained through limited additional training and with moderate levels of supervision.¹¹

Teaching mentalising skills

There has been a recent governmental drive to improve systems for staff support and supervision in managing these patients, and to develop courses teaching staff to better address patients' needs.¹⁻⁷ In that spirit, a 2015 pilot study found that a brief (4 h) teaching intervention in MBT skills improved psychiatry core trainees' understanding of mentalising and their attitudes to personality disorder.¹³ To test whether this finding is replicated in a larger sample and whether it generalises to other professional groups, we conducted a before-and-after comparison of mental healthcare staff who underwent a 2-day course in MBT skills (MBT-S). To our knowledge, this is the first published quantitative evaluation of MBT-S. It addresses an important clinical question: alongside MBT constituting a specialist treatment, does a mentalising skills intervention provide an accessible theoretical framework for staff working in generic mental health settings?

Method

Participants

Participants in the MBT-S courses included doctors, nurses, psychologists and allied healthcare professionals working in various mental health services within NHS Lothian. Once a clinical team was identified by the course leaders as potentially able to benefit from the course, all staff members working in that service were invited to take part in the training. In some cases, individuals and teams self-selected to attend the training.

All participants attending the first day of training were eligible to be included in the study. Participants who only attended the second day were excluded.

Intervention

MBT-S is aimed at generic mental health practitioners and is taught in an accessible format to help staff in difficult day-to-day interactions, with the aim of fostering more effective therapeutic relationships with their patients. The teaching is based on a MBT skills package developed by the Anna Freud Centre¹⁴ in conjunction with MBT Scotland. It was adapted by two of the authors (J.P. and C.M.), and these adaptations were authorised by the Anna Freud Centre.

The MBT-S training was delivered on two single days separated by a few weeks to allow participants to practise their skills and complete allotted tasks. The format was a combination of didactic teaching, role-play and DVD clips. It included a theoretical framework that explains attachment theory and how personality disorder and mentalising difficulties develop, as well as specific MBT techniques designed to strengthen both the patient's and the professional's ability to mentalise in stressful situations. The training was delivered in the Psychotherapy department at the Royal Edinburgh Hospital by Anna Freud Centre-accredited trainers, including two of the authors (J.P. and C.M.).

Aims

This study aimed to answer the following questions. (a) Is a 2-day course in MBT-S effective in improving general mental health practitioners' understanding of mentalising? (b) What effect, if any, does it have on their attitudes to personality disorder? (c) How do different professional groups compare in terms of outcomes?

Outcomes

Anonymised self-report questionnaires were given to participants by the study authors immediately prior to commencing the programme and again directly after the programme ended. Data on the participants' professional groups were collected from five of the six training courses.

The main outcome measure was the Knowledge and Application of MBT Questionnaire (KAMQ; see Appendix 1) (A. Williams, C Cahill, J Patrick, personal communication, 2015). This 20-item questionnaire asks about knowledge of MBT (e.g. 'A key component of mentalising is thinking about people's attachment relationships') and how to apply MBT techniques, using a five-point Likert scale from 'strongly disagree' to 'strongly agree'. A higher score indicated better knowledge of mentalising concepts and MBT techniques, with a maximum total score of 100 points. Work is currently in progress describing the development of this questionnaire and evaluating its psychometric properties.¹⁵

The secondary measure was the Attitudes to Personality Disorder Questionnaire (APDQ; see Appendix 2), which measures clinicians' attitudes towards people with personality disorder. This questionnaire has 37 items that ask about the intensity of a person's feelings (e.g. 'I feel understanding towards people with personality disorder') using a six-point Likert scale, from 'never' to 'always'. A higher score indicated a more positive attitude, with a maximum score of 222 points. The APDQ has good internal consistency (Cronbach's alpha = 0.94) and test-retest reliability ($r = 0.71$).¹⁶

Statistical methods

Data were entered into MS Excel by three authors (H.J.W., G.C. and C.M.M.). They were analysed by author T.C.R. using R for Windows 3.2.3. Linear regression was used to compute within-person change in score from baseline to end-of-programme for the KAMQ and APDQ separately. We used unadjusted models to explore the changes in scores over time and then constructed models adjusting for job category (whether different groups had differences in scores at baseline, i.e. had different intercepts) and an interaction term between job category and time (whether different professional groups were affected more than others over time, i.e. had different slopes). Effect sizes (Cohen's D) were calculated in order to examine the magnitude of difference between pre- and post-scores.

Missing data

An intention-to-treat analysis was carried out. Missing items at baseline were assumed to be missing at random, and the mean score among all responders for that item was entered. For missing end-of-programme items, baseline values were carried forward.

Results

Six training courses, with a median 16 participants each (range 12–19), were carried out between June 2014 and March 2016. Across all six courses, a total of 92 participants attended the first day of training and so were eligible for the study. All 92 were enrolled and completed the baseline questionnaires. Two participants attended the second day of training only and were excluded from the study.

Across all baseline questionnaires, 77 individual items (1.46% of the total baseline data) were left blank and imputed (mean) values inserted.

Across all completed end-of-programme questionnaires, 139 individual items (2.65% of the total end-of-programme data) were left blank. Eight end-of-programme questionnaires were not completed as the participant did not attend; this accounted for 8.69% of the total end-of-programme data. All end-of-programme missing data were treated in the same way, with their baseline scores being carried forward.

A *post hoc* power calculation suggested that our sample size of 92 at conventional levels of statistical significance ($\alpha = 0.05$) would have 80% power to detect a small effect size (0.2).

Data on professional groups

Data on professional groups were not collected for the first of the courses (June 2014) but were collected for all subsequent courses. The 74 participants whose job title was known were categorised according to professional background. The biggest group was nursing, representing 46 (62%) participants. The second largest group was psychology with 12 participants (16%), and the third largest was medical, with eight participants (11%). Other professional backgrounds included occupational therapist ($N = 3$), art therapist ($N = 3$), social worker ($N = 1$) and recreation assistant ($N = 1$).

For the regression analyses using professional groupings, we compared participants with medical and psychology backgrounds with those with a nursing background, to allow large enough samples for the analyses. The justification for combining these two groups was that there are likely to be parallels in the experience and training of participants with a medical and psychological background in relation to personality disorders. The comparison with participants from a nursing background was thought to be of interest. We excluded the smaller groups.

Outcomes

Knowledge and Application of MBT Questionnaire

The mean KAMQ score at baseline was 74.7 points (s.d. = 7.6). There was a mean within-person increase of 11.6 points (95% CI 10.0–13.3) from baseline to end-of-programme. The effect size was 1.2, which was considered a large effect.

Attitudes to Personality Disorder Questionnaire

The mean APDQ score at baseline was 148.7 points (s.d. = 12.3). There was a mean within-person increase in APDQ scores from baseline to end-of-programme of 4.0 points (95% CI 1.8–6.2). The effect size was 0.2, which was considered a small effect. In 23 cases, there was no change in APDQ scores from baseline to end-of-programme; in 42 cases, the scores improved, and in 27 cases, APDQ scores worsened (*Fig. 1*). *Fig. 1* Jacobson plot of within-person change in KAMQ and APDQ scores. Markings above the oblique line indicate an increase in scores from baseline to end of programme.

Participants with a medical and psychological professional background had better baseline KAMQ scores when compared jointly with those with a nursing background, but their APDQ scores increased to a lesser degree after the teaching compared with nurses (see *Table 1*). *Table 1* Linear regression model including fixed effects for time and professional group (doctors and psychologists *v.* nurses) and an interaction term between job category and time
 KAMQAPDQD-difference in baseline scores: doctors and psychologists *v.* nurses

 4.8 (CI 5.1 to 14.8)
 4.8 (CI 9.5 to 0.1)

Discussion

Interpretation of results

The main finding of our study is that MBT-S training improved mental healthcare professionals' KAMQ scores to a statistically significant degree and with a large effect size, suggesting that it is an effective way of teaching MBT concepts to staff working in generic mental health settings. Furthermore, this finding is in keeping with recent qualitative research that demonstrated that nursing staff who participated in an MBT-S course felt that it provided a 'straightforward but empowering skill set' in working with patients with personality disorder.¹⁷

Attitudes to personality disorder improved overall to a lesser, albeit still statistically significant, degree. By definition, attitudes are somewhat engrained in someone's personality and professional way of working, so they may, of course,

be hard to shift. It is interesting that in 27 cases, the APDQ scores worsened. Although we cannot rule out the possibility that the intervention might have resulted in a genuine worsening of a minority of participants' attitudes towards personality disorder, we think it is plausible that this reflects participants' increased awareness and acceptance (i.e. mentalisation) of negative feelings towards patients (c.f. limitations of the study, below). Alternatively, this may represent an artefact of test–retest reliability.¹⁶

We note the finding that doctors' and psychologists' APDQ scores improved less than those of nurses. Baseline APDQ scores were higher for doctors and psychologists, so it may be that we are seeing a 'ceiling effect' – there is less room to improve from a higher baseline. In the context of previous research,¹³ we think the salient point is that this intervention appeared to be effective for professional groups other than doctors in training.

Comparison to other literature

The only other study to date to evaluate staff knowledge and application of MBT following MBT skills training was a pilot study that also demonstrated an improvement in KAMQ scores with large effect.¹³

A number of studies have assessed the effect of training on staff attitudes to personality disorder. In a randomised controlled study, Clarke *et al*¹⁸ compared a psychoeducation programme with an intervention designed to help mental healthcare staff deal with the difficult feelings triggered by working with personality disorder patients (acceptance and commitment training). Participants had responded to an advertisement and volunteered for the free 2-day training. Both forms of training were found to significantly improve APDQ scores immediately post-training compared with baseline (based on their data, we have calculated Cohen's D to be 0.28 and 0.22 respectively), with no statistical difference between the two. The improvements were sustained at 6 months follow-up, although there was a high rate of drop-out resulting in a loss of statistical power.

A study assessing the effects of a 2-h personality disorder awareness workshop on prison staff ($N = 26$) found no significant difference in APDQ scores before and 2 months after the training.¹⁹

In a systematic review of interventions aimed at improving mental health nurses' skills, attitude and knowledge related to patients with BPD, Dickens *et al*²⁰ reviewed eight studies whose interventions ranged from a 90-min lecture to the complete 18-month intensive dialectical behaviour therapy training. None of these studies used the APDQ as an outcome measure. They found that changes in affective outcomes (including attitudes to personality disorder) were usually associated with small effect sizes, although changes in cognitive outcomes (including knowledge) were associated with larger effect sizes.

The outcomes of these studies indicate that these different forms of intervention have generally resulted in small improvements in participants' attitudes and emotional responses to personality disorder, but greater improvements in their knowledge relating to personality disorder. The ability to compare these outcomes with the present paper is limited owing to the use of different methodologies and the absence of studies that directly compare MBT-S with other interventions. Within this limitation, we note that the size of outcomes from the comparative literature mirror the results of the present intervention, MBT-S. This may confer preliminary support for the comparable efficacy of MBT-S.

Strengths and limitations of the study

To our knowledge, this is the largest quantitative study to evaluate the effects of MBT-S on clinicians. Strengths of the study include the low study drop-out rate (8.7%) and the intention-to-treat analysis.

One possible limitation is linked to the choice of questionnaire. The APDQ has no formal validity data, which limits the interpretation of our results. In addition, the APDQ relies on participants' reporting of feelings: the reporting of positive feelings is linked to a 'better' attitude, while the reporting of negative feelings is linked to a 'worse' attitude. Yet for clinicians, being aware of negative feelings towards patients is likely to be helpful, as it gives them a chance to consider and reflect on their responses, and makes them less likely to act on feelings in a counter-therapeutic way.²¹ A lower APDQ may not, therefore, indicate a less helpful clinician stance, and *vice versa*. Work is needed to establish benchmarks for the KAMQ – i.e. what constitutes a 'good' level of knowledge about mentalising.

That the training was delivered by two of the study's authors introduces the risk of bias. Data entry and analysis were performed by authors who had no role in the delivery or running of the courses, limiting this risk. Some individual participants and mental health teams self-selected to attend the training, which introduces a potential confounding factor. The internal validity would be improved by having a control group. This would pose some practical problems, not least the challenge of providing a convincing 2-day 'placebo' training. An alternative would be to have a practice-as-usual control group, who only complete the outcome measures.

There has so far been no longitudinal follow-up of the study's participants. Therefore, we cannot comment on whether the effects of training persist.

Research and clinical practice implications

Our study suggests that MBT skills teaching is a good way of improving staff knowledge about mentalising skills and is accessible to different professional groups. That attitudes to personality disorder improved overall is also encouraging in relation to the possibility of deeper learning in staff.

Our findings add weight to the need for a larger study of MBT-S that uses both staff and patient outcomes and incorporates a control group. We note the importance of follow-up beyond the intervention to investigate whether effects persist; accordingly, follow-up is planned. Future research should aim to establish the potential influence of teaching mentalising skills on 'real world' clinical work, such as better therapeutic relationships or reductions in self-harming behaviour. A recent case study assessing the utility of MBT-informed practice and reflection in the in-patient forensic mental health setting suggested that it may be helpful.²²

Drawing on guidelines on effective team approaches to working with people with personality disorder,²³ it would be prudent, in devising an intervention to train a clinical team in MBT skills, to ensure that good principles and structures are in place first. These include making time for formulation,²⁴ establishing a structured approach to clinical care (consistency, clarity of staff roles),²⁵ and ensuring that good systems of staff support, supervision and reflective practice are in place.²⁶

In summary, MBT-S is a short intervention that is effective in improving clinicians' knowledge of personality disorder and mentalisation. Recent UK health policies have urged mainstream mental health services to be more responsive to the needs of individuals with personality disorder.¹⁻⁷ Our findings suggest that MBT-S might be an effective way to respond to this need, and one that is accessible to a range of professional groups.

Mentalising Skills Training Questionnaire

Thank you for your time. Please answer all of the questions.

Have you previously attended a course in Mentalising? YES/NO/Strongly Disagree/Disagree/Neutral/Agree/Strongly Agree

1. I believe mentalising is simple to put into practice
2. I think mentalising skills have a theoretical basis
3. I think mentalising skills help promote therapeutic communication with people who have problems like Borderline and Anti-Social Personality Disorder
4. I think providing mentalising skills requires a specialist psychotherapist
5. I believe treating people using psychological techniques is a poor use of resources
6. I think childhood experiences can have a profound impact on adult relationships
7. Mentalisation therapies do not allow patients to take medication
8. A person saying that a visit in the middle of the night from her partner was the only way she was reassured he loved her is an example of a teleological stance
9. Breaks in therapy (or from relationships with people) are not considered important by MBT
10. A key component of mentalising is thinking about people's attachment relationships
11. A therapist using mentalising skills will be expressionless
12. Using mentalising, you can ask questions to promote exploration
13. Mentalising avoids exploring the current therapeutic relationship with the person you are working with
14. In mentalising, professionals do not consider their own feelings
15. The professionals might use a 'stop and stand' technique if they get muddled in mentalising
16. As mentalising is straightforward, there is no need for supervision
17. Strong disagreements between professionals about a person's management may be an indication of non-mentalising
18. A partner being certain about what people are thinking, without checking, is an example of psychic equivalence
19. I feel confident in applying MBT skills into working practice
20. I understand when to apply/use MBT skills

Attitudes to Personality Disorder Questionnaire

For the purposes of this questionnaire we would like you to think about your feelings towards patients with personality disorder (PD) overall. We realise that you may have different mixtures of feelings about different personality disordered patients you have cared for in the past. For this questionnaire we would like to you try and average those out and tell us what your responses are in general towards patients with personality disorder as a whole.

For each response listed below please indicate the frequency of your feelings towards people with a personality disorder. Please circle your choice quickly, rather than spending a long time considering it. We want to know your honest, gut feelings. Never/Seldom/Occasionally/Often/Very often/Always

1 I like PD people
2 I feel frustrated with PD people
3 I feel drained by PD people
4 I respect PD people
5 I feel fondness and affection for PD people
6 I feel vulnerable in PD people company
7 I have a feeling of closeness with PD people
8 I feel manipulated or used by PD people
9 I feel uncomfortable or uneasy with PD people
10 I feel I am wasting my time with PD people
11 I am excited to work with PD people
12 I feel pessimistic about PD people
13 I feel resigned about PD people
14 I admire PD people
15 I feel helpless in relation to PD people
16 I feel frightened of PD people
17 I feel angry towards PD people
18 I feel provoked by PD people behaviour
19 I enjoy spending time with PD people
20 Interacting with PD people makes me shudder
21 PD people make me feel irritated
22 I feel warm and caring towards PD people
23 I feel protective towards PD people
24 I feel oppressed or dominated by PD people
25 I feel that PD people are alien, other, strange
26 I feel understanding towards PD people
27 I feel powerless in the presence of PD people
28 I feel happy and content in PD people company
29 I feel cautious and careful in the presence of PD people
30 I feel outmanoeuvred by PD people
31 Caring for PD people makes me feel satisfied and fulfilled
32 I feel exploited by PD people
33 I feel patient when caring for PD people
34 I feel able to help PD people
35 I feel interested in PD people
36 I feel unable to gain control of the situation with PD people
37 I feel intolerant. I have difficulty tolerating PD people behaviour

date

2018-6

Abstract

The incoming editor Dr Norman Poole sets out a vision for his tenure at the helm of the *BJPsych Bulletin*. There will be redoubled focus on training and educational articles and an engagement with the cultural and social ramifications of this most vital of specialisms.

Declaration of interest

Dr Poole is editor of the *BJPsych Bulletin*.

Contents

- [What's the point of the *BJPsych Bulletin*?](#)

I am honoured and not a little trepidatious taking over the reins (or reign) of the *BJPsych Bulletin* from departing editor Jonathan Pimm. Earlier in his career, Jonathan was a *bona fide* newspaperman and clearly relishes the business, since he is now moving on to *The Lancet* to take up the role of associate editor. During his editorship of this publication, Jonathan introduced open access in pursuit of equality, FirstView online for efficiency, and fewer briefer editions for expediency. He is a hard act to follow, so I won't even try. I would, however, like to thank him for his work on the *Bulletin* over his 5-year tenure and to wish him all the best in his future endeavours.

While preparing for the interview for this post, I discovered that the *Bulletin* aspires to be 'the foremost source of information about all aspects of mental healthcare'. A high bar indeed. In practice, its articles predominantly cover education, service provision, op-eds and profiles of renowned psychiatrists, both living and recently deceased, plus a smattering of book reviews and letters. While the *Bulletin* is seen as a place to publish original studies about service delivery, we are not here to publish research in the sciences basic to psychiatry. A glance at the most-read articles on the website suggests our readers value this focus, so I'm mindful that this should not be lost sight of in any future revisions. Still, it's the new guy's prerogative to tinker, and so I feel compelled to shape the *Bulletin* in my own image; but what sort of image is that?

While I ought to have been reading cardiology textbooks, I was in fact nose-deep in Edward O. Wilson's *Sociobiology*,¹ a fact that was to be reflected equally in my final exam scores and the ensuing purchase of Stephen Rose's edited volume *From Brains to Consciousness*?² I diverted myself from the former circumstance with Tim Crow's chapter claiming an intimate link between language development and schizophrenia, alongside Richard Bentall's, which questioned the validity of diagnosis. I found the stark divergence of explanatory theories and dispute about the very grounds of the debate invigorating after 5 years of didactic learning, so decided there and then to become a psychiatrist. Much as I admire my cardiology colleagues – and if I ever have heart trouble, I'd like to see one who doesn't doubt its existence – nothing else in medical school compared to the dizzying exciting uncertainty of the science(s) of human behaviour.

Of course, psychiatry also interacts with culture and values, more so than other medical specialities. I still firmly believe we are incredibly fortunate and privileged to work in such an intellectually stimulating and diverse, even at times fragmented, field. Yet, it appears to me that there is nowhere obvious other than the *Bulletin* for essays and articles that deal with psychiatry's myriad relationships. For instance, proposed changes to the Mental Health Act, the representation of psychiatry in the arts and media, philosophical and cultural critiques of psychiatric concepts, and so forth. The intention is not to criticise psychiatry but for the *Bulletin* to be a place for genuine reflection, which

occurs within the profession and specialist journals but is not always easily accessible or visible to trainees. I'd like to strengthen the *Bulletin's* coverage of psychiatry in all its breadth and glory.

Although the *Bulletin* should not concern itself with basic neuroscience, a core function is training and education. As Professor Wendy Burn has identified (<http://www.rcpsych.ac.uk/discoverpsychiatry/pastpresidentsblog/neuroscienceincurriculum.aspx>), learning about the neuroscience that underpins psychiatry is an area trainees find challenging. The Gatsby Foundation is currently partnering with the Royal College of Psychiatrists to review the training curriculum for neuroscience, and I hope to support this initiative by using the *Bulletin* as a forum for discussion and dissemination. I encourage authors to submit clinically relevant and readable reviews of neuroscience topics, such as Nour & Nour's recent paper on visual hallucinations.³

Finally, I believe that psychiatry trainees (and non-training grades) would benefit from a specific section similar to the *BMJ's* *Endgames* format exploring complex psychiatric presentations and management issues. I envisage that this section, to be co-written by consultants and trainees, will support the development of clinical reasoning,⁴ which is often hard to fathom for trainees in a busy clinic. In particular, the series should focus on differential diagnosis (identifying or excluding 'organic' aetiology; differentiating between superficially similar conditions such as adult attention-deficit hyperactivity disorder and borderline personality disorder). I encourage prospective authors to contact the *Bulletin* with proposals for more detailed advice on guidelines. Do please note that standards must accord with the International Committee of Medical Editors' Uniform Requirements for Manuscripts (<http://www.icmje.org/>) and co-production with patients is encouraged.

So, more op-ed pieces on the state of psychiatry and a focus on trainees' needs around neuroscience and clinical complexity. Is it achievable? Like all journals, whether the *Bulletin* sinks or swims depends on the articles submitted for consideration. I take this opportunity as your new editor to encourage readers to consider what you'd like the *Bulletin* to be and to get writing. It is, in fact, not my image that will shape the *Bulletin*, but yours.

Norman Poole is Editor of the *BJPsych Bulletin* and Consultant Neuropsychiatrist at St George's Hospital, South West London and St George's Mental Health NHS Trust, London, UK.

1.5.35 General practitioner referral of older patients to Improving Access to Psychological Therapies (IAPT): an exploratory qualitative study

Noel Collins Laurie Corna

Correspondence

Noel Collins

(noel.collins@health.wa.gov.au)

date

2018-6

Abstract

Aims and method

To understand general practitioner (GP) reticence to refer older patients to a local Improving Access to Psychological Therapies (IAPT) service providing mostly cognitive-behavioural therapy (CBT)-based interventions. Semi-structured, hour-long interviews were conducted with eight GPs and then analysed by modified grounded theory and thematic analysis.

Results

GP views regarding the treatability of older adults with CBT influenced their willingness to refer to a CBT-based IAPT service. Perceptions of local IAPT assessment processes being distressing and onerous to older patients also motivated referral inaction. GPs expressed a preference to treat depressed older patients themselves (with medication and psychological approaches such as watchful waiting).

Clinical implications

Any strategy to increase referral rates of older adults to CBT-based IAPT services should address local GP concerns regarding assessment processes and the effectiveness of offered treatments.

Declaration of interest

None.

The National Health Service (NHS) England ‘Improved Access to Psychological Therapies’ (IAPT) program was launched in 2009 to improve access to evidence-based talking therapies for people with common psychiatric conditions such as depression. It originally targeted working-age adults but was opened to older adults in 2010, with most interventions being based on cognitive-behavioural therapy (CBT).¹ Although IAPT is now a service for all ages, only 7% of people in treatment are over 65, despite constituting 20% of the population. This unequal distribution of

treatment worsens with age. In particular, there is a miniscule number of people over 90 years old enrolled in IAPT nationally, despite this being the fastest growing demographic group (see <https://www.england.nhs.uk/mental-health/adults/iapt/older-people/>).² Part of the problem is that people over the age of 65 are rarely referred for psychotherapies.³ It is important to understand referral obstacles to IAPT services, as these are now the main providers of talking therapies for adults of all ages.

Aim

The aim of this study was to understand why GPs did not routinely refer their older patients to a local IAPT provider. This was done by examining the referral decision from the perspective of referrers themselves.

Method

This was an exploratory, qualitative study. An interpretive approach in the grounded theory tradition was chosen for this research to understand the nuances of the referrer experience and to meanings attached to referral decisions.⁴ Semi-structured, hour-long interviews were conducted with eight GPs practicing in a home county of London. The majority of therapy offered by the local IAPT provider was CBT in nature. The interviewer (N.C.) was a local old-age psychiatrist, previously CBT trained, who was also a member of the Royal College of Psychiatrists Older Adult Faculty work stream aiming to improve access to psychological therapies for older people. An indicative topic guide was provided to all prospective participants in advance of scheduling an interview. As interviews progressed, there was less reliance on interviewer prompts as themes that arose inductively from the data were explored.

Several approaches were employed to mitigate the effects of N.C.'s existing beliefs and assumptions on the qualitative study, including supervision and reflexivity. The latter is an explicit self-awareness of how the interaction between researcher and participant can influence data collection, analysis and subsequent theory development.⁵⁻⁷ The evolution of deductive ideas from previous professional experience and the evolution of inductive theory, as it emerged from the data, were both made explicit. Memo writing was conducted and recorded to provide clear transparency in the analysis.⁶ Care was also taken to delineate worker and researcher roles, and interviews were carried out either out of hours or in non-clinical settings.

Participants

Purposive sampling of GPs from a variety of backgrounds was carried out to scrutinise deviant examples and increase the scope of subsequent findings.⁸ All eight GPs, who were initially contacted by email, agreed to participate. Half of the GPs were male and half were female. Age and seniority varied between a trainee and commissioner level.

Ethical considerations

This study was conducted as part of a supervised Master's thesis in Gerontology and was approved by the King's College London Research Ethics Committee prior to the recruitment and interviewing of participants.

Analysis

Verbatim transcriptions of audio-recorded interviews were made and uploaded to a qualitative software platform (MaxQDA) to assist coding and analysis. Interviews were coded line and by line and analysed using thematic analysis to explore referrer beliefs and their associated meanings, as well as other factors related to referral decisions.⁶ Emergent codes and thematic categories were constantly re-checked regarding their utility in understanding, developing and interpreting emerging themes in the data.⁹ Thematic saturation was observed by the penultimate interview. Several emergent thematic categories, which best captured reluctance to refer to IAPT, were chosen for further examination: (1)deeming older patients ineligible for CBT;(2)concern regarding appropriateness of IAPT assessment and treatment;(3)preferential usage of alternatives to IAPT referral.

These were chosen as the main focus of analysis because these ideas arose inductively from the data and were stable concepts across all transcripts.

Results

Theme 1: deeming older people ineligible for CBT

Participants conceptualised anxiety and depression in later life differently to that which occurs in younger adults. This in turn affected practitioner assessments of eligibility for referral, as older adult depression was felt less amenable to CBT for a variety of reasons. These reasons included the beliefs that older adult depression was an inevitable consequence of ageing, loneliness and age-expected losses: “‘Sometimes they have lost children. Work has disappeared. They can’t get out and do the things they want to do. Recognising the fact that they are old. And I think people grieve over this almost.’ (GP 4)‘You’re isolated; you’re not able to get out. You will get more anxious as you get older.’ (GP 1)”

One GP, who had a senior commissioning role, framed his decision not to refer older adults to IAPT using ‘maximising’ health-rationing principles, namely distributing health resources to achieve maximum benefit in a population:¹⁰ “‘I think it’s just an unconscious bias, not because I think it becomes less useful as you get older but it’s more useful if you are younger. Because I believe that bit about psychological maturity and I think if I took 100 65 year olds and 100 18 year olds, with say anxiety, I believe you would more likely to help more of the 18 year olds rather than the 65s. Because the 65s have probably reached psychological maturity and the 18 year olds haven’t. So whilst you might be able to help some of the 65 year olds, you’ve missed the opportunity of consolidating over a lifetime those patterns of behaviour.’ (GP 8)”

GP participants appeared to conflate normal ageing with the development of frailty, sensory or cognitive impairment and the loss of mental agility, which were viewed as obstacles to successful treatment with CBT. This could also explain why non-referral of older patients for CBT was magnified in the over-85 age group: “‘Maybe the older eighty plus person with chronic depression, a bit of dementia, that sort of thing ... it’s just their life. Is it part of their health, that sort of age? Are we ever likely to make a significant improvement with talking therapy?’ (GP 6)”

Theme 2: concern regarding appropriateness of IAPT assessment and treatment

Some GP participants in this study stated that they did not refer to IAPT due to their concerns that IAPT assessment processes were not suitable for older patients. In particular, telephone assessment and the use of repeated questionnaires were felt to be insensitive and inflexible when assessing older patients, particularly those with comorbid sensory or cognitive deficits. One participant described the abandonment of referral as a ‘rescue’ from the traumatising process of IAPT assessments: “‘I can think of one particular person with early memory loss, you may remember, who was absolutely traumatised by the process ... and I said this isn’t for you, let’s stop all of these appointments and phone calls and all of that ... and they’ve done well, having rescued them from the process they are doing absolutely fine.’ (GP 2)”

Other participant concerns regarding IAPT structural processes included inflexible CBT delivery, the poor availability of face-to-face counselling and the skills of IAPT workers in dealing with cognitive impairment or medical comorbidity. The exclusion of nursing home patients was also a particular concern: “‘If I suggested to the homes that these patients

be sent to IAPT, they are going to be asking how will we get them there? How will the cognitively, hearing and vision impaired cope? I think that's particularly true with psychologically multi-morbid patients for example: a patient with dementia and anxiety. I suspect you wouldn't refer to IAPT because they wouldn't be able to handle it.' (GP 8)"

A common concern among all GP participants was that IAPT interventions were too short term and superficial to change entrenched maladaptive behaviours in older patients: "I think again, most people probably feel as I do in that if you think psychological therapy is going to be helpful – a lot of these people have such strongly held, long term views – that a short course of CBT is not going to do it.' (GP 4)"

All GPs in this sample described feeling isolated from IAPT practitioners. This meant that any concerns regarding the effects of IAPT processes on older patients were never raised with IAPT providers. Additionally, GPs described not receiving any guidance regarding which older patients may benefit from CBT: "Obviously that big thing sitting there ... where the anxiety that comes in older age, I don't know if that's whom the IAPT service wants to see.' (GP 1)"

Theme 3: preferential use of alternatives to IAPT referral

When responding to the needs of depressed older adults, GP participants described a number of approaches that are preferentially used instead of referring to IAPT for CBT. These approaches included addressing physical issues and social needs, prescribing medication and GP-led psychological approaches. Prioritising physical issues was viewed as a pragmatic response to the competing demands present in a time-limited consultation with an older patient. It was hoped that by improving physical issues, mood would lift as a result: "You also get sidetracked by their UTIs [urinary tract infections] and their arthritis is really bad. I tend to focus on the physical problems as with a lot of the frail people, your assumption is that because they can't get out, they're not mobile, they don't feel well that they're feeling depressed. You therefore focus on those issues – you try to improve those things to improve mood.' (GP 5)"

Addressing social needs, like treating physical issues, was a highly regarded strategy when treating an older adult with depression. Senior GP participants, in particular, had strong convictions in this approach. This was linked to beliefs that older adult depression was often fuelled by social isolation and loneliness, and was therefore more responsive to social interventions rather than psychotherapies: "In terms of social interventions that may make a difference, if you were to ask me what differences I've made to people's lives, I can remember a very depressed Finnish lady and I knew close by there was another Finnish lady and I put them in touch, this probably made more difference to her and she didn't come and see me every week after that!' (GP 7)"

Prescribing antidepressants, in contrast to IAPT referral for CBT, was described by some GPs as a reflexive act. Perceived benefits of antidepressants over referral to IAPT included relief of associated insomnia and pain, and taking a tablet being 'less work' for patients. Participants also felt that prescribing an antidepressant was more acceptable to older patients and that it satisfied an expectation for a rapid medical response. Some participants also believed that medication was more appropriate than CBT referral when depression had a clear organic cause, had significant somatic symptoms or was associated with medical comorbidity. Concerns regarding side effects were notably absent in all participant accounts. This may relate to the practice of using lower dose antidepressants, described by one GP as 'gentle pick me ups': "Again it comes down to expectation, if they leave with a prescription in their hand, you've done something. Whereas, if I say to them I'll refer you to a counselling service, it'll take 6–8 weeks before you see somebody, then might have to wait for treatment and in 4 months time, you might be engaged with the service and you might start to feel better ... you're not giving them a quick fix.' (GP 5)"

In contrast to referral to IAPT, GPs reported that prescribing made them feel less impotent and helpless: "With a depressed elderly, you worry that they are going to wait so long [for CBT]. I must do something in the interim. Doctors hate that hopeless feeling. You know what you need to do, but you can't access that.' (GP 5)"

GPs described using their own psychological skills with older patients with depression rather than referring them to CBT. These approaches included supportive counselling, exploratory brief therapy and problem solving. Like prescribing medication, these strategies were deemed within the GP's control: "You learn the older you get that some people just want to acknowledge an issue and they have it within themselves, and having acknowledged and having told someone like their GP about it, that they're able then to go away ... and ... change their thinking about it.' (GP 2)"

Watchful waiting was frequently used as a tried-and-trusted approach to treating elderly people with depression in primary care. This intervention, centred on regular review but without active pharmacotherapy or psychotherapy, was felt by participants to be a tangible and containing approach compared with referral to IAPT for CBT: “I think it’s the personal support and contact, the commitment. Because quite often people who I think need a lot of support, I will book the next appointment whilst they are in the room and give them that piece of paper. So again, it’s that tangible thing. Even if I don’t think they need medication, I will say let’s find an appointment. And they will go out and come back.’ (GP 4)”

Some participants felt confident in delivering simpler CBT interventions themselves, such as behavioural activation, activity scheduling and challenging negative thinking. The willingness and desire to improve these skills, even within the constraints of brief consultations, was most clearly expressed by a GP registrar: “I think the more you learn about CBT, the more you can do very basic interventions yourself with some patients. We’ve been encouraged to do that and deliver very basic CBT ourselves. In the 10 minute consultation!’ (GP 5)”

Study limitations

The findings presented here must be interpreted in light of the study’s limitations. The IAPT service referred to in this study was reported by local GPs to only offer only CBT-based therapies. Participants had strong views regarding the use of CBT in older patients and this clearly influenced willingness to refer to their local service. The findings of this study cannot be generalised to the experiences of other GPs with other IAPT providers. Additionally, the sample comprised GP participants in only one semi-rural locality with little ethnic diversity. This meant that the experiences of more urban-based GPs working with multicultural populations were also absent. The scope of the project precluded a larger sample size, but data saturation was achieved by the seventh interview. Notwithstanding these caveats, this study does provide some insight into the reasons for underutilisation of IAPT services by older adults.

Discussion

The GP respondents in this study gave a wide range of clear reasons for their reluctance to refer their older patients to a local IAPT provider offering mostly CBT. These include the belief that older adult depression was an inevitable consequence of ageing and therefore more difficult to treat with CBT. This is consistent with previous research showing how depression in older adults can be viewed as a ‘justifiable’ consequence of ageing due to age-expected losses and social changes, and therefore less in need of treatment.¹¹⁻¹³ This view may in turn relate to historical comments by Freud, e.g. ‘above the age of 50 the elasticity of mental processes on which treatment depends is, as a rule lacking – old people are no longer educable’, still having an enduring effect on medical practitioners.³

In general, GP participants in this study viewed IAPT assessment processes as inflexible, insensitive and potentially traumatising for older adults. This is compatible with existing concerns that CBT can be too protocol driven, measurement focused and inflexible for older patients.¹⁴⁻¹⁵ There appeared to be some ‘frail-ist’ views where the older, more frail, depressed individuals in particular were deemed the least likely to benefit from or access CBT and therefore were ineligible for referral. The treatment preferences of GPs in this study are consistent with existing research showing that some GPs prefer simpler and more exploratory counselling rather than a manualised approach like CBT,¹⁶ and that they believe that pharmacotherapy offers quicker relief to people with depression compared with a talking therapy.¹⁷

The results of this study point to strategies that could achieve higher referral rates for older patients to IAPT services. Increased co-location of IAPT therapists into primary care would be a good starting point in promoting CBT as an effective treatment for older people, who often have higher rates of adherence and completion of therapy than younger patients.¹⁵⁻¹⁸ Some IAPT providers could aim to offer a greater range of other modalities of treatment to older patients and publicise these increased options to referring GPs. IAPT providers could also revise assessment processes, such as the use of simpler rating scales of improvement, to address concerns regarding onerous outcome measurement. The use of tele-health could also be trialled to improve access for those with mobility impairments and those living in residential homes.¹⁹ IAPT supervisors could also take on an active role in training carers in residential homes to deliver basic CBT techniques to depressed, older and frail adults who are currently disenfranchised by poor access to conventional face-to-face treatment.²⁰ It is hoped that this paper helps raise the profile of unequal access to psychological therapies

for older adults and that some of the suggested strategies derived from this study's findings can be trialled by some IAPT services to improve the situation.

date

2018-6

Abstract**Aims and method**

Community treatment orders (CTOs) have been in used in England and Wales since November 2008; however, their effectiveness has been debated widely, as has the question of which methodology is appropriate to investigate them. This paper uses national data to explore the use of CTOs in England.

Results

About 5500 patients are subject to CTOs at any one time. Each year, ~4500 patients are made subject to a CTO each year and ~2500 are fully discharged, usually by the responsible clinician; fewer than half of CTO patients are recalled, and two-thirds of recalls end in revocation. The low rate of CTO discharges by mental health tribunals (below 5%) suggests that they are not used inappropriately.

Clinical implications

The introduction of CTOs in England has coincided with a reduction in psychiatric service provision due to the economic downturn. Pressures on services might be even more severe if patients currently subject to CTOs instead needed to be detained as in-patients.

 - *Discussion*

Background

Community treatment orders (CTOs) were introduced into legislation for England and Wales by the Mental Health Act (MHA) 2007. They can be applied to a patient who is already subject to a section of the MHA which makes them liable to detention for treatment. The patient is discharged from the treatment section on to a CTO, which broadly means that they need to comply with a set of specified conditions that may include accepting prescribed treatment. The responsible clinician has the power to recall a patient to hospital. If the CTO is revoked, the treatment section is reinstated. CTOs are initially valid for 6 months but can be extended indefinitely. They are subject to scrutiny by independent first-tier mental tribunals (Mental Health), or MHTs, which can discharge the patient from the CTO if the grounds for its use, as laid out in the MHA, are deemed not to be met. Following the introduction of CTOs, uptake was initially higher than some had predicted, and over the past few years usage seems to be fairly stable.^{1–3} The attitude of many clinicians to CTOs has been favourable,⁴ but they have also been the subject of controversy.^{4,5} The power to coerce patients to accept treatment in the community clearly represents a conflict between the principles of respecting autonomy and of preventing harm to the patient and/or others, and thus between providing the ‘least restrictive’ treatment option balanced against ‘preventive’ principles.⁶ The difficulties in resolving this conflict satisfactorily have resulted in significant variations in the nature and implementation of these orders in different countries. Factors which could reduce the usage of CTOs may include a reluctance to use coercive measures, objections from patients’ advocates, concerns about liability, operational aspects and the lack of a strong evidence base.⁷

CTOs are typically indicated for psychiatric patients, usually with a diagnosis of psychosis, presenting with a ‘revolving door’ pattern of admissions secondary to poor treatment adherence and poor engagement with psychiatric services.⁸ Although a main aim of CTOs is to reduce readmissions by preventing relapse, another motivation might be to attempt to improve quality of life for patients and their careers. The responsible clinician devises a set of conditions appropriate to the individual patient in the CTO. The responsible clinician has the discretion to recall the patient, initially for a 72-h period, for further treatment if deemed necessary. During this recall period, a clinical decision has to be made as to whether the CTO should be revoked, which leads to the patient returning to being subject to the original hospital treatment section from which they were discharged on to the CTO. Alternatively, they may receive some brief intervention and be allowed to return to the community, or they may be informally admitted while continuing to be subject to the CTO. The responsible clinician has considerable discretion as to when to exercise the power of recall. Some clinicians may aim to recall patients promptly, with the aim of quickly re-establishing treatment and preventing further deterioration, possibly without needing to revoke the CTO. Others may prefer to wait longer, in the hope that things will improve without having to subject the patient to a measure which may seem overly coercive or even punitive. A recent follow-up study found that fewer than half the patients subject to CTOs are recalled, with about a fifth being recalled multiple times.⁹ In that study, half of these recalls were due to deterioration in clinical condition and about 70% of recalls resulted in revocation.

Effectiveness of CTOs

If CTOs were effective and were used effectively, they might lead to an overall reduction in requirement for in-patient treatment and a decline in the number of patients detained on treatment sections.¹⁰ Two older American randomised controlled studies (RCTs) of similar measures failed to find clinical benefits, but it has been argued that they had significant methodological drawbacks, for example, in that they excluded high-risk patients.^{11·12} Subsequent American studies have claimed to demonstrate benefits, especially when considered as part of a wider public health system involving the criminal justice system.⁷ Given the difference in psychiatric service provision, these studies may have limited applicability to the UK. The OCTET study, a RCT which was carried out soon after the introduction of CTOs, did not find clinical benefits.¹³ However, this study has been criticised as having significant methodological problems, such as again excluding high-risk patients and the fact that the CTOs were only used for a brief period of time.^{14·15} Small naturalistic UK clinical studies using before and after methodologies have reported positive outcomes.^{16–18} Swartz and Swanson (2015)¹⁵ suggested that RCTs may not be the best way to study these complex tools, and that larger, naturalistic studies may be more appropriate. A Care Quality Commission (CQC) 2009/10 report claimed that a third of CTO patients in England did not have a reported history of non-adherence or disengagement.¹⁹

Figures from the Mental Health Minimum Data Set show that the majority of people on CTOs are of working age, and more than twice as many are male than female; however, in the 65 and over age group, more women than men are on CTOs.²⁰ The descriptive data indicate that patients are typically male and around 40 years of age, with a long history of schizophrenia-like or serious affective illness, previous admissions, poor medication adherence, aftercare needs, the potential for violence and displaying psychotic symptoms, especially delusions, at the time of the CTO.⁶ CTO usage is more prevalent in urban areas.²¹

Method

We examined national data on aspects of CTO usage alongside that of other provisions of the MHA and information on psychiatric service provision. National data from the annual reports of Digital NHS (previously the Health and Social Care Information Centre) and Mental Health Reports of the CQC (the independent regulator of health and social care in England since 2009/10) were studied to look at the trends in implementation of CTOs. Thus, although CTOs are used in both England and Wales, the results we report are only for England.

Results

All the figures quoted in the results below and accompanying tables were extracted from the NHS Digital report: *In-Patients Formally Detained in Hospitals Under the Mental Health Act 1983, and Patients Subject to Supervised Community Treatment: 2015/16, Annual Figures*.²¹

As shown in *Table 1*, the annual rate of new CTOs is fairly stable at around 4500, with the number of patients subject to CTOs at any one time being around 5400. The annual number of discharges from CTOs has steadily increased over 5 years from 1712 (2011/12) to 2575 (2015/16), and each year somewhat fewer than half of all patients subject to a CTO are discharged. *Table 1* Annual numbers of patients in England who are subject to CTOs at any one time, along with the number of new CTOs initiated and numbers and percentages of patients discharged from CTOs

Year	2011/12	2012/13	2013/14	2014/15	2015/16
Number of patients subject to CTOs	4764	5218	5365	5461	5426
Number of new CTOs	4220	4647	4434	4564	4361
Number of CTO discharges	1712	1622	2302	4912	2575
Number of discharges as percentage of number of patients subject to CTO, %	35.9	41.4	44.1	64.5	64.7

As shown in *Table 2*, there are about 45 recalls per year for every 100 patients subject to a CTO (HSCIC 2015/16). Over the past 5 years, the average rate of revocation following such recalls is 65%, albeit with a fair degree of variation between years, with absolute numbers fluctuating between 1000 and 1500. *Table 3* shows that, including these revocations, around 9000 patients are detained under Section 3 each year. Given that about 4500 patients are discharged on a CTO annually, it seems that about half of patients detained under Section 3 will be discharged on a CTO. *Table 2* Annual number of recalls and numbers of recalls per 100 patients subject to a CTO

Year	2011/12	2012/13	2013/14	2014/15	2015/16
Number of recalls from CTO	2082	2227	2231	623	692
Recalls per 100 patients subject to CTO	20.8	22.3	22.3	6.2	6.9

100 CTO patients 4844434342 Number of revocations 14691509140114271557 Percentage of recalls resulting in revocation, %70.666.460.560.267.9¹ Table 3 Annual number of patients newly detained under Section 3 (S3) of the MHA, number of CTO revocations and the sum of these two numbers Year 2011/12 2012/13 2013/14 2014/15 Non-CTO Section 37701777674817690 Revocations from CTO 1469150914011427 Total 9170928588829117

Table 4 shows that each year patients make 3000–4000 applications to MHTs to be discharged from CTOs. Most applications proceed to a hearing, and the proportion of MHT hearings resulting in discharge was running at 4–5%, falling to 3.3% in 2015/16 (CQC 2012/13, CQC 2013/14, CQC 2014/15, CQC 2015/16). These rates are not dissimilar to the rates for discharge from hospital treatment sections (Section 3 and Section 37) of 4.4% in 2013/14, and less than that for all sections, which was 8.9% (CQC 2013/14). The application may not proceed to a hearing if it is withdrawn by the patient or if the responsible clinician themselves discharges the CTO. Of all patients subject to a CTO in a given year, the percentage discharged by a MHT is around 2.5–3.5%. The low rates could partly be explained by the higher proportions of automatic referrals made to the tribunal by hospital managers, as opposed to applications made by patients. Table 4 Annual numbers of applications to MHTs for discharge from CTO, numbers of hearings, and numbers and percentages of hearings resulting in discharge by the MHT Year 2011/12 2012/13 2013/14 2014/15 2015/16 Patients subject to a CTO 47645218536554615426 Applications to MHT 39014211443143494317 MHT hearings 32723169355036293942 MHT discharges 161132185165132 Percentage of hearings resulting in discharge, % 4.94.25.24.53.3 Percentage of all CTO patients discharged by MHT, % 3.42.53.43.02.4²

The past few years have seen a 17% reduction in the number of in-patient beds for people needing care for mental health problems: from 26 448 in 2008/09 to 21 949 in 2012/13.²² HSCIC data (2015) show that annual patient contact numbers have fallen significantly, while patient numbers are increasing.²³ The same report also shows that the greatest fall has been for assertive outreach services (more than 20%) and general psychiatric, substance misuse and forensic services (around 15% each). By contrast, contact with criminal justice liaison and diversion services saw the greatest increase in contacts (36.2%), while contact with psychiatric liaison increased by almost 28%.

Discussion

The rate of CTO use is about 10 per 100 000 of the population, which puts it in the low to moderate range by international comparison with similar provisions for compulsory treatment in the community. Australia and New Zealand and some parts of the USA have much higher rates, whereas rates are much lower in Canada and New York.²⁴

The pattern of usage of CTOs seems to be fairly stable in the context of ongoing reductions in psychiatric service provision. A CQC report claimed that the powers were being applied ‘preventatively beyond those for whom they were primarily designed’.¹⁹ However, we note that the rate of discharge by MHTs is low and possibly falling, indicating that these independent tribunals do not seem to regard CTOs as being used inappropriately.

The number of recalls is nearly half the total number of CTOs, and somewhat fewer than a third of CTOs are ended by revocation. Again, the fact that such a large proportion of patients subject to CTOs end up requiring readmission might be taken as an indicator that CTOs are largely being used appropriately, in an attempt to provide treatment in the community to patients who would otherwise remain in hospital. It is not possible to tell whether the number of revocations could be reduced if patients were recalled more promptly, at an earlier stage in their relapse, or whether

¹ (Note that some patients may be recalled more than once.) Also shown are the number of revocations and the percentage of recalls that result in revocation.

²

Also shown is the percentage of discharges by MHT of all patients subject to a CTO.

the revocations represent a group of patients who are intrinsically difficult to maintain in the community. It would be helpful to investigate this aspect of clinical practice.

It is difficult to know the extent to which the use of CTOs has allowed psychiatric services to continue to function with reduced bed provision. Of course, many would argue that psychiatric services are in fact not functioning at an acceptable level, and the rise in contacts with the criminal justice system could be taken as evidence of this. The MHT will uphold a CTO only if it feels that the CTO is required for the patient to continue to accept treatment. Clinically, adherence to treatment is aimed at preventing relapse and hospital admission among ‘revolving door’ patients, and has wider significance for psychiatric in-patient service provision.

Overall, the success or failure of CTOs hinges on their appropriate application and implementation. There may well be large differences in practice between services and individuals; it would be helpful to explore these systematically and, if possible, relate them to outcome measures. Large numbers of patients are subjected to this provision, so it would seem sensible to take whatever steps possible to see that it is used effectively.

1.5.37 Ideology over evidence?

Sameer Jauhar Allan H. Young

date

2018-6

Contents

- *Ideology over evidence?*

In her narrative, Dr Moncrieff makes assertions about depressive illness, antidepressants, and psychotropic medications.¹ Her main points are that these medications are not clinically effective when using rating scales, and that the models proposed for antidepressant action are erroneous. We would suggest that the narrative reflects ideology, as opposed to evidence, and should be interpreted accordingly.

First, a 1969 narrative supplementary review is given as an example of the lack of efficacy of tricyclic and older antidepressants. A more recent (and comprehensive) review found significant benefits for monoamine oxidase inhibitors over placebo, which were surpassed by tricyclics.² The argument is then made that changes on the Hamilton Rating Scale for Depression (HRSD) are minimal, in comparison with placebo, and that differences are clinically insignificant when the Clinical Global Impression (CGI) scale is used, citing among other reviews the Kirsch meta-analysis (where the effect size was 0.313). A similar effect size was seen in a recent analysis of over 500 studies, which reported odds ratios of between 1.37 and 2.13 for response compared with placebo.⁴

In focusing the argument on change in total HRSD score, Dr Moncrieff appears unaware that the scale was never intended to measure change. A more robust way of analysing it was recently demonstrated, using the rating of subjective mood (item 1 on the HRSD), which would be akin to the CGI. This avoided the influence of antidepressant side-effects on the scale, and found clear benefits for paroxetine and citalopram over placebo.⁵

A study cited to indicate severity of depression did not predict outcome, evaluated the short-term efficacy of antidepressants and was not intended to test the hypothesis of severity, with the authors reporting significant benefits of fluoxetine over placebo in adults (improvement of approximately 35%).⁶ The 1964 Medical Research Council trial (which showed the efficacy of electroconvulsive therapy) is given as evidence of lack of effect of severity on response; however, the statement that antidepressants did not outperform placebo is not surprising, given that the dose of imipramine was

50 mg and that of phenelzine 15 mg. A more recent and influential publicly funded study (cited over 3000 times in Google Scholar) showed the effectiveness of imipramine (at a therapeutic dose of around 185 mg) in people with severe depression, in comparison with psychological therapies (cognitive-behavioural therapy and interpersonal therapy). These therapies showed little benefit over placebo in this group.⁷

The rest of the narrative dwells on ‘disease-centred’ models of psychiatric illness, as an alternative to the current ‘targeting a brain abnormality’ approach. We are unaware of modern psychiatry relying on the neurotransmitter models she discusses; the field has moved on significantly, and most neuroscientists would point to more nuanced models involving effects on neural networks and plasticity.⁸ The predominant references cited here are Dr Moncrieff’s own hypotheses.

In summary, we would suggest that Dr Moncrieff’s narrative is selective at best, and on cursory examination there is little effort to appraise the literature in a scientifically objective manner. One cannot help but assume that this opinion piece represents ideology over evidence, and therefore any interpretation should be cautious.

Andrea Brown (abrown@theretreatyork.org.uk)

date

2018-6

Abstract

Aims and method

A cognitive-behavioural therapy in-patient treatment model for adults with severe anorexia nervosa was developed and evaluated, and outcomes were compared with the previous treatment model and other published outcomes from similar settings.

Results

This study showed the Pathways to Recovery outcomes were positive in terms of improvements in body mass index and psychopathology.

Clinical implications

Adults with anorexia nervosa can achieve good outcomes despite longer illness duration and comorbidities.

Declaration of interest

 - *Discussion*

There is very limited guidance available regarding effective, evidence-based, in-patient treatment for those people with severe anorexia nervosa who cannot be managed safely due to high medical and/or psychosocial risk and/or who have not responded to treatment in out-patient services.^{1,2} Treasure *et al*³ have recently proposed that severe and enduring anorexia nervosa (SE-AN) may be defined by an illness duration of seven or more years and that interventions should be matched to illness ‘stage’. This proposed ‘staging model’ helpfully emphasises the importance of early intervention for people with recent onset anorexia nervosa. However, the suggestion of shifting focus away from recovery towards

enhancing quality of life and harm minimisation for those with more enduring difficulties^{4,5} has the potential to fuel pessimism with regards to outcomes for this group of patients and the clinicians who work with them.

Aims

This article aims to describe the development of a new treatment programme called Pathways to Recovery: an innovative cognitive-behavioural therapy (CBT)-based approach for the in-patient treatment of people with eating disorders, including those with significant chronicity and comorbidity.

The following questions are addressed: •What is the outcome for patients treated by Pathways to Recovery?•How do the outcomes of patients treated by Pathways to Recovery compare with the outcomes of patients treated by the previous approach that used body mass index (BMI) guidelines (i.e. treatment as usual (TAU))?•How do the outcomes of patients treated by Pathways to Recovery compare with the outcomes in comparable in-patient settings?

Method

Development of the Pathways to Recovery model

The model was developed in a regional specialist eating disorder in-patient unit for women aged 18 and over with complex eating disorders and comorbidities including personality disorders, substance misuse and autistic spectrum disorders.

A CBT approach was adopted in response to evidence that CBT was the most effective treatment for bulimia nervosa⁶ and it had the potential to be effective trans-diagnostically with other types of eating disorders⁷ and a wide range of comorbidities. The collaborative CBT approach was not compatible with the pre-existing framework of using BMI to inform treatment and evaluate progress (i.e. the BMI guidelines).⁸ The Pathways to Recovery model was developed as a solution by a multidisciplinary group of clinicians with consultation with patients, their families/carers and the wider staff team. Pathways to Recovery incorporated key CBT principles and enabled the whole staff team to work collaboratively and coherently in an integrated and holistic way with each patient.

The Pathways to Recovery model was piloted and evaluated independently using qualitative methodology. Overall, Pathways to Recovery was found to be acceptable and a positive alternative to BMI guidelines.⁹

Pathways to Recovery broadly defines recovery as learning to live with eating-disordered thoughts without using eating-disordered behaviours. Emphasis is thus placed on behavioural change while developing a repertoire of CBT skills to manage difficult thoughts and feelings. The programme consists of seven parallel pathways: physical monitoring, psychological, physical activity, meaningful living, meaningful eating, self-catering and leave (*Fig. 1*). Progression up the pathways corresponds to the person's stage of recovery, moving from medical stabilisation through to gaining skills and concluding with the transferring skills stage. Progression is discussed collaboratively at weekly multidisciplinary team meetings and regular care programme approach reviews, which are run transparently with the patient present throughout the meeting. CBT principles, methods and techniques are central to each pathway; for example, the concepts of hierarchies, graded exposure, behavioural experiments, problem solving and goal setting are used. A guided discovery approach is encouraged for both staff and patients. In addition to the poster which delineates the pathways (*Fig. 1*), each patient receives a folder containing information about every step of each pathway. The information includes the aims of each pathway and defines what the person will be expected to work on at each stage. A complete set of supporting documentation is also provided, which includes: planning and evaluation forms for meals, self-catering, activity and leave. The emphasis is on learning from experiences, enabling the patient to take ownership of their recovery and to progress to higher levels of the pathways. As the person progresses, the level of independence increases and they receive less support from staff. This leads to increasing periods of home leave where the person can practice the skills they have learnt. The benefit of this is that patients and their families are able to gain confidence that they will be able to continue using their skills independently once they leave the programme. *Fig. 1*The Pathways to Recovery poster.

Participants and procedure

Clinical outcome data were reviewed from admission and discharge of 161 patients admitted consecutively from July 2008 (when routine data collection was initiated) until April 2015 (when the data were analysed). All patients provided written informed consent at the start of their admission for their data to be used anonymously for research and service evaluation purposes. This project did not require a research ethics committee review as it was a service evaluation project using outcome data routinely collected as a normal part of clinical practice on the unit.

Although data were collected for all patients admitted during this time frame, only data related to patients with a diagnosis of anorexia nervosa at admission were included ($n = 123$). Patients with additional comorbid diagnoses were included.

Further exclusion criteria were as follows: currently receiving treatment in the unit ($n = 13$), previous admission already included in the analysis ($n = 15$), present at the time the service model changed and thus received treatment under both models ($n = 11$) and did not have two or more sets of outcome data ($n = 10$). A total of 74 participants were therefore included. Of these participants, 25 were treated using the former BMI-guidelines approach (hereafter designated TAU) and 49 were treated using the Pathways to Recovery programme (designated Pathways to Recovery). Treatment completion was not routinely documented, so all patients were included in the data analysis providing they had at least one data set in addition to admission data.

Measures

The key areas targeted by in-patient admission were symptoms of eating disorder, general psychological distress and weight restoration. To evaluate change in these areas, the following outcome measures commonly used in eating disorder research were selected for their clinical utility:

Eating Disorder Examination – Questionnaire (EDE-Q): A self-report measure assessing eating disorder symptoms over the previous 28 days.¹⁰ This instrument has good reliability and validity.¹¹ High scores indicate greater eating disorder psychopathology.

Clinical Outcomes in Routine Evaluation Outcome Measure (CORE-OM): A widely used, generic, 34-item self-report measure of psychological distress. This instrument has good reliability and validity.¹² High scores indicate greater psychological distress.

BMI: BMI (weight/height²) was recorded for each patient at admission and at discharge.

Statistical methods

Independent samples *t*-tests were used to compare the demographic and clinical variables between the two groups at admission. To evaluate the efficacy of Pathways to Recovery, comparisons between admission and discharge scores were assessed in the Pathways to Recovery group using paired sample *t*-tests. Cohen's *d* effect sizes are presented to enable comparisons across outcomes. To put any detected changes into a clinical context, outcomes were also compared to evidence-based guidelines and cut-off points. Comparisons between the TAU and Pathways to Recovery groups were assessed using a 2 (group: TAU and Pathways to Recovery) × 2 (time: admission and discharge) mixed design ANOVA, with repeated measures on the time factor. Data were explored to check assumptions of multivariate analysis. All statistics were carried out using SPSS version 22.0 for Windows. Missing data were dealt with using pairwise deletion.

Results

Sample characteristics

The demographic characteristics and clinical features of the two groups are shown in *Table 1*. There were no significant differences between the two groups in terms of these variables. The mean age of the overall sample was 27 years (range 18–57 years). Of the participants, 67% had previously been admitted for at least one specialist eating disorder in-patient treatment. The mean duration of anorexia nervosa was more than 9 years (range 0–31 years). More than half (51.9%) of the participants had an illness duration of 7 years or more, thus meeting the criterion proposed by Treasure *et al*³ for SE-AN. On admission the participants were significantly underweight: 86% had a BMI lower than 16 kg/m² and nearly one third (31%) had a BMI lower than 13 kg/m². More than half (54%) of the participants had at least one comorbid diagnosis including borderline personality disorder, post-traumatic stress disorder, obsessive compulsive disorder, generalised anxiety disorder, alcohol and substance misuse, autistic spectrum disorder, depression and gender dysphoria. *Table 1* Demographic and clinical features of the sample by group TAU (*n* = 25) Pathways to Recovery (*n* = 49) Test *P*-value Age at admission (years) 27.64 (8.12) 26.65 (9.27) *t* (72) = 0.45 *P* = 0.65 Ethnicity χ^2 (1) = 1.05 Fisher's *P* = 0.55 White (British) 25 (100%) 47 (96%) Black/African/Caribbean/Black British 0 (0%) 2 (4%) Age at onset of illness 16.07 (4.23) 17.44 (7.01) *t* (52) = 0.71 *P* = 0.48 Length of illness at admission (years) 11.97 (10.19) 8.05 (6.91) *t* (52) = 1.63 Levene's *P* = 0.11 Previous in-patient admissions 1.25 (0.97) 0.88 (0.95) *t* (59) = 1.42 *p* = 0.16¹

Question 1: What is the outcome for patients treated by Pathways to Recovery?

For participants who did not complete the programme, the last available set of outcome data was used as discharge data (*Table 2*). BMI data were available for all patients as this was recorded weekly. However, patients who dropped out within the first four weeks of their admission only completed one set of self-report questionnaires and were therefore excluded from the analysis. *Table 2* Clinical characteristics for Pathways to Recovery group Admission Discharge BMI 14.14 (1.65) *n* = 49 18.73 (2.3) *n* = 49 *P* < 0.001 CORE-OM 22.85 (8.22) *n* = 45 15.59 (8.30) *n* = 45 *P* < 0.001 EDE-Q 3.97 (1.59) *n* = 43 2.49 (1.42) *n* = 43 *P* < 0.001²

There was a significant response to Pathways to Recovery in terms of improvements in BMI, general psychological distress and symptoms of eating disorder. At the point of discharge, the mean BMI had significantly increased from 14.1 (s.d. 1.7) to 18.7 (s.d. 2.3; *t* (48) = 13.32; *P* < 0.001; *d* = 2.78) for patients in the Pathways to Recovery group. A significant proportion of the group achieved a BMI 18.5 kg/m² at discharge: 67% (33/49). The mean CORE-OM score decreased by 7.2 (*t* (44) = 4.50, *P* < 0.001, *d* = 0.88). On average, CORE-OM scores remained above the clinical cut-off point (10) at discharge; however, nearly one quarter of the patients (24.5%) were discharged with scores below the clinical cut-off point. The mean global EDE-Q score at discharge was also significantly lower compared to admission (*t* (42) = 5.04, *P* < 0.001, *d* = 0.93). The mean EDE-Q score had reduced to <1 s.d. above the community norm at discharge (mean = 1.55, s.d. = 1.21) 10 compared to 2 s.d. above the community norm at admission. Almost one quarter of the patients (24.5%) had a global EDE-Q score of within 1 s.d. of the community norm at discharge, representing minimal eating disorder psychopathology.¹³

¹ Data are shown as mean (s.d.) unless otherwise indicated. TAU, treatment as usual.

² Data are shown as mean (s.d.) unless otherwise indicated. BMI, body mass index; CORE-OM, Clinical Outcomes in Routine Evaluation Outcome Measure; EDE-Q, Eating Disorder Examination – Questionnaire.

Question 2: How do the outcomes of patients treated by Pathways to Recovery compare with the outcomes of patients treated by TAU?

There were no significant differences at admission between the two groups on any of the three measures used (Table 3). Table 3 Clinical characteristics at admission and discharge, by group TAU Pathways to Recovery BMI Admission 13.55 (1.89), $N = 25$ 14.14 (1.65), $N = 49$ Discharge 16.94 (2.32), $N = 25$ 18.73 (2.3), a, b $N = 49$ CORE-OM Admission 20.87 (7.59), $N = 21$ 22.85 (8.22), $N = 45$ Discharge 17.09 (9.78), $N = 21$ 15.59 (8.30), a $N = 45$ EDE-Q Admission 3.60 (1.68), $N = 203$ 97 (1.59), $N = 43$ Discharge 2.50 (1.85), $N = 202$ 49 (1.42), a $N = 43$ ^{3,4,5}

A mixed ANOVA revealed a significant main effect of time ($F(1, 72) = 221.67, P < 0.001$) and group ($F(1, 72) = 7.87, P = 0.01$) on BMI. Both of these main effects were qualified by a significant interaction ($F(1, 72) = 5.01, P = 0.03$), which indicated that the change in BMI as a result of time was different between the two groups (Fig. 2). Fig. 2 Effect of treatment on BMI.

The effect of treatment on BMI was thus greater in the Pathways to Recovery group than in the TAU group. To further explore this, simple-effect analyses were conducted. Independent t -tests revealed that although there was not a significant difference in BMI between the groups at admission ($t(72) = 1.37, P = 0.17$), the Pathways to Recovery group had a significantly greater mean BMI than the TAU group at discharge ($t(72) = 3.16, P = 0.002$).

A mixed ANOVA revealed a significant main effect of time ($F(1, 64) = 16.89, P < 0.001$) on CORE-OM. The main effect of group on CORE-OM was not significant ($F(1, 64) = 0.02, P = 0.89$), nor was there a significant interaction between time and group ($F(1, 64) = 1.68, P = 0.20$).

A mixed ANOVA revealed a significant main effect of time ($F(1, 61) = 25.67, P < 0.001$) on EDE-Q. The main effect of group on EDE-Q was not significant ($F(1, 61) = 0.28, P = 0.60$), nor was there a significant interaction between time and group ($F(1, 61) = 0.57, P = 0.46$).

The mean length of admission was 27.4 (s.d. = 14.55) weeks for TAU and 33.2 (s.d. = 17.47) weeks for Pathways to Recovery.

Question 3: How do the outcomes of patients treated by Pathways to Recovery compare with the outcomes in similar in-patient settings?

The outcomes for Pathways to Recovery were compared to those reported by Dalle Grave *et al*,¹³ who describe findings from a CBT in-patient service in Italy, and Goddard *et al*,¹⁴ who describe outcomes from 12 adult in-patient services in the UK (Table 4). Table 4 Pathways to Recovery outcomes compared to other in-patient settings Goddard *et al*¹⁴ Dalle Grave *et al*¹³ Pathways to Recovery Mean length of admission (weeks) 26.4 (17.9) Up to 20 weeks 33.2 (17.47) Discharge BMI (kg/m²) 17.3 (2.1) 18.9 (1.5) 18.7 (2.3) Those achieving BMI 18.5 (%) 22%^a 86.1%^b 67% (49%^a) Discharge EDE-Q 3.3 (1.6) 1.7 (1.0)^{b, c} 2.5 (1.4) Those achieving EDE-Q < 1 s.d. above community mean (i.e. 1.74) (%) Not known 51.4%^b 24.5%^{6,7,8,9}

Pathways to Recovery in comparison to Dalle Grave *et al*13

The mean discharge BMI in both settings was broadly similar. A greater proportion of the Italian patients left with a BMI in the healthy range (BMI 18.5–25 kg/m²) and met the criterion for minimal eating disorder psychopathology.

Pathways to Recovery in comparison to Goddard *et al*14

The Pathways to Recovery outcomes appear to be substantially better than the average outcomes reported by Goddard *et al*14 from 12 adult in-patient services in the UK: 49% of the Pathways to Recovery sample achieved a BMI greater than 19 kg/m² at discharge compared to only 22% of the Goddard *et al*14 sample. The EDE-Q on admission for both groups was similar, and both achieved a statistically significant decrease in scores. However, the improvement in the Pathways to Recovery sample appears to be more clinically significant, achieving values closer to the mean taken from the general female population.

Discussion

In addition to briefly describing the development of Pathways to Recovery, the aim of this paper was to evaluate the outcomes of this CBT-based approach for the in-patient treatment of people with severe and enduring anorexia nervosa. Although the programme is designed for people with any eating disorder diagnosis, the focus of this service evaluation was restricted to those with a diagnosis of anorexia nervosa. The people treated were complex, with almost one-third starting treatment with a BMI of less than 13 kg/m² and more than half having one or more comorbid diagnoses. More than half the participants met the criterion of illness duration proposed by SE-AN.³ It is worth noting that the term SE-AN implies both a severe level of symptoms, including serious medical comorbidities as well as a long duration of illness. Although people with shorter durations of illness may also experience physical comorbidities and other disabling features of anorexia nervosa, these symptoms become progressively more likely as time goes on.

The first key finding was that introducing Pathways to Recovery significantly enhanced weight restoration compared to TAU, with more than two-thirds of participants gaining enough weight to enter the World Health Organization's healthy BMI range. This is important since lower BMI at discharge has been found to be a predictor of relapse.¹⁵ Pathways to Recovery also led to significant improvements in general psychological distress and symptoms of eating disorder, with nearly one-quarter having minimal eating disorder psychopathology at discharge; however, these improvements were not significantly different from those achieved by TAU.

The outcomes for patients treated by Pathways to Recovery were broadly comparable to those produced by another CBT in-patient programme.¹³ The mean discharge BMI in both settings was similar. Although a greater proportion of the Italian participants left with a BMI in the healthy range (BMI 18.5–25 kg/m²) and met the criterion for minimal eating disorder psychopathology, this only represented the outcomes for those who had completed the programme; whereas the Pathways to Recovery data set includes those who did not complete the programme (except those who left within the first four weeks). Furthermore, the Dalle Grave *et al*13 sample included adolescents (29% were younger than 18), thus the mean age and median illness duration were less than the Pathways to Recovery sample. The Dalle Grave *et al*13 sample recorded depression (53.6%) and anxiety (20%) but did not report any other comorbidities. Depression and anxiety are recognised complications of starvation and may have been a feature of the anorexia nervosa rather than comorbidities *per se*. This could indicate a less complex cohort than the Pathways to Recovery sample. This indicates that Pathways to Recovery is effective for not only patients with SE-AN but also for those with other comorbidities. Such patients are often excluded from specialist eating disorder in-patient services due to the complexity of their presentations.

Another key finding was that Pathways to Recovery appears to produce better than average short-term outcomes for in-patients with anorexia nervosa when compared with similar adult in-patient settings in the UK.¹⁴ The length of illness in both groups was virtually identical and although the length of stay was longer for the Pathways to Recovery group, the outcomes demonstrated that instead of being treatment resistant, this group of patients can achieve positive outcomes in terms of weight restoration and improvements in psychopathology. This may be important for generating greater therapeutic optimism for clinicians working with patients on the more severe and enduring end of the spectrum,

and thus give hope to these patients and their families. Improvements in both of these outcome measures are likely to result in sustained recovery post-discharge.

Treasure *et al*³ have suggested changing the focus of those with SE-AN ‘to improving quality of life and minimising discomfort rather than achieving optimal weight’. This approach runs the risk of clinicians and patients assuming that weight restoration is not possible or even acceptable. Furthermore, chronic low weight has many long-term health risks affecting all organ systems,¹⁶ many of which can potentially reduce life expectancy.

However, Calugi *et al*¹⁷ caution: ‘there are strong reasons to indicate that pessimism regarding the recovery prospects of patients with SE-AN may not be entirely justified and consequently steering away from a recovery model may be premature at this stage’. They go on to describe the 1 year follow-up treatment outcomes of their intensive enhanced CBT programme that reveal no significant differences between SE-AN and non-SE-AN patients in terms of BMI and EDE (global and brief symptom inventory) scores at the 12 month follow-up. The mean length of illness for their SE-AN group was 12 years.

Our experience is that offering hope in the form of a recovery-based program to patients with eating disorders – irrespective of length of illness, severity or complexity – is positively received. The uptake following assessment is high, with some patients requesting to be referred nationally.

As a service evaluation, this study inevitably has a number of limitations. The programme was devised, used and evaluated at The Retreat which could introduce potential bias. In addition, two of the authors (L.H. and A.B.) currently work in the service. The outcomes could be positively affected by the fact that the team was actively involved in the development of the programme. On the other hand, the adoption of this new way of working represented a significant cultural shift for the team. Unsurprisingly, a number of changes to the supporting materials and the processes were required, particularly over the first year or so. Any changes were made in collaboration with the participants and team. It is worth noting that no additional resources were used and the staffing levels remained consistent before and throughout the development and implementation of Pathways to Recovery. The only cost incurred was the printing of the materials and the graphics for the poster and folders.

In terms of the comparison between Pathways to Recovery and TAU (i.e. the in-patient programme before introduction of the new model), the patients were not randomised to the different treatment groups and thus there may have been variations between the two groups that could explain the differences in outcomes, despite there being no significant differences in the key demographic and clinical characteristics measured.

If patients had more than one admission, only their first admission was included in the data set (15 sets of data from 14 patients were excluded in total). It could be argued that using their most recent admission would have been more representative for evaluating the effectiveness of the programme in treating people with severe and enduring eating disorders, assuming that difficulties may be even further entrenched by the time people have had more than one admission. However, it may be the case that those who have had a previous admission do better in a subsequent admission as they are able to build on their experiences.

Furthermore, 10 patients were excluded due to having only one set of data. These patients who dropped out in the very early stage of their admission may represent a subset of even more complex cases, making the final sample somewhat self-selecting.

Although patients were contacted at 3, 6 and 12 months post-discharge and asked to complete self-report outcome measures, the uptake was poor and has therefore not been reported in this paper. We are currently investigating alternative methods to collect follow-up data including the use of digital technology. One of the differences between Pathways to Recovery and TAU is the emphasis on transference of skills and the development of increasingly high levels of independence and self-efficacy, which would predict that longer term outcomes are likely to be encouraging.

Many thanks to The Naomi Unit patients, their family members and members of the Naomi team – present and past – without whom the development of Pathways to Recovery would not have been possible.

1.5.39 Rational antidepressant use

Daniel Dunleavy

date

2018-6

Contents

- *Rational antidepressant use*

In her contribution to the ‘Against the Stream’ series, Dr Moncrieff¹ articulates the case for the drug-centred model of antidepressant action. She notes that antidepressants do not typically outperform placebo in well-designed studies (particularly in rare instances where an active placebo is used as a control²), have little clinical effect and can cause serious adverse effects. Having made the case that antidepressants are not ‘specific’ antidepressant agents, she makes some comments about their use in clinical practice. I would like to offer a few remarks about these issues, including some musings about what ‘rational antidepressant use’ might look like.

Modern psychiatric practice has seen the rise and fall of several promising antidepressant agents (the monoamine oxidase inhibitors, the tricyclic antidepressants and selective serotonin reuptake inhibitors (SSRIs)). Recent efforts include testing the possible antidepressant properties of ketamine. But are these efforts futile? Perhaps yes, perhaps no. A truly specific antidepressant drug (if one is ontologically possible) appears to be a pipedream, given current diagnostic limitations. Our categorisation of major depressive disorder is highly heterogeneous,³ creating a disjunctive category of cognitive, behavioural and biological symptoms that do not reliably cluster together. Even if any of our current drugs had specificity for ‘depression’, this would be extremely difficult to uncover in clinical practice or research settings. As a result, drug development will be prone to ideological, as opposed to scientific, revolutions.⁴

Should we therefore abandon antidepressants as a treatment modality? As long as we are honest with our patients about our current state of knowledge, I think not. Drug use has always been an integral part of human life,⁵ helping to alleviate life’s various physical, emotional and existential pains. Antidepressants are no different in this respect. While researchers continue the search for a discrete condition called ‘depression’, drugs such as the SSRIs can be exploited for particular patient complaints. Antidepressants can cause emotional blunting, sedation, activation and decreased libido, among other things. Some have a proclivity towards one effect more than others. These effects can be exploited to relieve particular problems (e.g. sedation to alleviate insomnia, or emotional numbing to transcend an episode of intense anxiety or distress), without pretence towards a yet-to-be discovered condition. A rational provider would match a drug’s effects to the patient’s complaints, irrespective of diagnosis (or drug class); and would remain vigilant to the development of any adverse effects or deterioration of condition, start at the lowest recommended dose, and withdraw the patient from the drug as soon as possible. Psychosocial interventions can remain an important part of treatment, in many cases being the first treatment of choice. Antidepressants, like all drugs, are neither angels nor demons. They should be used selectively and thoughtfully, when used at all.

1.5.40 Author's reply

Joanna Moncrieff

date

2018-6

Contents

- *Author's reply*

In response to Dr Jauhar and Professor Young, I am used to being accused of using ideology, of being selective, of not being balanced or of being polemical. I take no personal offence, but it is important to point out that this is a useful tactic if you want to shut down debate. It harnesses the authority of science to present one view as neutral, objective and credible, and the other as self-interested and unreliable. In truth, we all bring assumptions and biases to our work. I am obviously unable to describe every study ever done on antidepressants in a short article, but I have written books and papers that address all the evidence I could find that supports the disease-centred model of drug action in relation to antidepressants and other psychiatric drugs.¹

Indeed, one of the most important points I am making in relation to drug action is that existing psychopharmacological research is based on unexamined assumptions about how drugs work. These consist of the idea that drugs target the neurological mechanisms underlying symptoms, whether the latest theory about mechanisms concerns abnormalities of neurotransmitters, neural networks or neuro-plasticity. This idea has allowed psychopharmacology research to ignore the alterations to normal functioning that psychiatric drugs produce, and that will affect mental states including mental disorders, regardless of the underlying mechanisms.

Jauhar and Young point out that the latest meta-analysis of antidepressant trials finds impressive odds ratios for effects of antidepressants, but it analyses categorical outcomes derived from continuous data, which has been shown to inflate drug–placebo differences.² Network analysis is also likely to exaggerate differences, since the degree of improvement in comparative trials is higher than in placebo-controlled trials.³ The continuous data, which showed a standardised mean difference (SMD) of 0.3, is in line with other meta-analyses in showing small and almost certainly clinically insignificant differences between antidepressants and placebo, equivalent to around two points difference on the Hamilton Rating Scale for Depression (HRSD).⁴⁻⁵

Jauhar and Young make a good point about the validity of the HRSD, but it is nevertheless used as the primary outcome of most trials. Analyses of the subjective mood item are thus more likely to be influenced by selective reporting of positive findings. However, they are wrong about the Medical Research Council trial, where the dose of imipramine was 200 mg and that of phenelzine was 60 mg. There is indeed evidence either way on the association between severity and antidepressant response, but even in studies with positive findings, effect sizes in those with severe depression are small and unlikely to be clinically significant, and the association may be accounted for by differing expectations in people with more or less severe symptoms.⁶

I agree with the gist of Dr Dunleavy's response. Recommending antidepressants because they produce emotion-blunting effects, or other useful mental alterations (sedation with tricyclics, for example), is a drug-centred model of prescribing. I don't have a problem with this as long as the patient is properly informed that placebo-controlled trials suggest little if any superiority of antidepressants, that they have full knowledge of all the potential adverse effects, and that they are quite clear that the idea that antidepressants correct an underlying chemical imbalance is not supported by evidence. Then they can make their own informed decision.

Abstract

Aims and method

To develop and pilot a clinician-rated outcome scale to evaluate symptomatic outcomes in liaison psychiatry services. Three hundred and sixty patient contacts with 207 separate individuals were rated using six subscales (mood, psychosis, cognition, substance misuse, mind–body problems and behavioural disturbance) plus two additional items (side-effects of medication and capacity to consent for medical treatment). Each item was rated on a five-point scale from 0 to 5 (nil, mild, moderate, severe and very severe).

Results

The liaison outcome measure was acceptable and easy to use. All subscales showed acceptable interrater reliability, with the exception of the mind–body subscale. Overall, the measure appears to show stability and sensitivity to change.

Clinical implications

The measure provides a useful and robust way to determine symptomatic change in a liaison mental health setting, although the mind–body subscale requires modification.

Declaration of interest

None.

Routine outcome measurement is important in mental health settings and can facilitate improvements in quality and outcome.¹ At present, there is no recognised, specific, routine outcome measure for liaison psychiatry services. The Health of the Nation Outcome Scales (HoNOS) have been used routinely in general psychiatry settings for the past 20 years,² but attempts to adapt them for liaison settings have never been realised. Liaison mental health services operate in a variety of different settings and treat people with a wide range of complex and heterogeneous clinical problems, which makes the development of a single outcome tool challenging.³

The Faculty of Liaison Psychiatry of the Royal College of Psychiatrists has developed an outcome framework (FROM-LP),⁴ which includes measures of patient and referrer satisfaction, and a generic clinician-rated measure, the Clinical Global Impression Improvement Scale (CGI-I).⁵ This measure, however, is not specific for liaison settings and does not generate individual symptom ratings.

The aim of this project was to develop and pilot a liaison outcome instrument to be used for local service evaluation, to supplement the FROM-LP framework and to provide data on symptom outcomes. Our intention was to develop a brief, acceptable and easy to use measure that covered common liaison mental health problems, with good reliability, stability and sensitivity to change. This paper describes the development of the measure and preliminary results from its use in two local acute hospital services in Manchester.

Method

Items included in the measure were determined using a modified version of the mini-Delphi method.⁶ We ran three cycles of the mini-Delphi process using panels of clinicians (nurses and psychiatrists) working in different types of liaison mental health services in the North West of England, including acute hospital wards, emergency departments, out-patient and community liaison services, and liaison services for older adults. A pool of potential items (64 items) was initially generated, and a prototypic measure was produced which then underwent 6 months of field testing in a Manchester liaison mental health service. Following this, the measure underwent a series of modifications, including the exclusion and rewording of many items. A subsequent 12-month testing period generated further minor revisions.

The final measure was piloted in this study. It had 22 items consisting of six subscales (mood, psychosis, cognition, substance misuse, mind–body problems and behavioural disturbance) and two additional items (side-effects of medication and capacity to consent to medical treatment). Each item was rated on a five-point scale from 0 to 5 (nil, mild, moderate, severe and very severe). In response to feedback from clinicians, a contextual subscale was also added to represent items which may not necessarily change because of a liaison intervention but may influence or affect outcome (e.g. prior history of severe mental illness). These items are meant to be rated at baseline only (*Table 1*). *Table 1* Liaison outcome measure subscales and items

Settings

Both services involved in the evaluation were based in Greater Manchester. The first was a consultant-led ward-based service for working adults, which operates on a 09.00 to 17.00 h basis from Monday to Friday, based in a hospital with 850 beds. The second was a consultant-led liaison service for older adults, which operates from 09.00 to 17.00 h, Monday to Friday, based in a hospital with 778 beds. The older adult liaison service sees patients on general hospital wards and has a broad reach within the community, including residential and nursing homes, intermediate care units, hospices, home visits and an out-patient clinic in a local mental health unit for older people.

Acceptability and ease of use

Acceptability was measured by asking clinicians who used the measure to record the time taken to complete the measure, and to rate on a seven-point Likert scale the ease or difficulty of completion (1 = very easy, 4 = neither easy nor difficult, 7 = very difficult). Feedback was obtained from nine clinicians, including one consultant liaison psychiatrist, one consultant liaison older adult psychiatrist, three higher trainees in psychiatry, one specialist liaison nurse, two core psychiatry trainees and one FY2 trainee.

Interrater reliability

Interrater reliability was assessed by independent paired raters. Paired ratings were obtained when a patient was assessed on the same day by different members of the same team, or when jointly assessed by a trainee and a senior colleague for the purposes of a workplace-based assessment. Ratings were made separately, without consultation between the raters. Agreement between raters was assessed using intraclass correlation coefficients (ICC).

Sensitivity to change

The sensitivity to change of an instrument is its ability to accurately detect changes if they occur. For the purposes of this evaluation, change was determined by the Clinical Global Outcome Scale-I,⁵ which is recommended by FROM-LP4 and was completed routinely as part of clinical care for patients who were reviewed on at least two occasions. The CGI-I is a seven-point scale (1 = very much improved, 2 = much improved, 3 = minimally improved, 4 = no change, 5 = minimally worse, 6 = much worse, 7 = very much worse).⁵ Patients were divided into three groups: improved (a score of 1 or 2 on the CGI-I), no change (a score of 3, 4 or 5 on the CGI-I) and deteriorated (a score of 6 or 7 on the CGI-I).

It was hypothesised that, if the liaison measure was sensitive to change, there would be a significant difference between the above three outcome groups, and the improved group would show significant improvement on pre and post ratings of the liaison measure, while the deteriorated group would show significant worsening on the liaison symptomatic scores, and the no-change group would show no difference on pre and post scores. The effect size⁷ ($M_2 - M_1/s.d._1$, where M_2 = mean at time 2, M_1 = mean at time 1, $s.d._1$ = s.d. at time 1) for each group was also calculated.

Comparability

It was beyond the scope of this service evaluation project to compare all of the subscales of the measure with appropriate recognised, validated instruments. However, it was possible to compare two of the subscales of the liaison instrument with recognised, validated measures that are used routinely in the Manchester liaison services. The CORE-108 is a brief outcome measure comprising ten items, which has been widely adopted in the evaluation of counselling and psychological therapies in the UK. The CORE-10 is recommended by FROM-LP for appropriate subgroups of patients. The Confusion Assessment Method (CAM)⁹ is a standardised evidence-based tool that enables clinicians to identify and recognise delirium quickly and accurately in both clinical and research settings.

It was hypothesised that the CORE-10 scores would correlate highly with the depression subscale of the liaison measure, but not with the other subscales. As the CAM scale produces a positive or negative outcome, patients who scored positively on the CAM were compared with those who had a negative score (i.e. no evidence of confusion). It was hypothesised that those who had a positive score on the CAM would score significantly higher on the cognitive subscale of the liaison measure than those who had a negative score (i.e. no delirium).

This project was checked using the Health Research Authority website to determine whether or not it would be classed as research, and discussed with the local Research and Development lead. There was collective consensus that it should be classed as a local service evaluation.

Statistical methods

Data were collated and stored, and descriptive statistics were completed using SPSS version 22. Further statistical analysis used the R statistical programming language (version 3.2.5) with the assistance of the ‘RKWard’ graphical user interface (<https://rkward.kde.org/>), as well as the ‘irr’ (<https://cran.r-project.org/web/packages/irr/irr.pdf>) and ‘psych’ (<https://cran.r-project.org/web/packages/psych/psych.pdf>). packages. Normally distributed data were compared using either independent or paired-sample *t*-tests (for before and after comparisons). Non-parametric tests were used for comparison of data that were not normally distributed.

Results

A total of 360 patient contacts with 207 separate individuals were rated using the liaison outcome measure. One person had two separate episodes of care under the liaison team, resulting in 208 individual episodes of care. One hundred and thirteen people had only one rating, 64 people had two ratings, 18 people had three ratings, eight people had four ratings, two people had five ratings, and one person each had six, seven and ten ratings, respectively.

There were 45 parallel assessments of the same individual at the same point in time. Of these, 41 were paired ratings and four involved three raters. There were 78 pre–post ratings which were of the same individual at different points in time. Of these, 47 were undertaken by the same rater and 31 by a different assessor. Demographic information was recorded for 198 individuals, of whom 104 (52.5%) were male. The mean age was 52.6 years (s.d. = 21.7 years).

Scale acceptability

The ease of use of the scale was rated for 228 (63.3%) contacts ($x = 2.1$; s.d. = 1.1). The time taken to complete the measure was recorded for 233 (64.7%) contacts ($x = 2$ min, 30 s; s.d. = 2 min, 8 s).

Interrater reliability

Table 2 shows the ICC for each item of the scale as rated by 45 rater pairs. Kappa () scores for 15 of the 22 items of the scale and five of the seven contextual factors demonstrated ‘good’ ($\kappa = 0.61–0.80$) or ‘very good’ interrater reliability ($\kappa = 0.81–1.00$), using agreement categories as described by Landis and Koch.¹⁰ Four items involving the mind–body subscale showed very low kappa scores (14, 15, 16 and 17). Table 2 Intra-class correlation coefficients (ICC) for items of the liaison outcome measure Measure item n ICC (95% CI) 1 Low mood 360.827 (0.687–0.908)*** 2 Suicidal ideation or self-harm 410.802 (0.658–0.889)*** 3 Problems with psychological adjustment to physical illness 340.656 (0.413–0.812)*** 4 Perceptual disturbances 400.929 (0.869–0.962)*** 5 Abnormal thought content 420.920 (0.856–0.956)*** 6 Abnormal mood (excluding depression) 380.828 (0.693–0.906)*** 7 Problems with orientation 410.861 (0.754–0.923)*** 8 Problems with concentration 330.816 (0.660–0.905)*** 9 Problems with memory 310.821 (0.662–0.910)*** 10 Alcohol-related problems 390.825 (0.691–0.904)*** 11 Illicit drug-related problems 320.921 (0.844–0.960)*** 12 Proprietary medication problems 370.947 (0.899–0.972)*** 13 Acute alcohol or drug withdrawal 400.954 (0.915–0.975)*** 14 Disproportionate disability 360.224 (0.109–0.511) 15 Excessive or major worry about physical health 380.0523 (0.362–0.268) 16 Pain 370.299 (0.023–0.565)* 17 Disproportionate treatment-seeking behaviour 370.211 (0.117–0.498) 18 Agitation or aggressive behaviour 420.776 (0.620–0.873)*** 19 Non-adherence to treatment 410.518 (0.253–0.710)** 20 Consciousness and hypoactivity 420.805 (0.665–0.890)*** 21 Side-effects of psychotropic medication 340.546 (0.259–0.744)** 22 Problems with capacity to give informed consent to treatment 310.593 (0.307–0.780)** 1–22 Scale total 450.799 (0.662–0.889)*** **Subscale scores** A Mood 450.768 (0.614–0.865)*** B Psychosis 450.924 (0.866–0.958)*** C Cognition 450.802 (0.667–0.886)*** D Substance misuse 450.930 (0.876–0.961)*** E Mind–body 450.253 (0.041–0.506) F Behaviour 450.748 (0.584–0.853)***¹²

The ICCs and their 95% confidence intervals for the contextual items were as follows: physical health problems ($n = 43$; ICC = 0.496; CI = 0.233–0.692**); physical disability ($n = 37$; ICC = 0.601; CI = 0.347–0.772***); intellectual difficulties ($n = 35$; ICC = 0.670; CI = 0.437–0.819**); psychosocial stressors ($n = 35$; ICC = 0.696; CI = 0.476–0.843***); enduring mental health problems ($n = 19$; ICC = 0.750; CI = 0.459–0.896***); social function ($n = 28$; ICC = 0.556; CI = 0.237–0.767**); and activities of daily living ($n = 28$; ICC = 0.727; CI = 0.491–0.864***).

With the exception of the mind–body subscale, all subscales of the measure showed ‘good’ or ‘very good’ interrater agreement (Table 2). Agreement for the total score was ‘good’ at 0.799. This increased to ‘very good’ with an ICC of 0.845 (CI = 0.734–0.911, $P < 0.001$) when the mind–body subscale was excluded from the total score.

Sensitivity to change

Seventy-eight patients had a baseline assessment and a final rating, at least 1 week apart. There was an overall improvement on the liaison outcome measure, with a baseline mean of 15.68 (s.d. 10.90) and a post-intervention mean of 8.41 (s.d. 7.66). This was statistically significant ($t = 5.28$, d.f. = 77, $P < 0.001$). Thirty-seven of these patients were classed as showing improvement on the CGI-I (a rating of much improved or very much improved), 35 patients were classed as showing no change (a rating of minimally improved, no change or minimally worse) and five patients were classed as showing a deterioration (much worse or very much worse). One rating for the CGI-I was not recorded, so this individual could not be classified. Table 3 shows the mean scores for each of the three outcome groups, at the baseline assessment and the final assessment. The change in outcome among the three groups was also significantly different (Kruskal–Wallis test, $P < 0.001$). Table 3 Baseline and post-intervention

Comparability with the CORE-10

Twenty-three patients completed the CORE-10. For these patients, there was a significant correlation between the mood subscale and the CORE-10 score ($r = 0.60$; 95% CI 0.31–1.00; $P = 0.001$) and the overall liaison measure ($r = 0.46$; 95% CI 0.13–1.00; $P = 0.013$). There was no significant correlation between the CORE-10 and any of the other subscales: psychosis ($r = 0.31$; 95% CI 0.04 to 1.00; $P = 0.072$); cognition ($r = 0.15$; 95% CI 0.48 to 1.00; $P = 0.705$); substance misuse ($r = 0.10$; 95% CI 0.26 to 1.00; $P = 0.322$); mind–body ($r = 0.24$; 95% CI 0.13 to 1.00; $P = 0.140$); and behaviour ($r = 0.06$; 95% CI 0.40 to 1.00; $P = 0.603$).

CAM

CAM scores were available for 41 patients; 11 of these were positive scores. Patients who scored positively on the CAM had a significantly higher score on the cognition subscale of the measure than those who did not (mean 7.18, s.d. 3.42 *v.* mean 0.47, s.d. 1.43; $P < 0.001$). They also had higher scores on the psychosis subscale (mean 7.37, s.d. 3.26 *v.* mean 1.50, s.d. 2.56; $P < 0.001$) and the behaviour subscale (mean 5.64, s.d. 1.51 *v.* mean 0.73, s.d. 1.68; $P < 0.001$), but not on the mood subscale (mean 1.91, s.d. 2.34 *v.* mean 2.1, s.d. 3.00; $P = 0.612$) or the substance misuse subscale (mean 3.09, s.d. 4.11 *v.* mean 1.43, s.d. 2.22; $P = 0.441$). Comparisons were made using the Mann–Whitney *U*-test for independent samples. Data for the mind–body subscale were not analysed owing to the poor interrater agreement for these items.

Discussion

This study represents a preliminary attempt to develop an outcome measure for local use in Greater Manchester liaison psychiatry services. The findings are encouraging, but cannot currently be generalised beyond the settings involved in the evaluation. Strengths of the measure include: extensive involvement of liaison clinicians in all stages of development, particularly item generation; field testing and refinement of the measure; positive feedback from clinicians regarding ease of use and acceptability; good interrater reliability for most items and subscales, with the exception of the mind–body subscale; preliminary evidence of the instrument’s stability and sensitivity to change, and reasonable comparability for two of the measure’s subscales with recognised instruments used routinely for sub-populations of patients seen by liaison services.

The measure shares some similarities with HoNOS, although many items are more specific to liaison settings (items 2, 12, 13, 14, 15, 16, 17, 21 and 22). Like HoNOS, however, the measure was designed to cover a broad clinical area, rather than a specific psychological dimension.

The measure appears to have face validity in that it covers areas relevant to liaison psychiatry, and all the items were generated by working clinicians in the field. On average, it takes approximately 2 min to complete, but clinicians who are familiar with the instrument can complete it in shorter periods of time.

The heterogeneity of the instrument makes it challenging to validate in a conventional way, as each of the six subscales would need comparison with a separate recognised instrument. We compared it with two measures that are used routinely in our services. There was a significant association between the CORE-10 (a measure of psychological symptoms) and the mood subscale of the liaison instrument, which provides some support for the utility of this subscale. The cognition subscale scores correlated well with positive CAM scores, as did the psychosis and behaviour subscales. These findings provide support for the clinical utility of the instrument, as one might expect that patients who are confused and suffering from delirium may also have symptoms related to behavioural disturbance and psychosis.

It was beyond the scope of this project to use any other recognised appropriate measures for comparison with the other subscales, as no other measures are used routinely in the clinical services involved in this evaluation.

The mind–body items showed disappointingly poor interrater reliability. In the development of the scale, clinicians felt it was important to include mind–body items, but judgements as to whether behaviour or treatment-seeking are ‘disproportionate’ are difficult to make in practice. These items have subsequently been revised and rewritten for further evaluation.

Our clinician panels recommended inclusion of contextual items in addition to the main measure, in order to assess the complexity of patients’ physical, mental and social status. We will report in detail on the utility of these additional baseline items in a subsequent report.

The measure was primarily tested on acute general hospital wards; we are currently exploring the potential utility of the measure in out-patient and emergency department settings with a view to field testing. In addition, most of the raters were doctors, as opposed to nurses. This reflected the staffing of the two services involved in the evaluation, and the requirement of psychiatric trainees to have training in audit and service evaluation. The measure has no items that require specific medical expertise; further evaluation of its use by nursing staff would be informative.

The main purpose of developing the measure was to be able to record symptomatic outcomes in our local services, which would be credible and informative. Despite the above caveats, we believe the measure is better than any other currently available instrument for recording overall outcomes in the liaison setting, and it has been adopted locally and incorporated into an electronic format for routine use, in addition to the FROM-LP framework.

The measure requires further development and field testing in different settings before it can be recommended for widespread use. With this in mind, we are now in the process of applying for funding and ethical approval for a more robust evaluation of the instrument.

1.5.42 Community treatment orders in England: review of usage from national data

- *Community treatment orders in England: review of usage from national data*

We read with interest the paper by Gupta *et al* on community treatment orders in England.¹ This and other reports on the use of compulsory mental health powers are particularly welcome now, as legislation is being reviewed.^{2–4} Scotland’s distinct but comparable law and practice may be more relevant than those of the other jurisdictions mentioned. We are pleased to provide data from Scotland to broaden the picture and consider unique Scottish community provisions for mentally disordered offenders.

Community-based detention was made possible in Scotland by the Mental Health (Care and Treatment) (Scotland) Act 2003, enacted in October 2005. It allows mental health officers (social workers) with two supporting medical reports to apply for a compulsory treatment order (CTO). The Mental Health Tribunal for Scotland can grant either a hospital-based or a community CTO. The criteria are that: the patient has a mental disorder; medical treatment is available which alleviates the effects of the disorder or prevents it from worsening; without the provision of medical treatment there would be a significant risk to the health, safety or welfare of the patient, or the safety of any other person; the patient's decision-making ability with respect to medical treatment for mental disorder is significantly impaired; and the making of the order is necessary. Only the Tribunal can vary the powers between hospital-based and community provisions. Unlike in England and Wales, a community-based CTO can therefore be sought without admitting the patient to hospital and, when they are returned to hospital, it is by varying the order not by revoking it.

Gupta *et al* note that new CTOs in England have been stable at around 4500 per year over the past 5 years.¹ This is in contrast to Scotland, where the use of CTOs (with community-only powers) has increased from 11.2 to 20.5 per 100 000 population between 2008 and 2017.⁵ The proportion of CTOs with community-only powers was 44.9% in January 2017.⁵ If the legislation was similar in England (taking CTOs as a proportion of the total long-term sections, i.e. new CTOs and Section 3s), this was only slightly lower at 37% in 2014/2015.¹

Uniquely in the UK, Scotland also has a provision whereby a community-only compulsion order can be made by a criminal court (which is distinct from the equivalent of a probation order). Compulsion orders with community-only powers operate similarly to their civil equivalent, with breaches addressed by the mental health rather than the criminal justice system. In the 10 years leading up to 2017, three orders with community-only powers were made (where the patient was unfit or lacking criminal responsibility), representing only 2% of compulsion orders made in those circumstances.⁵ Over the same time scale, 14 community-only compulsion orders were made as disposals, representing 2.6% of such disposals.⁵ The role of community detention as a criminal disposal is therefore much less prominent in Scotland than in civil mental health legislation.

We hope this Scottish context adds to the review provided by Gupta *et al*, and we agree, having considered these figures for community-based detention, that it seems 'sensible to take whatever steps possible to see that it is used effectively'. We respectfully suggest that adopting a broader range of data and jurisdictions for such a study would assist in that regard.

Abstract

The editor thanks the outgoing Correspondence Editor Greg Shields and welcomes Dr William Badenhorst as his successor. He reflects upon his own inadequacy as a letter writer in the hope it encourages others to be better.

Declaration of interest

None.

Contents

- *Dear BJPsych Bulletin...*

I must confess that I do not often write letters. As a child I had to be cajoled and then threatened into composing thank you letters at Christmas. I assumed (wrongly, it turned out) that a mumbled ‘Thanks’ was quite sufficient. If only I’d known Heidegger’s arguments for the supremacy of the spoken word at the age of eight, my life would have been easier in so many ways. I’m still no better at postcards, notes of condolence, or work emails, and even texts feel just a little too much effort. It should come as no surprise that as a medical student I did not attempt to submit letters to the *BMJ* to gain an ‘easy’ first publication. Nor do I Tweet.

All this avoidance of letter writing would not appear to be good preparation for a career in psychiatry, however, and I am always immensely impressed by those who do put pen to paper. Freud was of course a prodigious writer of letters;¹ these are worth a read for the light they shed on the man’s foibles as much as the development of his ideas. His letter to the concerned mother of a young gay man,² in which he assures her that homosexuality is ‘nothing to be ashamed of’ and its persecution ‘a great injustice’, exemplifies the qualities of a good letter: crafted, lucid and brief, with a hint of wit. Not everyone can aspire to such prose, but the correspondence section of a journal is often its most lively and combative. Recent notable examples within these pages include the exchange between Sameer Jauhar and Allan Young³ and Joanna Moncrief,⁴ following her typically provocative paper in our *Against the Stream* series. I was also struck by Martin Plöderl and Clemens Fartacek’s admirably brief account of complexity theory in risk assessment in April’s edition.⁵ A well-written rebuttal can influence minds as much as any original paper, and quicker too.

Notwithstanding some admiration for the scribblers’ art, you can imagine my state of mind when our correspondence editor Greg Shields handed in his notice just a few weeks into my editorship. (A temporal relationship need not imply causality!) Greg has worked on the section for 2 years, but a first consultant post means he will now be frantically trying to keep on top of his own correspondence. I’d like to take this opportunity to thank Greg for his sterling work over the past couple of years and wish him all the best in all future endeavours. And I’m able to say this sincerely because in between his tendering his notice and now, we have interviewed for a new correspondence editor and, from a selection of three excellent candidates, appointed William Badenhorst as Greg’s successor. William is certified in both general adult psychiatry and medical psychotherapy so is trained to efficiently process and analyse the many letters sent to the *BJPsych Bulletin*. He promises a fair but firm approach to the publication of eLetters online and in the correspondence section of the journal. Sadly, not every submission realises each of the qualities listed above, and some none at all. Don’t let this put you off writing your own letter to the editor, however. Re-read this editorial and remind yourself, ‘I could do better than that’, then get going. Just don’t expect a reply.

Dr Norman Poole is Editor of the *BJPsych Bulletin* and Consultant Neuropsychiatrist at St George’s Hospital, South West London and St George’s Mental Health NHS Trust, UK.

1.5.44 An evaluation of sleep disturbance on in-patient psychiatric units in the UK

Sam Horne Katherine Hay Stuart Watson Kirstie N. Anderson

Correspondence

Dr Kirstie N. Anderson

(kirstie.anderson@nuth.nhs.uk)

date

2018-10

Abstract

Aims and method

Sleep disturbance is common on in-patient psychiatry wards. This study explored subjective and objective patterns of sleep disturbance and contributory environmental factors. Participants were recruited from mental health acute admission wards and had a range of subjective and objective assessments of sleep. Light intensity and noise levels were measured to characterise potential environmental causes for poor sleep.

Results

We recruited 20 patients; 15% were high risk for obstructive sleep apnoea. Nineteen participants reported poor sleep quality on the Pittsburgh Sleep Quality Index, and 90% had significant sleep fragmentation with objective measures. Inside light levels were low (day <200 lux and night <10 lux). Night sound levels were 40–90 db.

Clinical implications

Sleep disturbance was highly prevalent. Increased awareness of sleep disorders is needed. Modifiable environmental factors on the ward were implicated, therefore increased awareness and a change of approach to sleep disturbance in in-patient psychiatry is recommended.

Declaration of interest

None.

* Limitations of the study

Sleep disturbance in psychiatric disease

The normal timing and duration of sleep is vital for normal mental health.¹ Poor sleep is a core symptom of many psychiatric conditions. However, sleep disorders such as insomnia, obstructive sleep apnoea, REM sleep behaviour disorder and circadian rhythm disorder are also common and remain underdiagnosed.² The frequent comorbidity of disrupted sleep and psychiatric disorder,³ and the negative prognostic effect of disrupted sleep, including on suicide risk,^{4,5} all demonstrate the challenge and importance for mental health professionals of assessing and protecting sleep when patients require admission.

Admission to a psychiatric unit represents both a particular need and opportunity to identify and manage disturbed sleep, including sleep disorders. However, it has been noted that sleep enhancement does not appear to be a priority on acute admission wards. In many trusts, for instance, hourly overnight monitoring of patients remains routine and is paradoxically used because of the risk of harm to the patient.

Overnight monitoring on psychiatry wards

Concerns about the risk of suicide⁶ place a perceived burden on staff in in-patient units to regularly monitor patients overnight. This monitoring can in itself further disrupt sleep and may therefore affect recovery. The standards for the safe care of patients on psychiatric wards by the Royal College of Psychiatrists⁷ do not include or specify protected sleep time, and current National Institute of Health and Care Excellence recommended in-patient pathways⁸ in acute hospitals make no mention of sleep beyond a single survey question about night-time disruption by staff. The best way to monitor, measure and enhance sleep on in-patient wards is unclear. We aimed to objectively assess sleep and the ward environment, and attempted to characterise patterns and causes of sleep disturbance on in-patient psychiatric wards.

Method

Participants were sequentially recruited from four acute psychiatric wards, two male and two female, in two separate in-patient units within Newcastle, Tyne and Wear NHS Foundation Trust. Recruitment was opportunistic, with all patients meeting the inclusion criteria being considered for the study. Inclusion criteria required that participants were aged 18–70 years, able to provide written informed consent and were fluent in English. All participants had capacity to consent and written consent was obtained after a period of at least 24 hours to consider the details of the study. Patients were approached after 72 h on the ward and were included in the study if they were expected to be staying on the ward for at least a 1-week period.

Sleep quality was then assessed with the Pittsburgh Sleep Quality Index (PSQI)⁹ and the risk of sleep apnoea was assessed with the STOP-BANG questionnaire.¹⁰ Using the PSQI, participants were categorised as having normal sleep (score <5), some level of sleep disturbance (score 10) or severe sleep disturbance (score >10). The STOP-BANG questionnaire is a validated screening tool for sleep apnoea. Participants scoring 5 were considered high risk for obstructive sleep apnoea. If a participant was found to be high risk for obstructive sleep apnoea, this was communicated by letter to their general practitioner.

Objective sleep quality was assessed with a wrist accelerometer with a light monitor (GENEactiv original). Participants were asked to wear the watch continuously for a week. Participants who continuously wore the wrist accelerometer for five or more continuous days and nights were included in the study (20 out of 32). The algorithm for analysis has been published and used to assess sleep–wake disturbance in those with and without mental health problems.^{11,12} Total sleep time, daytime naps and sleep fragmentation were all measured. Twelve participants were excluded because of incomplete data: patients were discharged sooner than expected, and for two participants, wearing the watch itself caused agitation and was not tolerated.

Participant medical records were accessed for basic demographics, current and past psychiatric history and any reference to sleep difficulties.

Sound level and light level were identified as potential environmental factors that could affect sleep quality. Monitoring of sound level was carried out with a decibel-metre (Extech 407760). The night-time noise level between 21.00 and 09.00 was analysed over three consecutive nights on two separate wards. Data was measured continuously to allow both baseline average to be calculated and spikes of higher decibel levels to be seen. An unused bedroom was used to avoid disturbing patients with the monitoring equipment itself.

Daytime and night-time light levels were measured with a portable lux meter (MINOLTA chroma meter cs-100). For daytime measurements, the lux level within the bedrooms, communal areas and dining areas across all the wards was measured. Once selected, the same areas were used for repeated measurements. Measurements were averaged over two separate days to account for any differences in inside light level attributable to outside light level. Light measurements were also taken at night-time after 22.00. Night-time measurements focused entirely on the patient bedrooms and were taken on two separate occasions on each ward.

Ethical approval was granted for the study by the East of England – Cambridge East Research Ethics Committee (approval number IRAS 222122).

Results

Over the study period (April 2017–July 2017), there were 150 admissions to the four study wards. Of these, only 40 met the inclusion criteria, mostly because of lack of capacity to consent or short duration of stay. Thirty-two patients agreed to participate and completed both the PSQI and STOP-BANG questionnaire. Twenty participants then provided five or more continuous days of accelerometry recording, and this group were analysed in more detail and the results are presented below. The median age of participants was 49 years (range 30–70 years). Female participants outnumbered male participants by a factor of just over 2:1, (13 women and 7 men). Depression was the most common primary diagnosis, followed by bipolar affective disorder and schizophrenia. Only a single patient had a diagnosis of mania during the admission.

All participants completed the STOP-BANG questionnaire, and three (15%) scored 5 and were therefore at high risk for having obstructive sleep apnoea. All three were male, aged 48, 51 and 57 years, respectively, and all had objectively abnormal sleep as measured by accelerometry, with prolonged sleep period and fragmented night sleep.

Nineteen participants had a global PSQI score 5, representing poor sleep quality, and 12 scored >10 in the more severe range. The single patient with mania self-rated sleep as normal, with a PSQI score of 4, but had objectively abnormal sleep on actigraphy, with irregular, short sleep periods. The range of PSQI scores was between 4 and 18. Fourteen participants scored 10 (severe sleep disturbance). The separate domains of the PSQI were also assessed with previously published subscales looking at sleep efficiency, daily disturbances and perceived sleep quality to see if there was one domain more likely to cause sleep disturbance. 13 Patients all had multiple causes of sleep disturbance including, but not exclusive to, the ward environment. All participants were prescribed some form of psychotropic medication, with 18 participants receiving multiple medications and 8 participants prescribed zopiclone for sleep disturbance.

Actigraphy

Twenty out of 32 participants wore the accelerometers continuously for five or more days. Representative actograms from six participants are shown in *Fig. 1*. Variable patterns of sleep and physical activity were easily visualised over 5–7 days of accelerometry. Participants were categorised as long (average duration of >10 h sleep in a 24 h period), short (<6 h within a 24 h period) or normal sleepers, with regards to the total amount of sleep achieved in 24 h. Eighteen participants had fragmented sleep during their main sleep period, with frequent night waking. No patient had an average sleep period of less than 6 h when on the ward, although three self-rated their sleep as short. Three were (15%) long sleepers and seven (35%) had sleep duration between 6 and 10 h. *Fig. 1* Accelerometry data from six patients showing variable sleep–wake patterns. For all participants, wrist accelerometry data is shown plotted over sequential days from 12.00 to 12.00 over a 48 h period to show the overnight sleep period. Periods of sleep can clearly be seen, as well as sleep fragmentation and night-time awakenings. (a) Female, 70 years of age with a diagnosis of schizophrenia.

A pattern of prolonged sleep with occasional night-time awakenings is seen and daytime naps. (b) Female, 59 years of age with depression. There is reduced daytime activity with naps, and also a very fragmented and prolonged total sleep time. (c) Male, 44 years of age with schizophrenia. There is a shorter sleep time, higher levels of daytime activity and a less fragmented sleep period. (d) Male, 53 years of age with depression. There is a pattern of prolonged sleep, fragmented night-time sleep and prolonged daytime naps. (e) Male, 39 years of age with schizoaffective disorder. There is a more delayed sleep onset between 00.00 and 02.00, with a wake time at 12.00. (f) Male, 48 years of age with depression, alcohol dependence and post-traumatic stress disorder. A striking pattern of delayed sleep phase is seen, with the sleep period during the day and high levels of activity at night.

Actigraphy results showed marked sleep fragmentation and night-time awakenings. It was apparent that light levels were intermittently increased during the night within the patient rooms, consistent with a disturbed night and often coinciding with night-time observations. Many of the long sleepers had fragmented nights with frequent awakenings. Prolonged daytime naps were also seen.

Light and noise levels across the wards

The sound level data showed that the wards maintained an overnight decibel level within a range of 38–70 db, between 21.00 and 05.00, with occasional spikes that reached 90 db. There was variation across the wards and a gradual rise in noise level between 03.00 and 07.00 across the wards to 45 db as an average background. Some causes of the brief spikes in noise included equipment alarms and safety doors closing.

Light intensity was measured across the entire unit and the data is summarised in *Table 1*. Throughout the in-patient areas, there was a very low level of light intensity across all communal areas. None of the indoor areas had a light intensity similar to that outdoors, however the light levels within the bedroom were very low. *Table 1* Mean light levels in different locations

Location	Mean light levels (lux)
Ward A	11.15
Ward B	15.35
Ward C	15.00
Ward D	11.15
Bedroom – door closed	23671138
Bedroom – door open	22881044
Bedroom – light on	231464752
Communal area	37326164221
Dining room	745012058
Outside	11 528
Night-time (approximate time)	23.1522, 4022, 4023, 30
Bedroom – door closed	0000
Bedroom – door open	0.30, 10, 80
Bedroom – side light on	3.73, 654, 1 ¹

Discussion

Subjective assessment of sleep quality showed disturbed sleep for almost all participants (19 out of 20), with marked sleep disturbance reported by 60%. The PSQI was tolerated well and completed by all patients, suggesting a variety of factors affecting sleep quality. Objective measures of sleep also showed significant sleep disturbance, and in particular sleep fragmentation, when measured with accelerometry. One potential cause was the hourly nightly observations, as fragmentation appeared regular and consistent in many participants along with brief periods of increased light levels, and all participants were subject to these hourly checks. We accept that this is simply one potential cause of sleep disturbance, as that it was not possible to correlate actigraphy at all times with the light and noise measurements, given the prolonged period of actigraphy over a 4-month period. However, if patient sleep is being disturbed by these checks, the implication is that this process could be counterproductive, slowing recovery because of the effect of sleep disturbance on mental health. The importance of regular observations is acknowledged in those at high risk of harm (accounting for a number of patients on the study wards); however, the most recent review from the National Confidential Enquiry

1

On each ward, measures were taken at approximately the same time on one cloudy day and one sunny day and the mean was calculated (May 2017). At night-time, measures were also taken on two separate days and a mean calculated.

into Suicide⁶ emphasised the need for a personalised care plan and the avoidance of routine checklists. Reports from this group have suggested that routine observations are not helpful and yet they remain widespread across acute mental health trusts throughout the UK.

There are clearly a number of potential reasons for sleep disturbance within an in-patient psychiatric population, including the mental health symptoms themselves and the medication used to treat symptoms; however, primary sleep disorders such as obstructive sleep apnoea are common in those with severe and enduring mental health problems, and will affect sleep quality and contribute to nocturnal hypertension.¹⁴⁻¹⁵ Risk factors include male gender, body mass index and obesity and age >50 years. It is notable that 15% of patients were high risk for sleep apnoea based on sleep questionnaire screening and all were male. Any in-patient admission offers an opportunity for physical health assessment, with increasing recognition of the poor cardiometabolic health of many with psychiatric disease.¹⁶⁻¹⁷ Obstructive sleep apnoea may be ameliorated by rationalising medication that may contribute to obesity and snoring (e.g. benzodiazepines) and via the effective, evidenced-based therapy of continuous positive airways pressure.

The ward environment may also be a modifiable part of sleep disturbance. It seems likely that sound levels were a contributory factor to sleep fragmentation. The sound level for both wards exceeded the recommended night-time noise level for a hospital ward of 30 db.¹⁸ They remained between 40 db (equivalent to the sound in a library) and 70 db (equivalent to the noise produced by a vacuum cleaner) during the overnight period. The occasional spikes of a much louder noise, which reached up to 90 db (equivalent to the noise produced by a food blender or a lawn mower), are likely to disrupt sleep. There have been previous reports highlighting concerns about noise pollution affecting health in hospitals. This seems an important and potentially modifiable part of night-time sleep disruption.¹⁹

The light levels recorded at night with the bedroom door shut did not exceed 1 lux. This implies that the night-time light environment of patient bedrooms is conducive for sleep when the doors are not opened for observations. At night, with the side light, the light levels recorded were <10 lux in the bedrooms. Daytime light levels, however, were also low, never exceeding 200 lux across the unit and <50 lux in the bedrooms. The retinohypothalamic tract controls circadian rhythm and is dependent on light intensity for normal function.²⁰ Lack of exposure to adequate light intensities may contribute to the dysregulation of circadian rhythms, which is increasingly recognised in psychiatric disorders and may, in turn, contribute to the tendency toward daytime napping and irregular sleep patterns, and may affect the ability of the patient to engage with psychological or occupational therapies.²¹ These data suggest that the light environment of psychiatric wards should be improved and highlight the importance of time off of the ward in outside spaces with natural light.

Limitations of the study

It was not possible to time-lock sound measurement to accelerometry data, as two different methods of recording were used. For future studies, more detailed in-patient assessments, such as video polysomnography, could be used or time-locked continuous video monitoring; however, this detail of recording may in itself cause patient agitation if symptoms such as paranoia and delusional ideation are present. Accelerometry was reasonably well tolerated but still only worn continuously for 20 out of 32 participants. Therefore, non-invasive methods of recording sleep-wake patterns are needed for this population to avoid distress. There has been only a single, smaller study that compared nursing observations, patient sleep diaries and 3 days of wrist actigraphy in eight patients in their initial 3 days on a psychiatry ward. This showed that nursing staff tended to overestimate sleep and that patient sleep improved from the first to the third night.²² This was one reason that we assessed all patients at least 72 h after admission.

The sample size was relatively small, and the study was not powered to look for significant differences across, for example, different diseases or those on or off of different psychotropic medication. A lack of capacity to give informed consent and short stay duration was a reason for many on an acute ward being unable to participate in the study. Therefore future studies may need to recruit over a longer time period to increase the sample size. This remains the first UK study to date to study sleep within acute psychiatry wards.

In summary, the results of this small study demonstrate high levels of sleep disturbance on in-patient psychiatric wards and variable patterns of sleep-wake disturbance. Sleep disturbance affects mental health and so should be a factor when developing care pathways; however, to date, there has been very little qualitative or quantitative research in this area. Some level of sleep disturbance may relate to ward environment and some may relate to an undiagnosed primary sleep

disorder. Therefore, further studies that evaluate a sleep care plan as part of standard in-patient care are recommended.

- *Alan Haworth, OBE (UK), GDCS (Zambia), FRCPsych.*

Head, Psychiatry Service, University of Zambia, Zambia

Alan Haworth, who died on 17 December 2017 at the age of 89 was a pioneering psychiatrist who, over a long period from 1964 until he retired in 2013, established psychiatric services in Zambia. Shortly after his death, the Zambian Minister of Health issued a statement describing him as ‘the father of mental health among the medical fraternity of Zambia’. When he arrived in Zambia, first as a missionary doctor and shortly afterwards as a psychiatrist in the government medical service, the mental health services were extremely limited or, in most parts of the country, non-existent. Haworth took up government positions and had a pivotal role in setting up the mental health services of newly independent Zambia. Following this, he became Head of the Psychiatry Department at the University of Zambia. He set up the National AIDS Counselling Services Unit (at the National Mental Health Resource Centre (NMHRC)) and remained its head for 17 years. He was elected National President of the Zambian Red Cross.

Most importantly, as Chairman of the paramedical committee of the Medical Council of Zambia, he drafted a new Medical and Allied Professions Bill. This enabled the registration of paramedics after highly regulated training, and their substantial but controlled contribution to general healthcare in a country which, at the time, had only a fragmentary health service and hardly any higher educational facilities. Under Haworth’s leadership, Zambia established its own medical school. This enabled a build-up of resources for supplying suitable workers at all levels and the establishment of a healthcare system modelled on the Alma Ata declaration on primary healthcare.

His second achievement was the development of a system for the provision of countrywide mental healthcare, integrated into primary healthcare, and ensuring that the training of various types of specialised workers could take place in close liaison with generic health workers. In an article published in 1988, he described the first 25 years of his experience as a psychiatrist in Zambia.¹ This initially involved travelling around the country by air in an ageing Dakota for three weeks out of four, visiting medical facilities to establish mental health clinics. He developed a course for clinical officers in psychiatry who worked in communities around the country.

In 1972, he applied to the World Health Organization (WHO) for funding to enable him to visit universities in African countries. An invitation from the WHO to participate in a multicentre study of community response to alcohol-related

problems seemed to be mapping a future area of specialisation, but the advent of AIDS in Zambia forced a change and led to what he considered his third most important achievement in the field of health. He was asked to join an AIDS management group and became Director of the Zambian Ministry of Health AIDS Counselling Services Unit. Crash training programmes with some elements of counselling were developed and were adopted by many organisations within and outside Zambia, while Haworth himself became deeply involved in many HIV-related projects, the most important concerning couples' counselling, as well as the long-term monitoring and testing of discordant couples drawn from over 35 000 couples recruited. As a member of the board of an NGO he had set up, in response to the AIDS epidemic and as National President of the Zambia Red Cross Society, he was soon involved in the plight of children (on the streets, as victims of abuse and at risk of acquiring HIV). He took part in a series of studies and helped set up a 'one stop' specialist unit for victims of child sexual abuse at the teaching hospital. He was one of the five founder members of the Family Health Trust. He acted as Chair, ensuring that the organisation would meet the needs of orphans and vulnerable children and women, and that people living with HIV/AIDS were well looked after.

Alan had some special assignments requested of him, first in Zambia where he advised on the approach to the members of a religious cult who had engaged in bloody fighting against the new government. Then, in Congo, he was asked to advise on the possibility of accepting as refugees into Zambia 'boy soldiers' who, with a group of mercenaries, had rebelled against Mobutu. Since they were currently under siege by the Congolese National Army, Haworth found himself under fire, looking after wounded rebels. He reported how he found this less stressful than being caught up in subsequent diplomatic shenanigans. He remained in close contact with 'freedom fighters' from South Africa and Zimbabwe and did consultancies in Mozambique and Liberia on a WHO mission, where he was briefly hijacked by a group of warlord Charles Taylor's soldiers. Throughout his professional life, he seemed to be on the fringes of violence, having once been within seconds of being lynched himself. This experience gave him confidence to know when to intervene, and he certainly prevented at least one other lynching. Called to see a close friend with a serious gunshot wound to the head in a third assassination attempt, he met the former President of Zambia, Kenneth Kaunda, who showed him his own linear graze made by a bullet across his scalp incurred in the same episode.

Haworth received public honours both in the UK and in Zambia. In the UK, he was awarded the OBE for services to medicine. He was made a Grand Commander of Distinguished Service by the President of Zambia in recognition of his services to psychiatry.

Alan Haworth came from an extremely modest background. His parents had both left school at the age of 13, his father to work as a cotton spinner and his mother as a seamstress. Brought up on a council estate in Blackburn, he won a place at the local grammar school. Then, after National Service in the RAF, he studied medicine at Cambridge and the London Hospital. While still a medical student, he had offered to become a missionary and was sent to work in Northern Rhodesia (now Zambia).

Early in his career, while working on prison medical duties, he had several conversations with Zambia's future first president (Kenneth Kaunda), then under detention, and these had a significant influence on his future career.

He never married. However, in 1979, following the tragic death of his cook of 17 years, he took over the care of the widow and her seven children. They became his adopted family. Almost 40 years later, the grandchildren and great-grandchildren of this family claimed that even if he looked different, as far as they were concerned, he was their real grandparent.

Alan's activities began to be curtailed in 2013, owing to ill health, and he returned to Blackburn, where he had been brought up. He had a passion for classical music and spent many long hours in his final years attending the Leeds Piano Competition.

Alan will be remembered as he wished, as a loving grandfather and uncle by his English family, and as a kindly, caring and understanding doctor by his patients. His many former students think of him with affection and respect.

1.5.46 Robert Spitzer's legacy: agreement is halfway to truth

Peter Tyrer

Correspondence

Peter Tyrer (p.tyrer@imperial.ac.uk)

date

2018-10

Abstract

Bob Spitzer died in December 2015 but is not likely to be forgotten quickly. His Herculean task in reforming psychiatric diagnosis, mainly by the development of the third edition of the *Diagnostic and Statistical Manual of Mental Disorders* in 1980, has been acknowledged by many, but it remains unfinished. To complete the process, we need more than good diagnostic reliability, we need better veracity.

Declaration of interest

None.

Contents

- [Robert Spitzer's legacy: agreement is halfway to truth](#)

Most psychiatrists will have heard of Robert Spitzer, but outside the USA he is essentially known for his association with DSM-III, the defining third edition of the *Diagnostic and Statistical Manual of Mental Disorders*.¹ Even this association took some time to establish, and in my lectures I used to explain that the rather unusual name of Spitzer was only an acronym for 'Structured Psychiatric Interviews To Zealously Enhance Research', until people started to believe he was not a real person. Then I stopped.

Shortly after this, I was giving a lecture on the classification of personality disorder in the USA. It was a fairly light-hearted event, and I presented the talk as a debate between two protagonists, one supporting a categorical classification and the other a dimensional one. When I was criticising borderline personality disorder from the dimensional perspective, I joked, 'the classification of borderline personality disorder in DSM-III was only approved after a dead heat on the vote, so it was decided to include it by the casting vote of the chairman. Is this the way to organise a classification system?'

A voice growled from the audience: 'What's the matter with you? Don't you believe in democracy?' The voice came from Robert Spitzer. I have thought about this event continually since and concluded that the single word that summarises the work of Robert Spitzer is 'agreement'. This needs explanation.

Before 1980, international psychiatric classification was in a mess. There can be no other word for it. There were large national differences in the incidence of major mental disorders such as schizophrenia,² fractured understanding because of conflict between psychodynamic and organic schools, and a general cynical attitude towards diagnosis by clinicians, who essentially picked a treatment first and gave the nearest diagnosis afterwards.

Robert (Bob) Spitzer changed all this with his approach to DSM-III. He, and the American Psychiatric Association, recognised that, without substantial agreement in diagnostic assessment, psychiatry was going nowhere. Robert had developed a system using operational criteria to improve diagnosis in research, and now he was being asked to extend this to clinical practice. This was a much taller order than might be thought. Clinicians in busy practice do not take

kindly to research-based formats, and operational criteria had to be understood by everybody if they were going to be accepted.

Once a rough set of criteria had been developed, it was necessary to test them in practice. Nowadays, this would be carried out in the form of field trials; Bob did not have the time, or the resources, for these. So he organised a set of mass colloquia. All the experts in each given field were invited to meet with him at the New York Psychiatric Institute to sort out the new diagnostic prototypes. In this task, Bob became the Great Persuader. As was noted by David Shaffer, one of the experts brought in to examine diagnoses in child psychiatry, these occasions were fairly chaotic, but Bob was clearly in charge and was found everywhere arguing about detail; a key element of all these meetings was that they continued until agreement was reached on all essentials.³ Sometimes, fatigue became the defining factor in getting this agreement; it can be a most effective enabler.

Within days of each meeting, Bob had produced a summary of each meeting in which a new classification emerged with all the levels of agreement listed. A few people scratched their heads – ‘did I really agree to that’ – but they were persuaded by the stellar company of other experts that this was indeed the right way forward. So, when Bob sent in his list of revolutionary proposals to the American Psychiatric Association, he had all the authorities in each field signed up to the new system, and so it had to be accepted.

Views about the DSM-III since its publication in 1980 have oscillated widely. The system of operational criteria worked well for some diagnoses, but not for others such as personality disorder,^{4,5} and there is continued argument over the status of the portmanteau diagnosis of ‘major depressive disorder’, which covers too wide a range of pathology.⁶ Although Spitzer is credited with the removal of homosexuality from psychiatric diagnosis in the 1970’s, it still appeared in DSM-III. There has also been criticism of the expansion of diagnoses and suggestions, some warranted but others unfair, that some of the new diagnoses were engineered to suit the products of pharmaceutical companies.

With each successive version of DSM, the contribution of Bob Spitzer has receded and the volume of dissent has increased, perhaps illustrated most forcefully in the popular writings of Allen Frances.⁷ But Bob kept an eye on these DSM revisions and was far from happy with many of them, particularly when they deviated from his firm notions about agreement, which he was not slow to express.⁸

Of course, agreement is not everything, and the search for validity has to follow. Since DSM-III was published 38 years ago, we have made only the slightest furtive steps towards the aim of independently verified psychiatric diagnoses. Bob Spitzer showed the way, quite brilliantly, but he left us halfway down the track, and it is now up to others to finish the race.

Peter Tyrer is Emeritus Professor of Community Psychiatry at the Centre for Psychiatry, Imperial College London, UK.

1.5.47 Maintenance doses for clozapine: past and present

Avneet Sharma

date

2018-10

Contents

- *Maintenance doses for clozapine: past and present*

We recently completed a quality improvement project for patients on long-term clozapine treatment, with the main aim of assessing the side-effect burden with a view to optimising the treatment. We compared our current clinical practice with one described in a publication 20 years ago in the *BJPsych Bulletin* in 1998 on maintenance doses for clozapine.¹

Murphy *et al* presented findings on 44 patients who had been on clozapine for 6 months or more. Our patient number was 41, and the information was retrieved from electronic case records, although this did not make the job easier as the relevant information was scattered across time and in different sections of the record system.

The patient group in Murphy's study had a mean age of 38 years (21–62 years) with 35 males and nine females, the majority being Caucasian, with a mean duration of clozapine treatment of 38 months (7–69 months). The highest treatment dose prescribed ranged from 300 to 900 mg per day (mean 568 mg), with 50% patients on 500 mg per day or less; only one patient received the maximum dose of 900 mg. The current or maintenance doses of clozapine ranged from 150 to 750 mg per day (mean 460 mg), with eight patients on doses of 150 and 300 mg per day. This was within the British National Formulary (BNF) guidelines at the time (BNF: number 33, March 1997), which clearly differentiated between the higher doses (200–450 mg daily, maximum 900 mg) required initially to stabilise the mental state, and the lower doses (150–300 mg daily) required subsequently for maintenance treatment. The authors found that dosage reductions had been achieved in 29 cases, while there was no attempt to reduce the dose in the majority of the rest of the patients, owing to partial response or less-than-expected symptom control.

Our group included older patients with a mean age of 44 years (29–70 years), who were predominantly Caucasian, with 30 males and 11 females. The mean duration of treatment with clozapine was more than 10 years (range 1–30 years). The dose ranged from 200 to 900 mg per day, with a mean dose of 405 mg per day; 25 patients were on doses between 300 and 500 mg per day, which would have been deemed higher by the BNF guidelines of 1997.

We found that that 80% of patients reported significant side-effects including drooling, sedation/tiredness, gastrointestinal symptoms, weight gain, urinary incontinence, and constipation. Also, a significant proportion (50%) were on medication for side-effects, generally in combination. There were significant metabolic problems, with an average body mass index (BMI) of 29.40 and most of the patients (apart from five) having a BMI above 23; two cases were diagnosed with diabetes and on treatment.

We also found that there had been no reduction in clozapine doses in any of the cases over the past 7 years including more recent cases. Of course, one big difference is that there are no current BNF guidelines for maintenance doses for clozapine; BNF (September 2016–March 2017) mentions a usual dose range for clozapine of 200–450 mg per day that one needs to titrate to when starting clozapine.

The side-effect burden on its own should be enough to make clinicians keep dose review on the agenda on a regular basis. Owing to large variations in metabolism, it is hard to predict the optimum dose and plasma level in an individual patient; the manufacturers² advise that once maximum therapeutic benefit has been established, many patients can be maintained effectively on lower doses with careful downward titration. The past BNF guidelines regarding maintenance doses were thought to be not based on evidence,¹ but empirical; it may be time to revisit the past, as patients appeared to be getting a better deal.

1.5.48 Michael Graham Gelder MA, DM Oxon, FRCP, FRCPsych (Hon), FMedSci, DPM

Philip J. Cowen

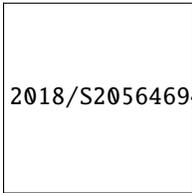

date

2018-10

Contents

- *Michael Graham Gelder MA, DM Oxon, FRCP, FRCPsych (Hon), FMedSci, DPM*

Formerly Foundation Professor of Psychiatry, University of Oxford, UK

2018/S2056469418000360_inline1.jpg

As a young clinical researcher at the Institute of Psychiatry in London in the 1960s, Michael Gelder was only too aware of the need for better treatments of the ‘neuroses’. Management of these conditions was limited to dependence-producing anxiolytic medications and lengthy psychoanalytic psychotherapies, neither of which were particularly effective. Around this time, psychologists had begun to apply learning theory to clinical anxiety disorders, which were conceived as a manifestation of faulty learning or, more specifically, the failure to ‘extinguish’ anxiety that was contextually inappropriate. However, it was not until Gelder’s work that these ideas influenced mainstream psychiatry. Gelder, with his characteristic intellect and scientific rigour, developed effective clinical methods to lessen anxiety by ‘desensitisation’, in which gradual exposure to the feared stimulus was coupled with physical relaxation. This resulted in his seminal 1966 publication with Isaac Marks, which described the first controlled trial of this form of therapy in patients with severe agoraphobia.¹

A few years later, Gelder’s growing reputation as someone able to carry out original and clinically important research across disciplinary boundaries led him to be recruited to the Foundation Chair in Psychiatry at the University of Oxford. Arriving at the Warneford Hospital in 1969, Gelder’s task was to establish from scratch, and with limited resources, a world-class psychiatric research department, as well as organising and conducting undergraduate and postgraduate teaching and sharing in the clinical work of the hospital.

These goals were formidable, but Oxford had chosen well. Rather unusually for a brilliant researcher and clinician, Gelder also possessed remarkable organisational abilities and committee skills, which he used tirelessly and selflessly to build a thriving Department of Psychiatry, one recognised as a world-leading centre for the development and clinical application of psychological treatments.² Early work on agoraphobia used home-based methods to enhance the effectiveness of the behavioural therapy he had developed at the Institute of Psychiatry. Although this was a major advance, Gelder was quick to realise the limitations of a purely behavioural approach and encouraged exploration of the value of adding cognitive strategies, focusing on modifying thoughts, attention and memory. The Oxford Centre that he led was distinguished by an unusually close interplay among psychological theories, experimental studies and clinical innovation – a particularly productive approach. New and highly effective forms of cognitive-behavioural

therapy were developed for panic disorder, generalised anxiety disorder, social anxiety disorder, obsessive–compulsive disorder, hypochondriasis, post-traumatic stress disorder, chronic fatigue syndrome and bulimia nervosa. These cognitive–behavioural treatments have been widely adopted in clinical practice, are recommended by the National Institute for Health and Care Excellence and provide better long-term outcomes than alternative approaches such as antidepressant medication. They have benefited enormous numbers of people worldwide.

In addition to his personal interest in psychological treatments, together with David Grahame-Smith, Nuffield Professor of Clinical Pharmacology, Gelder developed a research unit for the equally new field of psychopharmacology. At the time, this was an almost unique example of cross-departmental collaboration in the Oxford Medical School. The unit's work on the mechanisms by which treatments such as electroconvulsive therapy, anxiolytics and antidepressants actually work has fundamentally shaped our understanding of the biology underlying psychiatric disorders.

Michael Gelder was born in 1929 in Ilkley, the only child of Philip Gelder, a wool merchant, and Alice Gelder, the daughter of a general practitioner. The family soon moved to Bradford, where Gelder attended the local grammar school. Gelder had a longstanding desire to study medicine, but his parents discouraged this ambition, arguing that he should join his father in the family business. However, Gelder persisted, taking science A-levels at evening classes and then winning a scholarship to Queen's College, Oxford, where he took first class honours in physiology. A further scholarship to University College Hospital allowed him to complete his medical training, which was followed by National Service as a Medical Officer at the British Army of the Rhine Headquarters from 1956 to 1958. Through his medical training and early clinical work, Gelder became intrigued by the pervasive role of psychological factors in medical practice. This led him to embark on his training in psychiatry at the Maudsley Hospital, during which he won the prestigious Gaskell Gold Medal of the Royal College of Psychiatrists. Strongly encouraged by Professor Aubrey Lewis, he then worked as a Medical Research Council Research Fellow at the Institute of Psychiatry.

Gelder led the Oxford Department of Psychiatry until his retirement in 1996. He was notable for 'leading from the front', attending all departmental academic meetings, as well as carrying a significant clinical and teaching load. His unparalleled lucidity of thought and encyclopaedic knowledge made him an inspirational teacher; this was captured particularly in the Oxford Textbook of Psychiatry, which he co-authored with Dennis Gath and Richard Mayou. Translated into six languages, this became the standard textbook for psychiatric trainees. One of his most important priorities was to foster the talented young clinicians and scientists who joined his department. Many went on to be leaders in the psychiatric and research communities.

Although Gelder served on major research committees of the Medical Research Council and Wellcome Trust, he had no interest in the personal accumulation of power, and was self-deprecating and modest. Invariably dressed in a grey suit and tie – even when walking his Alsatian dogs – he had a formality of manner, which, coupled with his intense drive for clinical and scientific excellence and his formidable intellect, could make him a somewhat forbidding figure. However, patients spoke of his approachability and kindness, while trainees would comment on how his acute clinical perception and genuine concern for them helped them cope with and learn from the most difficult of situations.

This side of Gelder's nature was, of course, well-known to his family. His daughter Fiona remarked that, as a father, 'he was kind, fair and unfailingly supportive of us all – in school life, marriage and work decisions'. She is a general practitioner, Colin is a chest physician and Nicola runs her own business. Gelder met his wife, Mandy, when he was a medical student at University College Hospital and she was a nurse. Gelder regarded persuading her to marry him as his greatest achievement, and he was devoted to her throughout their nearly 64 years of marriage, showering her with flowers on anniversaries and Valentine's Days.

In retirement, Gelder was able to find more time to indulge his love of travel. He had a wide circle of fond and loyal friends who would have been astonished to learn of the trepidation he had sometimes engendered in junior colleagues. When he gained an Italian son-in-law, he joined Italian classes and at the wedding gave a speech in both English and fluent Italian. Until arthritis supervened, he continued to play real tennis at Merton College, where he was a Fellow. He was an affectionate and attentive grandfather to his eight grandchildren, one of whom, to his delight, recently qualified in medicine.

1.5.49 Individuals seeking gender reassignment: marked increase in demand for services

Josephine Fielding Christopher Bass

Correspondence

date

2018-10

Abstract

Aims and method

To describe the pattern of referrals and characteristics of people aged over 18 seeking gender reassignment in Oxfordshire over a 6-year period (2011–2016).

Results

A total of 153 individuals attended for assessment (of 162 referred); 97 (63.4%) were natal males and 56 (36.6%) were natal females. Mean age at referral was markedly different between the two groups, with females being younger. The number of referral significantly increased over the time period, by an average of 18% per year (95% CI 1.08–1.30). Eighty-seven patients sought transition from male to female, and 46 from female to male, while a smaller group ($n = 13$) had non-binary presentations. Twelve patients (7.8%) had autism spectrum disorder.

Clinical implications

There are various possible reasons for the increased demand for services for people with gender dysphoria, which we discuss here. When planning services in the UK, both the increase in overall referral rates and the apparent earlier age at referral should be taken into account.

Declaration of interest

None.

Gender dysphoria is the personal experience of dissonance between assigned and desired gender. It has always been considered to be a rare disorder, but in recent years there has been an extraordinary increase in the number of referrals to both adult and child and adolescent gender clinics, with services becoming overwhelmed.^{1–3} Five years ago, our group published a service evaluation of referrals to the adult (age 18 onwards) Oxford Gender Clinic between 2004 and 2009.⁴ In this 5-year period, there were 56 referrals. We found levels of psychiatric morbidity to be lower than described in other samples, and there were significantly more individuals seeking male-to-female transition (70%) than female-to-male transition (30%). The natal females (those assigned female at birth) were significantly younger than their natal male counterparts at referral. However, since 2011, there has been an increase in referrals to gender clinics, in particular to child and adolescent services,^{2,3} which has been noted in systematic reviews of prevalence as well as being the subject of considerable discussion in the media.^{5,6} We wanted to determine whether a similar pattern was occurring in services designed to cater for individuals aged 18 and over.

All individuals who request treatment for gender dysphoria in Oxfordshire are referred to a single clinician (C.B.) for psychiatric assessment and subsequent referral to a specialist centre. We aimed to review case notes for all referrals from 2011 until 2016 and to answer the following questions. (1) Have referral patterns changed over time? (2) If so, what are the main demographic and clinical characteristics? We also discuss possible reasons for any changes in referral patterns.

Method

Individuals referred to C.B. between January 2011 and December 2016 were identified from a referral database kept by the Gender Clinic based in the Emergency Department Psychiatric Service at the John Radcliffe Hospital in Oxford. C.B. and J.F. reviewed case notes, and data were extracted and entered into a spreadsheet. All patients who had attended an appointment had had a full psychiatric assessment, as well as a review of any available medical records, such as the general practitioner (GP) summary. All patients were asked at assessment about current or past hormone therapy (prescribed or non-prescribed).

Patients were excluded if they were seen for follow-up only (i.e. they had been referred prior to the start of data collection) or if they had been referred after having previously transitioned. Two patients were also excluded owing to rare conditions: as this was a service evaluation, specific consent was not required, and the small sample size and unusual nature of the conditions meant that there would be concerns about the individuals being potentially identifiable. Data on age at referral were analysed with independent sample *t*-tests using IBM SPSS Statistics version 24.0, and the relationship between year of referral and numbers of referrals was examined using a negative binomial regression model in Stata, version 12 (StataCorp).

Results

Demographic characteristics

From a total of 164 referrals received, 153 individuals attended for assessment. The majority of patients were referred for initial assessment, and the 'did not attend' rate was low at 5.6%.

The numbers of referrals, in 6-monthly intervals, between 2011 and 2016 are shown in *Fig. 1*. *Fig. 1* Referrals for gender dysphoria from 2011 to 2016.

Analysis of the numbers of referrals over time from 2011 to 2016, with data in 6-monthly intervals, was performed using a negative binomial regression model. This showed that the relationship between the numbers of referrals and year was significant at $P < 0.001$. The incidence rate ratio was 1.18 (95% CI 1.08–1.30), meaning that, on average, each year saw an average increase in the number of referrals of 18%. When the analysis was repeated separately by natal sex, the number of referrals of both natal males and females increased significantly over time, but there was no significant difference between the natal sexes in the relationship between number of referrals and time.

The increase appeared most marked in the second half of the time period: the number of referrals nearly doubled over the 6 years, with 59 referrals from 2011 to 2013 and 103 from 2014 to 2016. Furthermore, mean ages were significantly lower in the latter 3 years compared with the first 3 years (a mean of 5.7 years younger, $t(112) = 2.4$, $P = 0.018$) (*Fig. 2*). *Fig. 2* Mean age at referral.

Gender characteristics

Of the 153 individuals who attended for assessment, markedly more were natal males (97, 63.4%) compared with the 56 (36.6%) who were natal females (*Fig. 3*). The natal females were significantly younger than their male counterparts at referral: there was a mean difference of 10.5 years ($t(160) = 5.5$, $P < 0.001$), with a mean age of 34.4 years for males and 24.3 years for females. This is consistent with the findings of our previous study; see *Table 1* in Saunders and Bass (2011). There was no significant difference in the overall age of the sample compared with the previous study ($t(209) = 0.98$, $P = 0.33$). *Fig. 3* Diagnoses. *Table 1* Mean ages of all patients referred 2011–2013 and 2014–2016

Referral period	n	Mean ages	d.s.e.m.
2011–2013	59	34.37	1.49
2014–2016	103	28.70	1.34

Eighty-seven individuals (56.9%) were seeking to transition from male to female, and 46 (30.1%) from female to male, while 13 (8.5%) had non-binary gender identities. All but one of these 13 individuals were seen from 2014 to 2016. Overall, 146 patients (95.4% of those attending the clinic) were assessed as having gender dysphoria.

The remainder ($n = 7$, 4.6%) had a number of problems or reasons for referral that were not assessed as gender dysphoria (including body dysmorphic disorder, homosexual identity, discomfort with certain aspects of gender identity but not to the extent of gender dysphoria, fetishistic transvestism, and ideas about gender related to psychotic beliefs).

Hormone therapy

Twenty individuals (13.1%) reported taking hormone replacement therapy at the time of assessment, with an additional five who had had hormones at some time in the past, plus two who had been prescribed finasteride for male pattern baldness. Of the 25, six were taking or had taken male hormones (such as testosterone), and 19 were taking or had taken female hormones (such as oestrogens).

Educational level

Notably, perhaps partly because of the geographical location of the study, a high proportion of our sample (39.2%) had either been educated at BA degree level or higher (34, 22.2%, including those currently undertaking postgraduate study) or were current undergraduate university students (26, 17.0%).

Comorbidities

Of those who attended for assessment, 60 (39.2%) had a current psychiatric comorbidity, and 81 (52.9%) had a past history of mental illness. Twelve (7.8%) had a diagnosis of autism spectrum disorder (ASD). Depression was the most common mental disorder overall; 26 (17.0) had a current episode of depression and 59 (38.6) had had at least one previous episode. Seven patients (4.6%) also reported a current or past history of self-harm. Other comorbidities are reported in *Table 2*.

Comorbidity	Current, n (%)	Past, n (%)
Any	60 (39.2)	81 (52.9)
Depression	26 (17.0)	59 (38.6)
Bipolar affective disorder	3 (2.0)	0 (0.0)
Substance misuse – alcohol	2 (1.3)	8 (5.2)
Substance misuse – drug	1 (0.65)	8 (5.2)
Psychotic illness	2 (1.3)	4 (2.6)
Post-traumatic stress disorder	1 (0.65)	2 (1.3)
Generalised anxiety	6 (3.9)	7 (4.6)
Social phobia	9 (5.9)	4 (2.6)
Panic disorder	3 (2.0)	3 (2.0)
Obsessive–compulsive disorder	4 (2.6)	0 (0.0)
Other anxiety disorders	1 (0.65)	1 (0.65)
Dissociative episodes	0 (0.0)	1 (0.65)
Eating disorder	0 (0.0)	4 (2.6)
Body dysmorphic disorder	4 (2.6)	0 (0.0)
Autism spectrum disorder	12 (7.8)	0 (0.0)
Attention deficit hyperactivity disorder	5 (3.3)	1 (0.65)
Personality disorder	2 (1.3)	4 (2.6)
Chronic somatoform disorder	1 (0.65)	0 (0.0)
Learning disability	2 (1.3)	0 (0.0)

Outcomes

The majority of patients ($n = 135$, 88.2%) were referred on to a specialist referral centre for further assessment.

Of those not referred, 11 (7.2%) had gender dysphoria but were not ready to pursue transition or onwards referral was considered inappropriate. For example, some did not wish to disclose their transgender identity to their spouses, or felt that transition would be unacceptable to their social networks given their cultural backgrounds. Of the remaining seven patients described above who were not thought to be transgender, six (3.9%) were not referred but were offered alternative treatment or discharged, and one (0.65%) was nevertheless referred on to a specialist gender clinic for a second opinion.

Discussion

Summary of findings

In a study of 162 patients referred to the Oxford Gender Clinic between 2011 and 2016, we report a significant increase in the number of referrals over the 6-year period, despite no changes in local policy or funding of the clinic. In particular, there is no designated endocrine clinic for patients to access in Oxford. The increase was marked in the past 3 years, with 103 referrals from 2014 to 2016 compared with 59 from 2011 to 2013. Similar findings have been reported in child and adolescent services.² Our experience is also consistent with recent findings from a paediatric endocrinology service:³ of 38 patients seen over a 13-year period, 74% of referrals to the clinic occurred during the past 3 years. In our detailed case note review of the 153 patients who attended for assessment, we also found a high rate of psychiatric comorbidity (in particular, depression and ASD), consistent with existing literature.

Strengths and limitations

The strengths of our study were that there is a single point of access in Oxfordshire for onward referral to specialist gender clinics, so our case note review was able to capture all patients referred within a certain time period in this geographical area. We were also able to compare the results with those of our previous study in 2004–2009.

Limitations of our study were that the clinic's assessment does not include a structured diagnostic interview, and although previous medical records were available in some cases, this was variable. Patients who had recently moved to the area, for example, might have had incomplete information in their local records, which might have particularly affected the large student population. Some information, such as on the number of patients taking hormones, was largely gathered through self-report, which may lead to underestimation.

Consideration of reasons for changes in referral patterns

Examination of our referrals in more detail revealed that the patterns of referrals changed during the 6-year period, with mean age at referral decreasing. The prevalence of non-binary gender presentations also increased during the 6-year period, echoing the phenomenon discussed by Richards *et al.*⁷ This may reflect a change in how people's gender identities are developing, possibly because of the increased availability of information about non-binary genders from social media, the internet and peers. An alternative explanation might be that patients identified in this way previously, but perceived that if they disclosed this at assessment they might be denied treatment. It is conceivable that with greater awareness and less social stigma, these individuals may be developing more confidence about explaining their complex gender identities to professionals. The provision of comprehensive and accessible information to patients about options for gender identity and expression and possible medical interventions is crucial.⁸

We found similar rates of comorbid psychiatric disorders to those reported by others,⁹ with depression being the most common comorbidity. Like de Vries *et al.*,¹⁰ we found anecdotally that after patients had declared their gender dysphoria to others, or 'come out', their mood often improved and self-harming behaviour reduced in frequency or ceased. Also, as in previously published literature,¹¹ we found high rates of patients referred with a diagnosis of comorbid ASD (in our sample, about 8% of those attending for assessment). Although the assessment in the clinic does not include a structured diagnostic interview or a formal autism assessment, and hence our case note review only included previously established autism diagnoses, even this potential underestimate was still notably higher than the prevalence in the general population (estimated at 62 per 10 000 in a worldwide review¹²). This echoes the findings of de Vries *et al.*,¹⁰ who systematically assessed children and adolescents referred to a gender identity clinic and found an incidence of ASD of 7.8%. They commented on the diversity of their findings, with both males and females having increased rates of ASD, and the variety of gender identity disorder diagnoses found in those individuals in their study with ASD. They speculated that in some individuals with ASD, feelings of gender dysphoria might be related to an experience of being 'different' generally and having difficulty with identity development, or to more rigid and concrete ideas about gender norms.

An unexpected finding was that only 20 (13.1%) of patients were taking hormone treatment at the time of assessment, which is below the figure of 23% reported by Mepham *et al.*¹³ Our study methods did not allow us to explain this discrepancy, although, like Mepham *et al.*, proportionately more of our patients were transwomen taking oestrogens. Our findings do raise the possibility of underreporting, as hormone use was assessed through self-report, but this cannot be confirmed without more invasive methods such as blood tests, which were beyond the scope of our study. Another possibility would be that our sample truly had a lower rate of taking hormones, perhaps owing to an increased awareness of the medical risks of non-prescribed hormone treatment.

How can these recent marked increases in referral rates be explained? Our study does not provide any clues as to aetiology, but there are many possible explanations. An increase in referral rates can be due to an increase in the prevalence of the condition in the population, or to a change in help-seeking behaviour. Although our study does not provide evidence to differentiate between the two explanations, there have certainly been some recent cultural shifts which could influence the likelihood of patients with gender dysphoria seeking treatment. First, the public profile of transgender issues has been raised of late, with a recent increase in high-profile media figures such as Caitlyn Jenner and Chaz Bono coming out as transgender, and the broadcasting of a variety of documentaries about transgender people, including transgender children.¹⁴ The internet also provides much greater access to information about gender issues, so

that individuals can research their condition and treatment options, and connect with others for support and advocacy. Many people, for example, document the story of their transition on YouTube to provide others with encouragement and advice from their personal experience. Lesbian, gay, bisexual and transgender (LGBT) support groups may also be more accessible because of the internet, and these also provide a source of peer support and information. Second, there have been campaigns to promote transgender people's rights and reduce discrimination in the UK and elsewhere, although significant stigma and discrimination do remain.¹⁵ All of this may have helped individuals with gender dysphoria to overcome barriers to seeking treatment, and potentially to presenting to healthcare professionals at an earlier age. Third, when patients present in primary care, or other contexts such as secondary mental healthcare, GPs and other health professionals have acquired a greater awareness of gender dysphoria and may be more likely to refer people for assessment.

However, decreased stigma and increasing access to information may not wholly account for changes in referral patterns, and additional factors may be needed to explain this. Advances in understanding the cause of gender dysphoria could help account for changes in prevalence; however, neurological studies investigating the possibility of structural or functional changes in the brains of those with gender dysphoria have as yet been inconsistent or inconclusive,¹⁶ and it is difficult to see how they could account for rapid changes of the nature seen in this and similar studies.

The implications of our findings support those of other recent studies, and together suggest that commissioners and others need to take into account the accelerating trend in referrals when planning services. People with gender dysphoria are distressed by long waiting lists and perceived health inequalities.¹⁷ In order to cope with increased demand, services need to provide multidisciplinary and interdisciplinary teams and networks that work and collaborate in the provision of services for people with gender dysphoria, as recommended in the Royal College of Psychiatrists' guidelines.¹⁸ Given the recommendations in ICD-11¹⁹ that gender dysphoria be removed from the mental health section and renamed gender incongruence, a further question arises as to which medical discipline is most appropriate to provide these services.

We thank Achim Wolf for his invaluable help and advice on statistical analysis and comments on the manuscript, and Dr Kate Saunders for her work on the previous study.

1.5.50 What leads to innovation in mental healthcare? Reflections on clinical expertise in a bureaucratic age

Neil Armstrong

Correspondence

Neil Armstrong

(neil.armstrong@anthro.ox.ac.uk)

date

2018-10

Abstract

This paper considers a witness seminar in which healthcare professionals discussed working on an acute admissions ward run along therapeutic community lines from the 1960s to the 1980s. Participants remarked that older styles of working are ‘unimaginable’ today. This paper discusses why. Literature from the humanities and social sciences suggest healthcare is reactive, reflecting wider cultural changes, including a preference for a more bureaucratic, standardised, explicit style of reasoning and a high valuation of personal autonomy. Such a reflection prompts questions about the nature of professional expertise, the role of evidence and the importance of the humanities and social sciences.

 - *Understanding the Phoenix from the perspective of the present*
 - *Conclusion*

Professional autonomy as a source of authority

It is tempting to think of clinical expertise as autonomous. Indeed, it appears to be an essential part of the role of mental healthcare clinicians that they do not merely reflect or reproduce everyday ideas and assumptions about mental disorders and their treatment, but bring something distinctive to the table. This distinctive contribution is the result of intensive training, painstaking clinical experience and robust scientific research. Understood in this way, collective professional sovereignty seems to be a critical ingredient in differentiating experts from the lay public. It is on the basis of this differentiation that expert opinion may be seen as deserving more weight than the views of a non-specialist. This might suggest that a contrast between expert knowledge and lay knowledge is both necessary and desirable. Educating patients, their family and friends, and the wider public typically means challenging lay assumptions and replacing them with clinically authorised knowledge. This has been the way that campaigns against stigma have been conceived.¹ Similarly, ‘psychoeducation’, which is deemed to be a possibly beneficial adjunct to care for people receiving treatment for mental disorders, is designed by clinicians and intended for the patients, and not the other way round.

There a number of reasons that disciplinary autonomy might be a useful and attractive notion. Autonomy contributes to authority in a setting where authority is both justified and necessary. However, these considerations might encourage a lack of attention to the real status of mental healthcare expertise. This autonomy may not be quite as it appears. I do not want to suggest here that the collective professional sovereignty of mental healthcare clinicians is entirely false, illusory or illegitimate. Instead, I want to make a more cautious argument that, in practice, professional expertise is deeply reactive. Rather than being the sole active agent, mental healthcare professionals as a group are acted upon by wider social and cultural forces. Factors external to professional bodies can shape expertise and practice in ways that are critical and yet difficult to detect.

The views of the general public about, say, what might count as a pathological personal trait and how this might be differentiated from what might better be thought of as eccentric, shape clinical judgement. In practice, any other relationship would be rather odd: mental healthcare professionals are in a position to develop common-sense thinking about distress and madness, but if it were to diverge too far from public opinion, it would be likely to lose its claim

to authority. A concrete example might be homosexuality. In the 1960s and 1970s, this was first modified and then dropped as a diagnostic category, not because of research findings, but because of wider shifts in public opinion.^{2,3} This is instructive. However much it is predicated on science, the authority of mental healthcare practitioners also rests on popular consent. A widespread loss of confidence in mental healthcare would mean an existential challenge for the discipline as a whole. This complex and two-way relationship between expert knowledge and common sense is not unique to mental healthcare. In a major study of scientific and folk thinking about biology, Atran found continuity between ‘ordinary thinking’ categories describing vegetation and those of the biological sciences, such that each can learn from the other.⁴

Healthcare and its cultural surround

An important point for this discussion is that the external factors that shape clinical work are not always as simple as popular views about sexuality, or the acceptability of unusual character traits. More subtle influences are at work. Basic clinical categories and practices that clinicians might typically think of as arising out of autonomous clinical expertise seem to resonate with widely discussed social and cultural processes. These processes are moral as much as scientific, dealing with values, commitments and orientations. We might wonder whether the cart is pulling the horse or, indeed, which is which.

Take, for example, the notions of risk, accountability, responsibility and anxiety. All figure large in clinical practice. Drawing on the work of Beck, Giddens argues that accountability is linked to risk and anxiety, forming part of what he calls the ‘contours of high modernity’ in which personhood is being ‘reshaped’.^{5,6} It appears that this high modernity shapes medicine as much as medicine shapes high modernity. Giddens notes how individuals increasingly see life as containing risks, and that dealing with risk and controlling the future is one of the ‘core aspects of modernity’. Critically, according to him, dealing with risk is now an individual challenge. The modern individual seeks to personally equip himself or herself by means of gaining knowledge to enable autonomous decision-making. These ideas seem to be reflected in the way that patient-centred care or patient empowerment is conceptualised. We might conclude that the personalisation of care and the goal of patient empowerment are part of modernity rather than arising out of autonomous clinical reason.

In a similar way, for many commentators, what knowledge is and what might count as good reasons for a decision are changing. For example, it is increasingly the case that a good decision is one that might be defended in an impersonal way. In *Trust in Numbers*, Porter makes a distinction between what he calls ‘disciplinary objectivity’ and ‘mechanical objectivity’.⁷ The former arises out of a consensus of experts. As it consists of expert judgement, it demands trust. By contrast, mechanical objectivity is derived from the use of quantified data and the following of rules. This appears impartial, rigorous and unbiased.

Porter suggests that much of the appeal of quantitative, mechanical objectivity is ‘mythical’ and confused. It is nonetheless very attractive. Part of the reason for this is that it appears impersonal, in that data and algorithms replace personal judgement. According to Porter, underlying mechanical objectivity is an ethic that ‘rules should rule’, rather than people ruling. He puts it like this: ‘Scientific objectivity thus provides an answer to a moral demand for impartiality and fairness. Quantification is a way of making decisions without seeming to decide’⁷ (p. 8). These epistemic preferences shape our sense of what expertise consists of. Expertise is taken to be a capacity for explicit and auditable decision-making. Good decisions are impartial and fair, which is signalled by the erasure of the decision maker.

These trends are widely recognised. A great deal of professional work today is being reconfigured. Whether it is education, banking, the military or international development, expertise is becoming formalised and ‘managerialised’, reinterpreted as a sequence of explicit decisions, capable of being scrutinised externally, and underwritten by the mechanical objectivity of evidence and policy. Graeber talks of the ‘era of total bureaucratization’ in which standardised forms of knowledge are reductive and yet dominant, unsatisfactory and yet overpowering.⁸ The effects of this are ubiquitous, but particularly found in medicine. Porter⁷ comments that: “In public even more than in private affairs, expertise has more and more become inseparable from objectivity. Indeed, to recur to the previous example, it is in part because the relation of physician to patient is no longer a private one – due to the threat that it might be opened up in a courtroom – that instruments have become central to almost every aspect of medical practice (p. 7).”

Harrison argues that the rise of evidence-based medicine and the introduction of market mechanisms in the National Health Service has led to a change in the way that clinical knowledge and expertise are conceived of, a transition away

from instinct or personal judgement, and towards propositional knowledge and instrumental rationality.⁹

Clinical memory as a source of knowledge

One way of thinking through these issues is to attend to the experiences of staff whose careers span different working styles. The Phoenix Unit was an acute admissions ward run according to the therapeutic community concept at the Littlemore Hospital in Oxford. It was set up by Bertram Mandelbrote in 1959 and closed in 1996. The ethos of the Phoenix was to explore the behaviours and feelings of residents through community life and, in particular, in group settings. Daily community groups formed the centre of care and were supplemented by working groups, occupational therapy, crisis groups and relatives' groups. Over time, the ward became well known and attracted considerable interest.

A reunion of Phoenix Unit staff members took place on 19 October 2016 in the Barns Conference Centre, part of the Planned Environment Therapy Trust (PETT), near Cheltenham in Gloucestershire. There were 23 participants, including psychiatrists, nurses, a psychologist, a social worker, an occupational therapist and an art therapist. The reunion consisted of six recorded sessions. After a 30-min introductory session, the group split in two, with each subgroup talking for about 80 min. There followed three sessions involving all participants, totalling almost 2.5 h. So, the total record is a little short of 6 h discussion. All the recordings were transcribed, and both the recordings and the transcriptions are archived by the PETT. There was a lot of mutual recognition among the participants. Many were happy to be reunited with former colleagues. Some participants were longstanding friends, others less known. Participants were mostly confident about speaking in a large group. In fact, participating in group discussion might be understood as a facet of clinical skill. No formal methodology was adopted to analyse the material. As might be appropriate, given the themes of the paper, the author relies on his own judgement about the discussions, rather than seeking authority through algorithm or quantification.

Staff remember the Phoenix as 'very 60s' and 'very permissive'. A culture of openness extended to patients, ex-patients, families and staff. 'We were all part of it', said one. The atmosphere on the ward was described as 'apparent chaos' or 'chaos', and by one person as 'the maddest place I've ever seen'. Hierarchies were flattened, professional roles blurred, and staff understood themselves to work 'alongside' patients as equals. Interaction was relaxed and informal. Patients were encouraged to express themselves. One participant said people 'came to be mad'. Another remarked that staff 'allowed behaviour'. Expertise was not located solely with the professionals. Patients helped other patients, and staff learned from patients. It was said that 'Everyone was a therapist, including the patients'.

The unit gave staff huge amounts of freedom. Discretion and professional judgement were favoured over routines and standardised rationales. Care seemed to rest on spontaneous creative decisions. A spate of broken windows led to patients being paid to break windows. As one participant put it: 'there was no plan ... no structured response' to events. There was a stress on 'carrying the culture' but less emphasis on note-taking. Written documentation was minimal. It is telling that key therapeutic events took a form that, to the bureaucratised imagination, sounds like an oxymoron: 'agendaless' meetings.

Diagnosis and targeted medications seem to have played a small part. The flexible, non-medicalised culture of the unit was described as helping staff to understand patients as people, rather than carriers of impersonal disorders. It helped one participant to see 'the person behind the patient', and another to see that 'we're all human beings'. In addition, a less medical approach to distress reduced the superordination of doctors and meant all the staff members had a part to play. The opinions of cleaners, for example, were frequently sought. However, patients had to commit to the process. Group attendance was compulsory, and patients who didn't engage might be considered for discharge. And when drugs were prescribed, even if it was to 'contain' excessive mania or anxiety, rather than to treat a disorder, they were in what one psychiatrist dubbed the 'monster doses' typical of the period.

Understanding the Phoenix from the perspective of the present

The witness seminars are remarkable because they show how profoundly and how rapidly care has changed. My suggestion is that this change reflects wider cultural processes. It isn't that accurate forms of measurement showed that the unit was less effective, or less safe or more expensive than contemporary arrangements (although it may have been some or all of those things). Rather, the cultural surround changed such that less patterned practice seems less professional. In Porter's terms, improvised, intuitive exchanges between staff and patients are not constitutive of mechanical authority.

Several participants remarked that problems with the production of paperwork are why such a unit could not be imagined today. People on the Phoenix 'were bad at taking notes', which made it 'the opposite of what is going on now'. It is hard to see how the kinds of activities described by the participants could be recorded in an economical and standardised way. Unpatterned, improvised and complex activity is difficult to document. In highly bureaucratised times, care that can't be documented is not professional. Personal judgement and the 'culture' of the institution are weak justifications for treatment.

Moreover, care was more organised around personal development than patient empowerment. As a permissive setting in which individual preference trumped rules, the unit might be seen as the vanguard of individualism. Yet care in the Phoenix was modelled around goals that reflected a more social and less individualistic conception of personhood and human flourishing. The reunion suggests something further: that seeing people as social beings might be difficult to square with bureaucratic culture. This social dimension of mental health might fall somewhere beyond what we might expect an accountable bureaucracy to successfully address. To use Giddens's phrase, the Phoenix shared few of the contours of high modernity.

The influence of all of this on staff members appears mixed. Routinisation can protect staff members from the pressures of deliberation and personal responsibility. Rule-following requires less of a staff member than thinking problems through afresh. In Porter's terms, impersonal 'mechanical objectivity' erases the individual clinician. By contrast, spontaneity is hard work. As a result, staff seem to have found it extremely taxing to work at the Phoenix, but also enormously educative and influential. More was expected of them, and more was gained by them. Staff could flourish, but they could also burn out. Working at the Phoenix led to self-exploration that was at once therapeutic and intensely stressful. The impression created by the seminar participants is that standardisation and mechanical objectivity protect clinicians. It appears that this comes at a cost: clinicians who are shielded by rules have reduced opportunities for learning.

Conclusion

The recollections of the Phoenix staff resemble in striking ways widespread changes in professional culture discussed in the humanities and social science literature. A trend towards more bureaucratic working practices, and for expertise to consist of a capacity to adopt a standardised, explicit style of reasoning, are widely observed in the literature and were widely remarked upon by the Phoenix staff. This suggests that innovations in clinical practice are, to a degree at least, determined by cultural factors external to the mental healthcare professions. This is not to claim that the only source of innovation is the cultural surround. However, clinical practice, styles of service delivery and planning, and even notions of professional expertise and patient health are being reconfigured in ways that appear to be part of a wider transformation of professional lives. Whether we like it or not, we live in bureaucratic times. Bureaucratic values increasingly enter professional domains, blurring distinctions between formerly separate bodies of expertise. Clinical sensibilities about risk, for example, resemble those of a policy maker or bureaucrat.¹⁰ It is telling that good mental health is increasingly framed in terms of personal autonomy and social and economic independence. There is nothing specifically clinical about these categories. Instead, they are rather open and flexible notions, which may be transferred across professional frontiers. They seem to naturally belong to Giddens's high modernity.

This might seem an unappealing state of affairs. As I tried to suggest in the first part of the paper, one reason for unease might be that admissions of cultural influence can be seen to undermine clinical authority. I suggest that this need not be the case. Further, I argue that such influence is anyway inevitable. The relatively unstructured and hard-to-document working practices in the Phoenix unit would be unthinkable today not for reasons of evidence of effectiveness, safety

or value for money. Instead, they look unprofessional. They would be difficult to audit. We might imagine they would stick out in documentation presented to the Care Quality Commission, or to the local clinical commissioning group.

This has a number of implications, not least regarding how to understand innovation in medical practice. If a cultural impetus as identified by Porter, for ‘rules to rule’ and not people to rule, leads to shifts in clinical practice such as those described by the Phoenix staff members, what are we to make of other accounts of innovation, such as those that refer to accumulating evidence? If the old style of working is just out of epistemic fashion, where does that leave the rise of evidence-based medicine? Perhaps Grimley Evans is right when he comments, acerbically, that part of the appeal of evidence-based medicine is that it offers ‘total managerial control’ of healthcare.¹¹

These reflections also prompt questions regarding the status of ‘expertise by experience’. We might suspect that the kind of expertise that patients have by virtue of first-person experiences of health and healthcare more closely resembles the expertise of the Phoenix Ward staff than that of contemporary clinicians. Do current epistemic sensibilities prejudice us against expertise by experience? Do we undervalue expertise by experience because of quite recent changes in how we understand the nature of expertise itself?

These questions are of significant clinical weight. Yet they are more the province of the humanities and social science disciplines, not least anthropology and philosophy, than the disciplines that make up mainstream mental healthcare research. Mental healthcare is increasingly the subject of investigation by disciplines whose starting assumptions and methods are not those of medicine. This appears to be an opportunity, not a threat. If the reunion attendees tell us anything, it is of the potential value of the contribution of the humanities and social sciences to the investigation of biomedicine.

1.5.51 Mental health problems, benefits and tackling discrimination

Alexander Galloway Billy Boland Gareth Williams

Dr Alexander Galloway

(alexander.galloway1@nhs.net)

date

2018-10

Abstract

Poverty is strongly associated with mental illness. Access to state benefits can be a lifeline for people with mental health problems in times of hardship and can assist them on their journey of recovery. However, benefit application processes can discriminate against those with mental illness and can result in individuals unjustly missing out on support. Clinical evidence from mental health professionals can ameliorate these challenges and ensure that people get access to financial help.

The relationship between money and mental illness

There is a clear link between financial hardship and mental disorder.¹⁻³ In 2009 the global financial crisis was estimated to be responsible for an additional 4884 suicides worldwide.⁴ In Britain, people with severe mental illness are three times more likely to be in debt than the general population.⁵ The aim of this article is to help clinicians understand Employment Support Allowance (ESA) and Personal Independence Payments (PIP) (*Box 1*), two key state benefits in England and Wales, as well as provide further advice on writing supporting clinical evidence for applications. *Box 1* 'We can provide the best treatment in the world for our patients but if they can't afford accommodation, heating or food this will be ineffective. It's essential that clinicians know how to support their patients in applying for the benefits they are entitled to.' Professor Wendy Burn, President, Royal College of Psychiatrists (personal communication, 2017)

The modern, post-war British welfare state was founded to eradicate what *The Beveridge Report* of 1942 identified as the five 'giant evils' in society: squalor, ignorance, want, idleness and disease.⁶ In 2011 the World Health Organization reported mental illnesses to be the leading cause of worldwide disability,⁷ with global costs estimated to exceed \$6 trillion by 2030.⁸ It is therefore no surprise that people with severe mental illnesses are the largest group (49%) claiming working age sickness benefits in the UK.⁹

Disadvantage and discrimination

However, in England and Wales the benefits system often does not work, especially for people with mental disorders, leaving some claimants ‘fearful, demoralised, and further away from achieving their work-related goals’.¹⁰ In 2013 the Court of Appeal upheld a ruling that people with mental disorders, along with those with intellectual disabilities and autism, are specifically disadvantaged by the ESA application process.¹¹ Many benefits assessors do not have prior training or experience in mental health.¹² Award decisions are often inaccurate; 67% of ESA and 68% of PIP decisions are later overturned by appeal tribunals.¹³ ¹⁴ In January 2018, the Government announced a review of 1.6 million PIP claims following a High Court ruling in December 2017 that described recent changes to the mobility component as ‘blatantly discriminatory’ against people with mental health problems.¹⁵

The reliance on self-reported information in claims is a major obstacle, particularly for those with impaired insight.¹⁶ Submission deadlines are short and those who miss them (perhaps because they do not check their post or were in hospital) may be penalised for the very problems that led them to apply for benefits in the first place. Disturbingly, there is evidence that the assessment for ESA, known as the Work Capability Assessment (WCA; see below), is linked with harm as it is independently associated with an increase in suicides, self-reported mental health problems and prescribing of antidepressants.¹⁷ Clinical and academic experts have long argued that clinicians should have a good understanding of benefits to better care for patients.¹⁸ People using community mental health services frequently under-claim and, for these people, benefits advice can result in additional payment.¹⁹

ESA and PIP claims

ESA and PIP claims share much in common; both require assessment by an independent provider of the functional impact of a claimant’s condition based on a completed medical questionnaire, supporting clinical evidence and, potentially, face-to-face assessment. Nevertheless, there are notable differences: ESA provides a basic day-to-day income for a claimant unable to work full time due to illness, whereas PIP provides a supplement for the increased costs of living with disability. Claimants may receive either benefit, or both, if eligible.

ESA

ESA is awarded instead of Jobseeker’s Allowance when a claimant is determined by the Department for Work and Pensions’ (DWP) WCA to have limited capability for work due to illness or disability. ‘Limited’ does not imply *no* capability and claimants are assessed in terms of whether they can sustain full-time work (16 h per week or more).

ESA applications, once separate, are now being integrated into Universal Credit claims as the programme rolls out nationwide. As the assessment process remains the same, this article will use the term ESA to refer to either route of application.

To establish limited capability for work, a claimant initially needs only to provide a medical certificate from their doctor. At this point, their claim is processed and provisional payment is issued (if applicable). The claimant is then placed in the ‘assessment phase’, which lasts for 13 weeks, or until the DWP completes the WCA, whichever is longer. If this phase lasts longer than 13 weeks, successful claims will have any additional payment due as a result of passing the assessment backdated to the 13th week.

Following the WCA there are three possible outcomes: (1)The claimant is found to be fit for work and is redirected to claim Jobseeker’s Allowance (or their Universal Credit claim is adjusted accordingly).(2, 3)The claimant is found to have limited capability for work and is awarded ESA. Within this cohort are two subdivisions: •The ‘limited capability for work group’, typically shortened to the ‘work group’. In this group, a claimant can be mandated to attend work-focused interviews at their local Jobcentre (or by phone if necessary) and perform ‘work-related activity’, for example skills or CV training. Failure to participate can result in financial sanctions, although a claimant in the work group cannot be asked to apply for or take paid employment. •The claimant is found to have ‘limited capability for work-related activity’. In this case, they are placed in the ‘support group’ (technically the ‘limited capability for work-related activity group’), which has no attached requirements. Claimants may still choose to do part-time or voluntary work, or other forms of work-related activity if they wish.

PIP

PIP has replaced the Disability Living Allowance for new claims for 16–64 year olds. Both are based on the presumption that functional impairments incur additional living costs. Unlike ESA, PIP is not means tested and eligibility is unaffected by savings, income, household or work status. Award duration varies from 1 to 10 years (an ‘ongoing award’) and successful claimants may still appeal the award length.²⁰

The PIP assessment separates functional difficulties into two components: daily living and mobility. Support for either or both components may be awarded, with payments at a standard (requiring 8 points) or enhanced rate (12 points).

The assessment process

For both ESA and PIP assessments, points are scored for key functional tasks known as ‘descriptors’, according to the claimant’s assessed level of difficulty. For PIP there are ten daily living descriptors (such as preparing food, dressing and budgeting) and two for mobility. ESA assessments are split between ten descriptors for physical disabilities and seven for mental, cognitive and intellectual function (see *Box 2*). Scoring 15 points or more anywhere in the ESA assessment qualifies a claimant for the work group. There are also specific descriptors that, if awarded, will further qualify a claimant for the support group. *Box 2* ESA and PIP assessment criteria

ESA descriptors concerning mental, cognitive and intellectual impairment:

- learning tasks
- awareness of everyday hazards
- initiating and completing personal action
- coping with change
- getting about
- coping with social engagement
- appropriateness of behaviour with other people
- conveying food or drink to the mouth/chewing or swallowing food or drink (if due to severe disorder of mood or behaviour)

Adapted from *A Guide to Employment and Support Allowance – The Work Capability Assessment*.²¹

PIP criteria:

- Daily living activities: Activity 1 – preparing food
- Activity 2 – taking nutrition
- Activity 3 – managing therapy or monitoring a health condition
- Activity 4 – washing and bathing
- Activity 5 – managing toilet needs or incontinence
- Activity 6 – dressing and undressing
- Activity 7 – communicating verbally
- Activity 8 – reading and understanding signs, symbols and words
- Activity 9 – engaging with other people face to face
- Activity 10 – making budgeting decisions
- Mobility activities: Activity 11 – planning and following journeys
- Activity 12 – moving around

Taken from *PIP Assessment Guide Part Two: The Assessment Criteria*.²²

ESA contains ‘substantial risk’ rules that may allow claimants with insufficient scores (including zero) to qualify for either the work or support group if ‘there would be a substantial risk to the mental or physical health of any person if the claimant were found not to have limited capability for work/work-related activity.’²³ As well as obvious risks, such as self-harm or hospital admission, substantial risks may also include that of causing increased distress (e.g. if forced to travel by public transport) or the possibility that medication will need to be changed as a direct consequence.²³ Reportedly up to 23% of ESA claims are awarded by this route.²⁴

There is some degree of overlap in the descriptors for ESA and PIP, as well as notable differences; the activities relevant to mental, cognitive and intellectual functioning can be found in *Box 2*. For further information on specific criteria and how they are judged, please see the Royal College of Psychiatrist’s guidance to clinicians on the ESA WCA²⁵ (see *Box 3* for a summary). Similar College guidance on the PIP assessment is in development. *Box 3* Advice on writing supporting clinical evidence

The general structure for supporting letters advised by the Royal College of Psychiatrists²⁵ is as follows:

- (1) Basic clinical details: diagnosis, medication, side effects, length of service contact, current contact, variability of condition (e.g. diurnally, between episodes and during the most severe peaks of illness), impact of stress and overall symptoms.
- (2) How this affects level of functioning in regards to the specific descriptors. If unaware whether a specific criteria applies, a clinician can still state they believe it is likely it does on the balance of probabilities.

Information about difficulties a claimant may have travelling to an assessment centre or completing paperwork should be clearly stated.

In addition to ensuring accurate award decisions, supporting clinical evidence can also provide assistance and safeguards throughout the application process itself. Given the disadvantages claimants with mental health problems face,¹¹ there are numerous areas where problems can arise.

Completing the questionnaire and initial review

Once a valid claim for ESA or PIP has been made, the case is referred to an independent medical assessment provider. The claimant is sent a Limited Capability for Work questionnaire (ESA50/UC50) or How Your Disability Affects You form (PIP2), covering their condition and its impact, and it is to be completed by them, or on their behalf. This is submitted along with any supporting clinical evidence. Once received, the assessor – who may be an occupational therapist, nurse, physiotherapist, paramedic or doctor – conducts an ‘initial review’ of the file. They may request a face-to-face interview or decide there is sufficient evidence to make an immediate determination. Supporting clinical evidence can therefore make the process far more straightforward for the claimant.

Notably, supporting clinical evidence is not mandatory at any stage of the process. An independent review of the WCA for the Government concluded: ‘it is essential that all relevant medical and allied evidence about the claimant is available to the DWP Decision Maker at the earliest possible stage in the assessment process.’²⁶ Following a more recent independent review of the PIP assessment,²⁷ the Government accepted the DWP should make clear that the responsibility to provide further evidence ‘lies primarily with the claimant and they should not assume the Department will contact health care professionals.’ The same problems exist with ESA applications.¹¹

Questionnaire problems

Claimants can face numerous difficulties when completing the initial questionnaire. In 2013 the High Court¹¹ identified 11 reasons why people with mental health problems may struggle with self-reporting at this stage, including: failure due to lack of insight, inability due to difficulties with social interaction or confusion and unwillingness because of shame or fear of discrimination. Failure to return the questionnaire may result in termination of the benefit. There are some safeguards against this for ESA, as the WCA Handbook²⁸ states: “‘Where a claimant has a mental function problem an assessment will be carried out even if the [medical questionnaire] is not returned.’”

However for PIP claims, failure to return the questionnaire can be more problematic. Regarding customers with additional support needs, the PIP assessment guide²² states: “‘1.12.2 Some may have an Appointee ... or support from a family member, carer, Community Psychiatric Nurse or other person who will usually ensure that the claimant is supported throughout the process. In those circumstances, the claimant would not be classified as requiring additional support from the DWP. These people already have support.’”

This assumption effectively means less protection for PIP than ESA applicants and makes early termination of claims more likely. In this event, supporting clinicians can write to the DWP to provide evidence as to how the claimant’s condition has adversely affected their ability to fulfil their requirements, ask for good cause to be accepted and for the claim reinstated.

Arranging the assessment

A determination is not usually made on initial review of paper evidence. The assessor may attempt to contact professionals named in the questionnaire for additional information or, more commonly, refer the claimant for a face-to-face assessment (as with 72% of ESA assessments in 2013).²⁹ If a claimant cannot reasonably be expected to travel to an assessment centre they can request a home visit, but this will almost certainly require specific supporting clinical evidence.

Assessment problems

If a face-to-face assessment for ESA or PIP is missed, the case file is returned to the DWP to decide whether to accept good cause or to terminate the claim. Both ESA and PIP legislation require that the decision maker consider the claimant's state of health and the nature of their disability in making this determination.³⁰³¹ As such, these decisions can be challenged using clinical evidence to justify why the claimant was unable to attend.

Assessment providers will typically refuse to conduct a home visit if there is a history of violence or aggression, which may lead to an impasse if the claimant cannot attend the assessment centre. In such cases, it is advisable to write directly to the assessment providers, explaining why the individual cannot travel and offering to provide further evidence. This may allow a paper-only assessment to be conducted.

The face-to face assessment

The face-to-face assessment can be extremely stressful for claimants, although they can be accompanied by a person of their choice who may also provide evidence. The assessor should have read all available information beforehand, although further clinical evidence can be provided on the day. The claimant's overall presentation at the interview can form a large part of the assessment, which may be problematic for those who lack insight, have a fluctuating condition, under-report or have become adept at masking their difficulties. This further highlights the importance of supporting clinical evidence to provide the full context.

Following the assessment, the health professional completes a report including recommendations to the DWP, who make the final decision.

Challenging decisions

The two initial stages of challenging an outcome are mandatory reconsideration and formal appeal. To challenge a decision, claimants must first request a mandatory reconsideration by the DWP, the legal term being 'any grounds revision'. Mandatory Reconsideration requests must be submitted within 1 month of the original decision, however this can be extended by up to 13 months if there is good cause.³² This 1-month rule applies not only to final award decisions but to any decisions made by the DWP, which carry right of appeal. For example, claimants could challenge the termination of their claim for failing to attend a face-to-face interview. In the real world, such situations are likely and mental health services may only discover essential information long after the designated 1-month limit. In these cases, clinical evidence should support both the original challenge and also why a late application for revision should be accepted. Even if application for a late revision is denied, a recent Upper Tribunal case³³ ruled that a claimant still has a statutory right of appeal if a late request is not considered.

If the Mandatory Reconsideration outcome is unfavourable, the claimant can then submit (within a month) an appeal to the independent Courts and Tribunals Service. Further clinical evidence can be provided. It is important to ensure claimants are aware that reconsideration or appeal of one aspect of a decision could lead to a potentially disadvantageous revision of the whole decision. For example, challenging a decision about PIP mobility could theoretically lead to an existing daily living award being revoked. Appeals can be withdrawn at any point prior to the hearing.

Supporting clinical evidence

Reports can be sent directly to the assessment centre or, preferably, given to the patient to submit with their completed questionnaire. Additional evidence can be provided at any point, however early submission ensures its use throughout all subsequent stages and may allow for a quicker decision. Most supporting evidence will be requested to establish whether a claimant meets the qualifying descriptors (*Box 2*), however it might also be necessary to provide evidence in response to, or in anticipation of, specific problems outlined above. For example, if a patient reports their ESA has stopped, it may be due to insufficient points scored during their WCA or because they failed to attend it at all. The clinical evidence should address the issue in question.

It is important that supporting letters are objective, link functional problems to health issues, expand on common clinical concepts (e.g. negative symptoms of schizophrenia) and state obvious clinical inferences explicitly (e.g. negative symptoms persist even during periods of remission). It should be remembered that DWP decision makers are not medical professionals and they may have a limited understanding of terminology or mental health problems.

Care plans can be valuable evidence if they demonstrate that a claimant cannot manage relevant domains of functioning, such as their own self-care. However, there is a danger of care plans inadvertently giving a positively skewed impression of functioning if they are too simplistic. One example is preparing meals: PIP defines a 'simple meal' as 'a cooked one-course meal for one using fresh ingredients'. Therefore, a care plan that refers to independent cooking but does not clarify that this extends only to the use of a microwave could adversely affect the outcome.

The DWP's overall definition of capability is more narrow than it might first appear and requires some measure of consistency; the claimant must be able to perform the given tasks reliably (defined as 'safely, repeatedly, to an acceptable standard and as often as is reasonable to require'²⁸) on a majority of days. In addition, judgments about qualifying for a particular descriptor need not be unequivocal and may be accepted on a balance of probabilities.

Finally, when providing clinical evidence, it is always worth bearing in mind that you must demonstrate not only whether a claimant is affected by their condition, but also whether they are affected in the specific legal ways that qualify them for the benefit. The best evidence will therefore directly address the descriptors and, as such, a working knowledge of the criteria is vital in ensuring that claimants have the best possible support throughout the process.²⁵

Conclusions

With some basic knowledge, mental health professionals can play a key role in redressing the discrimination against people with mental health problems and ensuring accurate award decisions by providing relevant, well-written clinical evidence for benefits assessors. Clinicians should be vigilant in demonstrating individuals' needs eloquently, accurately and in a timely way. Through an appreciation of the additional stresses on patients applying for benefits, mental health services can provide better support and signpost appropriately to agencies such as Citizens Advice. Welfare expertise is outside the experience of many mental health clinicians, but a patient's access to (eligible) benefits is an important part of recovery. Clinicians should work towards forging closer links with the benefits system and supporting services such as benefits and welfare advice to enable better outcomes for patients. Professionals need to understand the subtleties and potential for discrimination in the system to best support people.

Julia Samuel, grief psychotherapist and Founder Patron of Child Bereavement UK, presents a moving and thoughtful collection of therapeutic encounters. Each brief narrative traces a careful line between study and story, reminiscent of *The Examined Life* by Stephen Grosz. The style of the case story captures the uniqueness of grief and the therapeutic process, reminding us that these are not illustrations of pathology.

Samuel's studies, written in spacious and measured prose, are fearless in their approach. She includes those bereaved by miscarriage, trauma and suicide, and explores the many ways people try to cope. She gently reveals the complex emotional experiences and interpersonal difficulties that emerge, yet her own human response is never far from the text.

The case stories are divided according to the relationship to the deceased, and each section is followed by Samuel's own reflections and references to existing research. The author is keen to present positive accounts of healing and recovery, together with practical advice for the bereaved. This may explain why abnormal grief does not feature among the selected cases.

Samuel's person-centred psychotherapeutic approach is apparent throughout. This alliance carries through to her reflections and may explain why she often does not grapple with conceptual questions or distinctions. Indeed, Samuel avoids an explicit espousal of any particular model of grief. While classical theorists such as Bowlby and Kübler-Ross are summarily acknowledged, Samuel maintains her person-centred focus, helping to construct narratives with her clients. She reveals the tensions that arise and hints at the inner workings of grief while resisting any theoretical speculation. At times, Samuel uses a more integrated therapeutic approach, allowing for a broader understanding of her clients' difficulties according to different modalities. She identifies unhelpful defence mechanisms and cognitive distortions: where grief is bound up in strong cultural identity, Samuel makes reference to Jungian archetypes; to help a client struggling to achieve emotional stability, she works with a transitional object.

The significance of grief may be immediately recognisable to the psychotherapist, whether in the form of bereavement or as part of uncomplicated psychosocial development; however, hidden among Samuel's optimistic reflections are many reminders of why grief matters to the psychiatrist. Historically, grief has represented a line in the sand, demarcating normal experience from psychopathology. However, the removal of the 'bereavement exclusion criteria' from DSM-5 appears to challenge this, reintroducing grief as a viable precipitant in some disorders. Additionally, failure to recognise features of normal or unresolved grief can lead to misdiagnosis. Even in cases of uncomplicated grief, hallucinatory phenomena remind us that the boundary between normal experience and mental illness may not be a fixed one. Though choosing to err on the side of hope and resolution, Samuel's tenderly written accounts give voice to the weight of these experiences. Unresolved grief nonetheless continues to raise many questions and, as noted in the DSM-5, remains a recommendation for further study.

1.5.52 The transition from child and adolescent to adult mental health services with a focus on diagnosis progression

Ann Collins Antonio Muñoz-Solomando

Correspondence

Dr Ann Collins

(ann.collins@wales.nhs.uk)

date

2018-10

Abstract

Aims and method

This article examines mental health disorders as individuals transition from adolescence to adulthood. Data were collected from clinical records of patients who had transitioned from child and adolescent mental health services to adult mental health services in a region in South Wales. Demographics and clinical diagnoses under both services were recorded. Patterns between adolescent and adult disorders as well as comorbidities were investigated using Pearson's χ^2 -test and Fisher's exact test.

Results

Of the 98 patients that transitioned from one service to the other, 74 had changes to their diagnoses. There were 164 total changes to diagnoses, with patients no longer meeting diagnostic criteria for 64 disorders and 100 new disorders being diagnosed. Comorbidity increased in adulthood.

Clinical implications

Diagnoses can evolve, particularly during adolescence and early adulthood. Therefore regular re-assessment is paramount for successful treatment.

Declaration of interest

None.

- *Results*
- *Discussion*

The majority of mental health disorders are identified during adolescence and early adulthood.¹ By the age of 21, more than half of the population have experienced at least one mental health disorder.^{2,3} Adolescent mental health disorders also place individuals at an increased risk of further difficulties as adults.^{4,5} However, this effect has been found to be limited when adolescent episodes are brief, emphasising the need for prompt and effective treatment.⁶ Despite many studies having identified adolescence as a risk period for the onset of mental health disorders, the course these disorders take is not yet fully understood. To date, it is unclear why some individuals develop a recurrent pattern of mental illness, whereas mental illness is confined to the adolescent period for others.

Patterns of diagnostic transition

As people with mental health disorders transition from adolescence to adulthood, their disorders can follow different trajectories. In some cases, they can be predecessors of a different disorder in adulthood, displaying a heterotypic pattern.^{4,5,7,8} In other cases, they may remain diagnostically stable and follow a homotypic pattern.^{1,4} It is possible for both a heterotypic and homotypic pattern of transition to be displayed along with the development of comorbid disorders, especially as these are more likely to develop during the adolescent and young-adulthood phase of development.^{9,10}

Study aims

Using a clinical sample, this study aims to examine mental disorders as people transition from adolescence to adulthood in a population in South Wales, UK. Patterns between adolescent and adult mental health disorders as well as comorbidities were investigated.

Method

Data were collected in July 2013. Clinical records were examined retrospectively for all patients referred to adult mental health services (AMHS) within Cwm Taf University Health Board over a 5-year period.

Inclusion criteria

Included participants were aged 15–22 at the time of referral and had a documented history of involvement with child and adolescent mental health services (CAMHS) in the 2-year period prior to referral to adult services.

Exclusion criteria

People were excluded from the study for the following reasons: •lack of sufficient engagement with CAMHS or AMHS to allow a full assessment;•AMHS involvement of less than a year;•lack of documented diagnosis from CAMHS or AMHS;•CAMHS service provided by another health board.

Data collection

Electronic AMHS notes were analysed. CAMHS paper documentation were accessed if required. The data collected included: •date of referral to AMHS;•age at time of referral;•geographical area;•documented diagnosis in discharge paperwork from CAMHS;•documented diagnosis in AMHS clinical notes or correspondence.

Diagnoses were recorded as per clinical coding, based on the ICD-10 (1992). In a small number of participants ($n = 17$), no formal ICD-10 diagnosis was made by CAMHS clinicians. Instead, formulation was used to describe the participant's presentation at the time. The term emotional difficulties was used to capture these cases.

Some disorders were grouped into categories. Hyperkinetic disorder, conduct disorder and oppositional defiant disorder (ODD) were classified together as externalising disorders. Generalised anxiety disorder, obsessive–compulsive disorder (OCD) and phobic disorders were classified together as anxiety disorders. Different forms of substance misuse were categorised as mental and behavioural disorders due to psychoactive substance use. These disorders were grouped in this way because of their level of comorbidity within the category. No diagnosis of conduct disorder or ODD presented without comorbid hyperkinetic disorder. Phobic disorder and OCD did not present as single anxiety disorders. Those participants who misused substances, misused at least two. Therefore, we could not make conclusions regarding an individual diagnosis transition for those individual disorders. Listing all the individual disorders led to a multitude of combinations within the categories and a pragmatic decision was made to group the disorders.

Ethical approval

Support for this research was obtained from the Research and Development Department within Cwm Taf University Health Board, which is responsible for both the AMHS and CAMHS clinical records. The need for ethical approval was discussed extensively but deemed unnecessary for the following reasons: we were trust employees and collected data on site, originally as part of an audit; the method of data collection allowed identifiable information to be anonymised at the point of collection; and the data used in this study were limited to demographic and diagnosis details.

Statistical analysis

Pearson's χ^2 -test and Fisher's exact test were used for the comparison of frequencies between two discrete variables. All of the reported P -values are two tailed. Statistical significance was set at 0.05 and analyses were conducted using the SPSS version 21 statistical software for windows. Standardised residuals (S_i) were calculated where a significant result was found.

Results

A total of 207 people aged 15–22 were referred to AMHS in the study period. *Figure 1* illustrates how the final sample of 98 participants was created. Of the 98 participants, 60 were male (61.2%). The mean age was 18.1 (s.d. 1.46), with an age range of 16–23. There were three sources of referrals to AMHS: 60 participants (61%) were referred by their general practitioner, 37 (38%) by CAMHS and 1 (1%) by the AMHS Crisis Resolution Team. There were 42 participants (43%) who had been referred within 1–12 months of 1 July 2012; 19 (19%) were referred within 13–24 months; and 19 (19%) were referred within 25–36 months, 9 (9%) within 37–48 months and 9 (9%) within 49–60 months. Fig. 1Flow chart illustrating the selection process for participation in the study.

The CAMHS disorders were categorised into 13 diagnostic categories. A total of 65 participants (66%) had a singular diagnosis, 29 (30%) had two diagnoses and 4 (4%) had three diagnoses. This led to 135 individual diagnoses. The most common diagnostic category in CAMHS was the externalising disorders. The AMHS disorders were also categorised into 13 diagnostic categories, 10 of which were present in the CAMHS sample. A total of 46 participants (47%) had a singular diagnosis, 37 (38%) had two diagnoses, 14 (14%) had three and 1 (1%) had four diagnoses. This led to 166 individual diagnoses. Externalising disorders remained the most prevalent diagnosis. Frequencies of individual diagnostic categories are detailed in *Table 1*. Table 1Frequencies of individual diagnostic categoriesClinical code of

disorders (ICD-10 codes) CAMHS frequency (%) AMHS frequency (%) Bipolar affective disorder (F31) 2 (1) 5 (3) Depression (F32) 19 (14) 30 (18) Elective mutism (F94) 1 (1) 0 (0) Dissocial personality disorder (F60.2) 0 (0) 8 (5) Anorexia nervosa (F50) 5 (4) 0 (0) Emotional difficulties 17 (13) 0 (0) Emotionally unstable personality disorder (F60.3) 0 (0) 12 (7) Externalising disorder (F90–91) 57 (42) 38 (23) Learning disability (F81.9) 1 (1) 1 (1) Neurotic disorder (F40–42) 14 (10) 23 (14) Mental and behavioural disorder due to psychoactive substance use (F10–19) 5 (4) 25 (15) Mental disorder due to brain damage or dysfunction (F06) 0 (0) 1 (1) Pervasive developmental disorder (F84) 8 (6) 7 (4) Schizophrenia (F20) 4 (3) 6 (4) Acute and transient psychotic disorders (F23) 1 (1) 9 (7) Tic disorder (F95) 1 (1) 1 (1)

When the diagnoses of participants in CAMHS were compared with the diagnoses in AMHS, 164 changes (mean 1.65, s.d. 1.15) were found. Of the disorders diagnosed by CAMHS, 64 were no longer present after participants transferred to AMHS, and 100 new disorders were diagnosed in AMHS. Of the 98 participants, 23 (23%) had no changes to their diagnosis.

Disorders diagnosed in CAMHS were examined retrospectively, observing how these cases developed diagnostically under AMHS. Heterotypic continuity was observed to be significant in three disorder categories. These categories were CAMHS externalising disorders to dissocial personality disorders (DPP) ($P = 0.01$), CAMHS eating disorders to emotionally unstable personality disorders (EUPD) ($P = 0.01$) and CAMHS emotional difficulties to EUPD ($P = 0.01$). Homotypic continuity was evident for externalising disorders ($\chi^2 = 37.5$, $P < 0.001$), neurotic disorders ($\chi^2 = 6.04$, $P = 0.01$), bipolar affective disorder ($P < 0.001$), pervasive developmental disorder ($P < 0.001$), mental and behavioural disorder due to psychoactive substance use ($P = 0.01$) and Tourette's syndrome ($P = 0.01$). Several disorders displayed an inverse relationship and, if present in CAMHS, the presence of other disorders in AMHS decreased. This was the case for the following diagnoses: CAMHS neurotic disorder and AMHS externalising disorder ($\chi^2 = 5.47$, $P = 0.02$), CAMHS externalising disorders with both AMHS neurotic disorders ($\chi^2 = 5.02$, $P = 0.03$) and EUPD ($\chi^2 = 8.07$, $P < 0.001$), and CAMHS depression and AMHS externalising disorder ($\chi^2 = 6.08$, $P = 0.02$).

There were two new cases of schizophrenia in the AMHS sample. The participants had diagnoses of emotional difficulties and externalising disorder while under CAMHS. Of the three new cases of bipolar affective disorder, one participant had a diagnosis of externalising disorder and two had a diagnosis of depression while under CAMHS.

Discussion

In our sample, the majority of participants experienced a change in diagnosis between adolescence and adulthood. The aim of this study was to explore the patterns of this change. A total of 59% of participants recovered from their CAMHS diagnosis, indicating effective treatment or evolving symptoms. After transitioning to AMHS, 75% of all participants had been diagnosed with a new diagnosis. This highlights that comorbidity and complexity is still developing.

Cwm Taf University Health Board has an agreed transition policy between CAMHS and AMHS. Since 2011, patients are referred from CAMHS when they are 17.5 years old. A period of transition is then expected, with joint clinical reviews, until the patient reaches the age of 18. Prior policies recommended the transfer to adult services at age 16 or when formal education ended. Previous research has indicated that only 49% of CAMHS patients that have reached the age of service transition successfully engage with AMHS.¹¹ If these individuals had a history of severe mental illness, prescriptions or previous admissions they were more likely to transition. Our study includes people who have been assessed and diagnosed by both CAMHS and AMHS. In this context, it is therefore difficult to establish if the sample is representative as comparable research has mostly been done on a population level. This may explain why several disorders displayed an inverse relationship although research indicates a comorbid relationship.^{8, 10, 12} In our sample, externalising disorders were more prevalent than depression. This is a possible explanation for the higher proportion of male participants in our sample.¹³ This is important as females are at a higher risk for adolescent mental illness continuing into adulthood⁶ and are more likely to develop comorbid mental disorders than males.¹⁴

Homotypic continuity into adulthood was statistically present for several disorders, including externalising disorders. This was an expected finding as attention-deficit hyperactivity disorder has an accepted degree of diagnostic stability, continuing into adulthood with population rates ranging from 1.2 to 7.3%.¹⁵ Neurotic disorders also continued into adulthood. This supports research showing adolescent depression and neurotic disorders displaying a modest continuity into adulthood, in a relapsing and remitting pattern.^{4, 16} This pattern may have influenced why neurotic disorders, but not depression, showed homotypic continuity in this cross-sectional study. Homotypic continuity was also evident for bipolar disorder. Despite this being a small sample, the finding is in keeping with research showing bipolar disorder

to be relatively stable diagnostically.¹⁷ Homotypic continuity was also present for pervasive developmental disorder. This is to be expected as it is considered a lifelong diagnosis.

All CAMHS participants with anorexia nervosa had recovered, and 60% developed EUPD. The DSM defines borderline personality disorder (BPD) instead of EUPD. As EUPD and BPD are comparable, research into both disorders may provide insights into their relationship with eating disorders. Eating disorders have been reported in histories of people with BPD at a rate of 54%, a percentage comparable with our findings.¹⁸ Difficulty in mood regulation, less distress tolerance and a history of childhood emotional abuse are shared findings for these disorders.^{19–22} Identifying such shared characteristics may be the key to developing an understanding of which individual's disorders progress and which resolve.

Within the EUPD population in AMHS, six participants (50%) had a history of emotional difficulties in their childhoods. In the ICD-10, diagnostic categories separate children and adults at times. It could therefore be argued that homotypic continuity be considered despite a change in diagnosis. However, we would argue the existence of these age-related restrictions highlights that symptoms are different at different developmental stages. It is important to note that no diagnostic criteria for child- or adult-specific disorders are the same, minus the age restriction. For this reason, CAMHS emotional difficulties progressing to AMHS EUPD was considered a heterotypic transition. Similarly, externalising disorders transitioning to DPD was considered a heterotypic transition. This is despite the frequency of this particular diagnostic transition.²³ Research has shown that particular traits make the transition to DPD more frequent.²⁴ These traits include persistent conduct problems and engaging in more victim-orientated and violent offences. In our sample, 15% of CAMHS externalising disorders progressed to DPD. All of these participants were initially diagnosed with conduct disorder. As antisocial behaviour peaks in adolescence, this could be considered the ideal time to target intervention, especially as research indicates poor outcomes when antisocial behaviour is related to conduct disorder and substance misuse.²⁵

Two cases of adolescent depression developed into bipolar disorder. Bipolar disorder is commonly diagnosed within the first 5 years after the first depressive episode.^{26–27} This time frame highlights diagnostic progression during the transition to adulthood. Prodromal syndromes, preceding schizophrenia, are also often associated with this epoch. These non-specific changes to a person's mental state are often assumed to be normal behaviour or mental disorders, such as depression or anxiety.²⁸ It is debatable as to whether these adolescent diagnoses should be seen as displaying heterotypic change or are better characterised as prodromal syndromes. Although prodromal symptoms may be present in the childhoods of people with schizophrenia, diagnosable mental health difficulties may also be present. It is hoped that further research in this area will benefit from the DSM-5 (2013) inclusion of attenuated psychosis syndrome.

This study has highlighted patterns of disorder transition as individuals move from adolescence to adulthood. A developmental perspective of mental illness would postulate that these disorders develop from common vulnerabilities, displaying different symptoms at different developmental stages.^{1–4} Research has also indicated diagnostic transition peaks in adolescence and early adulthood.^{4–9–10} Future research, focusing on adolescence and young adulthood as the formative years for mental health, could facilitate an early identification of individuals at risk and the development of targeted interventions.

Owing to this study's sample size, there is a limit on how generalisable the results are to other mental health teams. This study also contained young people, on average aged 18, and over half had transitioned within 2 years. Follow-up until the mid-twenties may have better captured the diagnostic change during the at-risk period of early adulthood.^{6–29} It is assumed that the standard of practice would have been similar among the CAMHS professionals as they worked for the same organisation and used the same diagnostic criteria, and the same is assumed for the AMHS professionals. However, bias may have been introduced into this study during the transition from CAMHS and AMHS. CAMHS services were developed using the Common Assessment Framework or the Choice and Partnership Approach, with a focus on formulation. Care and Treatment Plans, with a diagnostic focus, were more common in AMHS. In Wales, both teams are now required to produce a Care and Treatment Plan in keeping with Part 2 of the Mental Health Measure.³⁰ This was made law in 2012 and one of the key aims is that it would improve consistency. As this study captures a predominately earlier cohort, it would be interesting to see if legislation has had its desired effect and if bias in diagnosis is now less of a concern. In our opinion, further research would benefit from a larger sample size, longer follow-up and structured interviews by blinded researchers.

Abstract

Background

Psychiatric in-patients are often transferred to an emergency department for care of minor wounds, incurring significant distress to the patient and cost to the service.

Aims

To improve superficial wound management in psychiatric in-patients and reduce transfers to the emergency department.

Method

Thirty-four trainees attended two peer-led suturing and wound management teaching sessions, and a suturing kit box was compiled and stored at the Royal Edinburgh Hospital. Teaching was evaluated using Kirkpatrick's model, and patient transfer numbers were acquired by reviewing in-patient Datix reports and emergency department case notes for 6 months before and after teaching.

Results

The proportion of patients transferred to the emergency department decreased significantly from 90% 6 months before the workshop to 30% 6 months after ($P < 0.05$). Trainees engaged positively and there was a significant increase in self-confidence rating following the workshop ($P < 0.05$). The estimated cost saving per transfer was £183.76.

Conclusion

The combination of a peer-led workshop and on-site suturing kit box was effective in reducing transfers to the emergency department and provided a substantial cost saving.

Declaration of interest

None.

Junior doctors working within in-patient mental health settings are often required to assess self-harm injuries and wounds sustained from unintentional accidents. Such superficial wounds are encountered frequently by trainees in surgery and emergency medicine, but less commonly by junior trainees in psychiatry. National clinical guidelines advise that all clinical staff involved in the treatment of self-harm should have appropriate training in the treatment and management of superficial uncomplicated injuries.¹ However, we noted that there was no provision in our department for this kind of tailored teaching. In our methods, we describe a retrospective audit which revealed 18 episodes in 6 months where a patient was transferred to the emergency department for simple wound management. As a result, it was hypothesised that significant savings could be made by training junior doctors in psychiatry in the recognition of wounds that could be treated without transfer to the emergency department. Furthermore, this could reduce the stress and perceived stigma that patients experience when attending the emergency department for self-inflicted wounds. We

identified two key interventions that could be made: first, compiling a suturing kit box to be kept available on site; and, second, providing a suturing and wound management workshop for trainees. In this paper, we describe the process of designing a workshop, compiling a kit box and evaluating the effect of this teaching programme using Kirkpatrick's Hierarchy of Learning.²

Methods

Wound management workshop design

A 1-h workshop was designed by two psychiatry trainees, a surgical trainee and a consultant in emergency medicine. This was offered to all trainees working in adult, intellectual disabilities, adolescent and elderly care psychiatry at the Royal Edinburgh Hospital (REH). It was advertised by email at the time of trainee induction, and an emphasis was placed on making the workshop accessible to all (it was run in two separate time-slots in an afternoon session reserved for trainee teaching). Our learning objectives were to: manage common wounds, safely use local anaesthetic, select an appropriate treatment for a wound, demonstrate correct handling of suture and instruments, and perform interrupted sutures. An example lesson plan is outlined in *Table 1*. *Table 1* The structure of our workshop, showing topics covered and the time taken

Topic	Time allocated (min)
Introduction and learning objectives	2
Common types of wound	10
Principles of wound management	5
Safe use of local anaesthetic	2
Choice of closure technique – dressing, steri-strip, glue and suture	5
Post-closure care	2
Demonstration – local anaesthetic and interrupted suturing	20
Practice	20
Discuss four images	5
Summary	2

Suturing kit box design

We compiled a list of equipment required for closing wounds with either sutures or steri-strips. The equipment was stored in a portable plastic box and kept on site at REH. In order to keep track of stock, all items were photographed and displayed along with their order codes on the lid of the box (*Fig. 1*). We purposefully included only the equipment required for simple suturing. This included 3-0 or 4-0 non-absorbable suture, a basic instrument pack, a sterile dressing pack, lidocaine without adrenaline, and needles for drawing up and injecting. In choosing this limited range we hoped that trainees would not treat wounds beyond their level of competence. *Fig. 1* Suturing kit box.

Evaluation of teaching

To assess engagement in teaching (Kirkpatrick level 1), attendees completed an online questionnaire with Likert-rated statements. This was emailed to attendees 1 week following the workshop, and a certificate of attendance was provided on completion of the questionnaire. These statements were: 'I enjoyed the wound management workshop', 'The content was relevant to me as a trainee' and 'I feel confident to suture wounds independently'.

To assess knowledge and confidence acquisition (Kirkpatrick level 2), attendees completed a questionnaire prior to and following the workshop. In this questionnaire, they viewed two images of deep wounds (e.g. wrist laceration with tendon visible and deep laceration through muscle) and two images of superficial wounds (i.e. only through skin with subcutaneous fat showing). Trainees were blinded to whether a wound was deemed superficial or deep – they had to assess it by appearance alone with no other history provided. They were asked to view the images and respond on a Likert scale to the statement 'I could manage this wound without referral to the emergency department'. An example of the wound images used is shown in Supplementary Appendix 1, available at <https://doi.org/10.1192/bjb.2018.41>.

Collecting transfer data

In order to assess whether trainees displayed a behavioural change (Kirkpatrick level 3), we collected Datix (an on-line incident reporting system) reports from all in-patient psychiatric wards at REH. These are completed by nursing staff whenever there is a self-harm or wound incident. Datix reports were in an electronic SBAR (situation, background, assessment and recommendation) format which allowed free-text search. Incidents which mentioned 'laceration', 'wound', 'doctor' and 'suture' were identified and the individual entries reviewed. This allowed us to ascertain how many patients were treated on site with first aid or simple wound management (steri-strips, sutures and dressings).

To assess the effect on service delivery (Kirkpatrick level 4), we identified the number of patients transferred for superficial wound management to the Royal Infirmary of Edinburgh (RIE) emergency department over a 6 month period before and after the workshop. These data were collected retrospectively from August 2016 to August 2017. All patients transferred from REH to RIE were identified using the 'Trak' electronic healthcare record system, and the case notes for each patient were reviewed. In each case the documented presenting complaint was noted, along with any treatment provided. This allowed us to identify a subset of patients with superficial wounds which could have been managed without specialist input. Inclusion criteria were: (a) wounds documented as subcutaneous or superficial; (b) wounds closed by either a junior trainee or emergency nurse practitioner; (c) wounds which needed no treatment. Episodes where the wound was significant enough to be referred to a senior emergency department clinician or specialty doctor were excluded.

Calculating cost savings

We itemised the steps involved in patient transfer and requested a breakdown of cost from our hospital finance department. This included an estimate of the time an emergency department clinician spent assessing and treating the patient. The cost of treating a patient on site was estimated by summing the cost of raw materials required to close a wound (i.e. suture, local anaesthetic and dressings) and 30 min of clinician time. The cost of running the workshop in terms of materials, room booking and clinician time were also outlined.

Results

Evaluation of teaching

A total of 34 trainees attended two workshops in February ($N = 14$) and August 2017 ($N = 20$). Attendees were foundation year 2 ($N = 17$), general practice ($N = 12$) or core psychiatry ($N = 5$) trainees.

Level 1 – Engagement in teaching

Of the 34 trainees, 24 rated the statements in *Fig. 2* – 91% of responses were 'agree' or 'strongly agree'. *Fig. 2* Agreement of trainees attending the workshop to the statements illustrated.

Level 2 – Knowledge acquisition

Self-confidence rating was completed by 32 of the 34 attendees (94%) prior to the workshop and by 26 of the 34 attendees (76%) following the workshop. *Figure 3* shows the Likert responses for wounds that could be managed by a novice trainee and those that should be referred. Responses of 'agree' and 'disagree' pre and post workshop were analysed with a chi-squared test in a 2×2 contingency table. *Fig. 3* Self-confidence rating of trainees before and after the workshop for (a) superficial wounds and (b) deep wounds which should be referred.

For simple superficial wounds, there was a significant increase ($P = 0.001$) in post-workshop confidence, with a reduction in 'disagree' responses and an increase in 'agree' responses (to the statement 'I could manage this wound without referral to the emergency department').

For complex deep wounds (which should be referred), there was an unexpected, significant increase in confidence. Following the workshop, several attendees changed their response, with 23% stating that they would be confident to manage these wounds without referral to the emergency department.

Levels 3 and 4 – Assessing behavioural change and effects on service

Combining data collected from emergency department referrals and review of Datix reports of in-patient self-harm, *Fig. 4* outlines locations of treatment before and after the teaching workshop. Chi-squared analysis showed a significant difference between patients treated on site and those transferred to the emergency department ($P = 0.0001$). *Fig. 4* Data from Datix incident reports and emergency department case notes showing the number of wounds treated on site compared with those transferred in the 6 months before the workshop and 6 months after.

Calculating cost savings

Table 2 compares the itemised cost of transfer to the emergency department with treatment on site. *Table 2* Itemised costs involved in transferring a patient to the emergency department compared with the cost of raw materials required to treat on site and the cost of the teaching intervention

Transfer to the emergency department	Treatment on site	Teaching intervention
Item	Cost	Item
Patient transport return trip	£28	Suture instrument pack
1 h room booking	£1.90	1 h room booking
Nurse escort (minimum estimate of 4 h)	£823	0 non-absorbable suture
£91.20	Attendance at emergency department (including triage, review by doctor and treatment materials)	£901
× 10 mL vial lidocaine with syringe and needle	£0.35	Artificial skin pad x 12 (£16 each)
£17.60	Suture instrument pack x 12 (£1.90 each)	£22.80
Total	£200	Clinician time (estimated 30 min)
		£13.05
		Suture x 20
		£17.60
		Total
		£16.24
		Total
		£339.60

Discussion

To the best of our knowledge, this is the first study aiming to reduce the number of psychiatric in-patients transferred to the emergency department for treatment of minor wounds. Specifically, we were interested to know whether simple superficial wounds could be treated on site, negating the need for transfer and reducing the psychological distress to the patient.³ Several studies have described the effects and cost to the emergency department of self-harm in general, but these primarily involve self-presentation rather than transfer from an in-patient setting.⁴⁻⁷ One study did describe psychiatric in-patient self-harm episodes and reported that 8% of these resulted in emergency department attendance, although the nature of treatment in the emergency department was not outlined.⁷

One possible reason for transferring such superficial wounds to the emergency department could be that our junior trainees lacked confidence and skills in managing simple wounds. This may be representative of national challenges in the UK: a recent national survey of undergraduate medical students suggested that most leave medical school lacking in confidence in basic suturing skills and knowledge of which suturing technique to deploy.⁸ This is despite 'skin suturing' and 'wound care and basic wound dressing' being stipulated as expected outcomes for medical undergraduates by the end of their medical training within the UK.⁹ While junior doctors working in psychiatry may be expected to be less knowledgeable in wound management compared with those in surgical or emergency specialties, the Royal College of Psychiatrists expects core psychiatry trainees to be able to 'Know the principles underlying management and prevention of ... self harm'.¹⁰

Therefore, the first challenge of this study was to engage junior doctors working in psychiatry and empower them to manage simple wounds without transfer to the emergency department. We accomplished this by adopting a peer-led, multi-specialty approach. The workshop described above (*Table 1*) was facilitated by junior psychiatry trainees who had invited attendees via email. It was then taught by a surgical trainee who demonstrated practical suturing skills and an emergency medicine consultant who outlined general wound management principles. With this combined range of expertise, we found that most participants engaged positively (91%), agreeing that they enjoyed the workshop, felt more confident and that the teaching was relevant to their skill level (level 1 outcome, *Fig. 2*). Having input from a senior emergency department clinician was a crucial factor in this, as trainees often enquired as to what complexity of

wound they should treat and what should be referred. This does raise the question of what level of wound management should be expected of a junior doctor in psychiatry. With reference to National Institute for Health and Care Excellence guidance for self-harm,¹ we suggest that skin lacerations greater than 5 cm in length which are deep enough to reveal underlying structures (not just subcutaneous fat) should always be discussed with the emergency department. We believe it is reasonable to expect a junior doctor working in psychiatry to manage a wound which is superficial and less than 5 cm in length, given the correct training. This was one of the key learning objectives in the workshop and was the rationale behind our evaluation of confidence change (level 2 outcome).

Assessing the competency of trainees in differentiating deep from superficial wounds was beyond the scope of this workshop. Equally, formally assessing the acquisition of technical suturing skills was not required, as this is an expected outcome of undergraduate medical education.⁹ Instead, in our level 2 outcome, we sought to measure the change in self-confidence rating following the workshop (*Fig. 3*). Confidence ratings are commonly used when evaluating surgical skill workshops. There is no relationship between confidence and competence prior to surgical skill teaching, but confidence does increase when a competency is gained.¹¹ Since all attendees at our workshop had been taught suturing as undergraduates, we sought to enhance their confidence by focusing on re-teaching wound management and refreshing technical skills, rather than formally assessing technical competence. Trainees responded to an online questionnaire presenting them with a series of wound images. They were asked to rate the statement 'I could manage this wound without referral to the emergency department' on a five-point Likert scale. Prior to teaching, only 42% of trainees agreed with this statement, suggesting that they would be confident to treat the wound with their current skill set. Following teaching, this confidence was increased, with 71% of trainees agreeing with the statement. This increase was only true for wounds which were visibly superficial. When rating images of deep wounds (including those with visible tendon damage), there was an unexpected significant increase in trainee confidence (*Fig. 3*). Responses stating they would manage the wound without referral rose from 1.6 to 22.9%, suggesting that there is potential for trainees to treat wounds beyond their level of competence. Encouragingly, during the study period, there were no reported complications from the increased number of patients having their wounds managed at our psychiatric hospital, and no reports of inappropriate suturing attempts. We suggest that the change in confidence may reflect the challenge novice trainees encountered in determining the depth of deep wounds based only on a two-dimensional photograph.

As an objective measure of knowledge application (level 3), we collected Datix reports of in-patient self-harm episodes. Unfortunately, this is a free-text system based around an SBAR template; as a result, some incidents mentioned a laceration but did not outline how it was treated. In the remaining entries (where a treatment was recorded), we found a statistically significant increase in the number of wounds treated on site following our workshop. There was a corresponding decrease in the number of transfers to the emergency department in those same 6 months, as outlined in our level 4 outcome (*Fig. 4*).

The cost saving per patient is outlined in *Table 2*. This shows that a single transfer to the emergency department can cost a minimum of £200. To the best of our knowledge, no other study has investigated the costs of in-patient transfer to the emergency department for superficial wound management. One study estimated the cumulative cost from admission to discharge of a patient with self-harm presenting at the emergency department to be £425.24 per patient.¹² Another more recent study suggested the mean immediate cost to the hospital for each episode of self-harm to be £809.4. The latter estimate includes an average of £254 for psychosocial assessment. It also includes the costs of in-patient admission and medical treatment that would be required for certain types of self-harm, such as poisoning, trauma (e.g. fall from height, asphyxiation, jumping in front of a moving object) and drowning. These studies discuss self-harm which results in a superficial wound; however, the cost of treating this is not expanded on as a subcategory of self-harm. In our paper, we identify a very specific subset of self-harm patients that could benefit from on-site treatment. Such self-injury represents only 22% of emergency department presentations,⁴ and so it is likely that our estimated costs are considerably lower because they represent only the treatment of simple, superficial wounds.

There is a substantial difference in cost between treating the patient on site and transferring to the emergency department. *Table 2* outlines the costs of treating on site, of treatment at the emergency department and of running the teaching workshop. A single, hour-long teaching workshop for 12 trainees cost an estimated £339.60. This included an hour of clinician time (two middle-grade trainees and a consultant), although in reality clinicians volunteered to teach in their spare time. Equally, we included an estimate of room booking cost, although this was provided to us free of charge as a departmental seminar room. Considering a single transfer costs £200 and treatment on site costs £16.24, it becomes cost-effective to run the workshop when the outcome is two or more patients being treated on site (this represents a potential £183.76 saving every time a patient is treated on site instead of being transferred to the

emergency department).

This study was limited by being a small, single-centre study across two cohorts of junior doctors working in psychiatry. Data were collected retrospectively, and wounds documented in the emergency department notes were observer dependent. Equally, follow-up was limited to 6 months after teaching. A larger-scale study could more fully assess the effects of peer-led teaching interventions and could account for seasonal variation in patient transfer numbers. Additionally, future qualitative work should focus on the perspectives of patients and staff following such training.

This teaching evaluation showed that a peer-led workshop improves trainee self-confidence in managing superficial wounds. We have shown there was a significant reduction in transfers and considerable cost saving from two key interventions: providing training on wound management and making resources available on site. Combining these interventions had an effect on service delivery, and as a result more patients were treated without transfer to the emergency department. We hope that our findings illustrate a small but important improvement in the care we give to our patients, which could easily be replicated in other centres.

We would like to thank Andy Johnston from eHealth analysis and our self-harm nurse Merrick Pope for their contributions to data acquisition in this study.

date

2019-2

Abstract

People affected by health conditions bring insights and wisdom to transform healthcare – ‘jewels from the caves of suffering’. Yet traditional patient and public engagement relies on (child–parent) feedback or (adolescent–parent) ‘representative’ approaches that fail to value this expertise and buffers patients’ influence. This editorial outlines the emergence of ‘patient leadership’ and work in the Sussex Musculoskeletal Partnership, its patient director (the first such role in the National Health Service)

and a group of patient/carer partners, who are becoming equal partners in decision-making helping to reframe problems, generate insight, shift dynamics and change practice within improvement and governance work.

Declaration of interest

David Gilbert is Director of *InHealth Associates Ltd*, a small consultancy organisation that supports patient and public engagement.

“‘Some important principles are becoming well established: these are the antiseptic power of transparency, a commitment to both personal and shared responsibility and a renewed engagement with patients and the public.’ Rethinking Regulation. (p. 21)¹” Calls for patient engagement in mental healthcare seem ubiquitous. There appears to be a consensus that people who use services must now work alongside staff to identify solutions to current healthcare challenges. However, if we are serious about this renewed engagement, we need to think carefully. The task is fourfold. First, we need to learn to value what patients can bring, which I call ‘seeing patients as partners’. Second, we need to change how engagement is done, by rethinking the engagement process. Third, we need to support people’s capabilities to better work together. This includes developing the right skills. Finally, we must develop new opportunities for patients to influence decision-making by creating new roles.

Valuing what patients can bring – patients as partners

People who have been affected by life-changing illness, injury or disability can help. We bring jewels of wisdom and insight from the caves of suffering² – we know intimately what it is like to feel vulnerable and powerless, the effect of pain and suffering on lives, the primacy of healing relationships in care and what good and poor services look like. This combination of vision, humanity and integrity are essential components of high-quality leadership.

About 20 years ago, I was sitting on a psychiatric ward with nothing to do – the lunch had been awful, the occupational therapist had been sacked (so no activities that afternoon) and the ward seemed full of screaming folk. A doctor strolled onto our bay and gave a perfunctory nod before gingerly pulling on the curtain rail beside my bed. Even in my disturbed state, I could see his behaviour was odder than mine. I asked him what he was doing. ‘Just checking to see if you could do anything stupid’, he replied, before walking back down the corridor. I was left contemplating the sudden and unintended addition to my range of ‘treatment’ options.

Fast forward 10 years: I was Head of Patients and the Public at the Commission for Health Improvement, the health inspectorate at the time (predecessor of the Healthcare Commission and Care Quality Commission). I was reading the National Patient Safety Agency standards on mental healthcare (though I don’t recall which one, exactly). One of them was to decrease in-patient psychiatric suicides to zero by... removing all non-collapsible curtain rails. I remembered that doctor who had checked my curtain rail. At about that time, three fellow in-patient friends of mine died. One had choked to death on her food while unsupervised, after she had left the psychiatric unit and gone to a nursing home (she had earlier been paralysed from the neck down through a failed suicide attempt). One had gone to his caravan and hanged himself. And one had drowned himself in the local reservoir.

All those deaths had occurred away from the in-patient environment, so the unit would have passed its inspection by having removed ligature points. It might also have been congratulated on its risk policies. This was ‘hitting the target and missing the point’. The unit had responded to the caravan and reservoir deaths by locking the doors at 20.00 h. This deprived me of my one visitor, a local chaplain who I could only get to see at 21.00 h. Nights became a pressure cooker of aggravated emotions – the consequence of this lack of trust and forced containment felt unsafe. I wonder whether dialogue between us in-patients and staff about what makes for a safe environment might have saved my friends.

Later, as part of a Collaboration for Leadership in Applied Health Research and Care Fellowship (North-West London), I undertook qualitative research that revealed seven benefits of high-quality patient engagement in improvement work (<https://futurepatientblog.com/2015/03/22/seven-things-that-patients-bring-the-benefits-of-patients-as-partners-for-change/>).³ I found several distinct benefits. Having patients as partners in the room will reframe the problems to be tackled. Focusing on what matters to patients leads to pathway redesign with better awareness of access issues, information and explanations needed at each stage, more humanity and better customer care. Patient engagement also promotes the finding of potential solutions to problems. Patients have the passion, insight, imagination and freedom from institutionally limited thinking to ask ‘What if...?’ They also widen the array of options for improvement and change.

This process necessarily leads to changed relationships. With patients in the room, others are given permission to explore. Dynamics change, trusted relationships develop, people work together and move beyond us–them conversations to dialogue. Shared decision-making emerges. There are also individual benefits. Patients feel more confident, develop new skills and build on those skills buried during times of illness – and come to feel better. Staff gain too. Morale is lifted as conversations become about what can be done, they can feel that we are truly all in this together. This sort of work rehumanises healthcare. It should be noted that this approach may also help staff who suffer emotional distress. In mental health (and perhaps beyond) there has never been a better time for people with health problems to work with staff (clinicians and support staff alike) to change and improve approaches to well-being and to explore our common humanity, rethink professional role boundaries (the ‘them and us’ mentality) and approaches to safety and risk.

The result is better quality decisions. If people know why decisions have been made and been part of that process, this generates trust, confidence and it becomes easier to build consensus. This has deep implications for transparency, governance and accountability. I have seen and heard about dozens of changes in policy and practice as a result of patients being partners in improvement work: making guidelines more flexible, better ways to tackle access and equalities, tackling attitudes and behaviours, different ways of meeting unmet need, the list is endless. There are even benefits beyond the project. When people see the advantages of patients as partners for improvement and change in one area, they will help spread it to others. It is a virtuous cycle with implications for scaling up improvement processes, spreading good practice and sustainability.

Changing how engagement is done

The traditional approaches to involving or engaging patients do not work, and so we fail to value the jewels offered or to change the ‘currency’ of healthcare toward what matters. Patient and public engagement, as traditionally conceived, buffers power by distancing patients from decision-making. Thus, it maintains the status quo by preserving the institutional authority of professional system leaders. Ironically, when engagement is seen to fail, as it often does, this can be attributed to the lack of value that patients bring rather than to faulty mechanisms. The engagement industry focuses largely on inputs, activities and processes (the methods of gathering data, how to capture views, etc.) over impact and outcomes.

The approaches and methods used rely on two main styles. The first is that of feedback: patients are invited to fill in questionnaires, attend focus groups or tell their stories (if they are lucky) at board meetings or the like. The focus is what happened to them in the past, mostly about their experience of services (rather than living with a condition, or about their lives beyond the institutional scope of interest), and the meaning of their data is left to professionals to assess through their own lenses based on their own assumptions and often narrow institutionalised thinking (often what is seen as feasible rather than necessary). Patients are not permitted to eyeball the data or bring their own interpretations to it, let alone be partners in decisions about what to do. This feedback approach mirrors traditional medical paternalistic models – you tell us the symptoms and we will provide the diagnosis and treatment. It is stuck in child–parent mode.

The second style is scrutiny. Whenever there is a governance committee, an advisory group or the like, the call goes

out for a lay representative. I know a patient and public involvement lead who likened her role to that of ‘lay rep pimp’. Without clarity of role, support or training, a representative is expected to bring the patient perspective to the decision-making table. I was once asked ‘so David, what do patients think?’. What, all of them? I thought. In search of credibility and leaning on what we know, we tell our stories, and half the people in the room applaud this ‘telling truth to power’ and the other half fall asleep (‘another patient with an axe to grind’ or ‘personal agenda’ they mutter later in the corridors). If we wise up and come to the table next time wearing a suit and tie, brandishing data, those that were awake last time fall asleep and accuse us of ‘going native’. I have written about this representative trap in more detail elsewhere.⁴

The consequence of failed representational mechanisms is that committees lapse into a default ‘us and them’ mode. Frustrated, marginalised and unprepared representatives start finger-wagging or fall silent. This is adolescent–parent style engagement. If we are serious about partnership, then we need to overhaul the engagement industry.

Supporting people’s capabilities – the emergence of Patient Leaders

The past few years have seen the rise of new forms of engagement such as online dialogue, experience-based co-design, health champions, peer support and the like. Mark Doughty and I founded the Centre for Patient Leadership to support patients (those with life-changing illness injury or disability, and/or with long-term conditions) to be influential change agents. CPL trained over 1000 patients to develop the capabilities to work with professionals as equal partners. Further information on patient leadership is available online (<http://www.inhealthassociates.co.uk/patient-leadership-articles-and-reports/>).

Patient Leaders are those who have been affected by life-changing illness, injury or disability and want to work with others in partnership to influence change. This can, of course, include carers. They can have many roles. Some are entrepreneurs like Michael Seres, a patient who had undergone a bowel transplant and then invented a Bluetooth sensor-enabled colostomy bag that does not overflow. He has also led the way on remote-access technology to allow people to communicate with their clinicians, and is Chief Executive of his own company, Health 11. Others are campaigners or activists, online dialogue specialists, improvement advisors or help organisations as governors or are part of inspection processes. They work at local, regional and national levels. (I am writing a book entitled ‘*The Jewel Merchants*’, which will be published in 2019, that is based on the stories of 15 such people, including Alison Cameron, Ceinwen Giles, Dominic Makuvachuma-Walker, Patrick Ojeer and Sibylle Erdmann).

There needs to be wider investment in skills development; indeed, one might question why tens of millions of pounds is spent investing in the capabilities of managerial and clinical leadership, and none on this emerging army of people who could – and I think will – regenerate healthcare. There is still a widespread assumption that system leaders are professionals, but for Patient Leaders to achieve their full potential, they also need the learning and development that enables them to be true leaders.

Finally, there has to be an equal emphasis on creating the right opportunities, for example, in governance, research and audit, service improvement and training and education. This could be at a local or national level, but needs to be where professionals are willing and able to work as partners too. Opportunities must also be created at a senior level. In much the same way that it is not considered appropriate that a service purporting to deliver ‘women-centred care’ is led entirely by men, in a few years’ time it will seem odd that we have ever had a patient-centred National Health Service (NHS) run entirely by clinical and managerial leaders. The Sussex Musculoskeletal (MSK) Partnership (Central Sussex) receives referrals from general practitioners of people who have joint, muscle or bone problems. The service stretches from Brighton and Hove, through mid-Sussex and Horsham to Crawley. Clinicians screen referrals, and many are offered an appointment at our specialist clinics, with advanced MSK practitioners or physiotherapists (often working alongside consultants and others, such as psychologists). The Partnership is a lead accountable provider. It comprises the Sussex NHS Community Trust, Sussex Partnership Trust, HERE (a social enterprise) and The Horder Centre (a charity). In Autumn of 2015, three clinical commissioning groups pooled a total of £50 m per year for 5 years to us, so we could run a better system for people who use services. We want to get it right first time, so that people do not have to go here, there and everywhere for different diagnostic and treatment interventions. And we, like the NHS rhetoric always says, want patients to be at the heart of what we do.

New opportunities – the patient director and patient partners

The Sussex MSK Partnership (Central) made a brave decision to appoint the first patient director – someone who has had experience of a life-changing illness, injury or disability (in my case, mental health problems) and can harness these experiences at senior decision-making levels. This role ensures that patient leadership is embedded at a senior level, within an executive team that includes a clinical director and managing director. This models shared decision-making at corporate level. The patient director's role is to help the Partnership focus on what matters. This includes embedding patient-centred cultures, systems and processes such that they become 'hardwired' and making sure we learn from, and act on what patients' think about services. The patient director will also support patients to enable them to be influential and valued partners in decision-making.

Being a patient director has enabled me to experiment with a different approach to engagement. For example, we have eight patient and carer partners. They bring professional and personal wisdom alongside their experiences of using our services. Patient and carer partners are not representatives or there to provide feedback, but are 'critical friends' who check assumptions, ask questions, provide insights into reframing issues or identifying problems, change dynamics and model collaborative leadership.

My role is to broker opportunities in improvement or governance and support them to ensure they have the capacity and capability to be effective. Patient and carer partners augment other involvement and feedback work. This work has been developed during a period of intense operational pressures. During the past 3 years, the Partnership has transformed the way MSK services are delivered (through a lead accountable provider model – see box) and patient partners have been alongside as we have done so. We wanted them to be partners in every MDT that oversees quality in each of our musculoskeletal pathways (orthopaedics, rheumatology, pain management and physiotherapy).

The first step was for the patient director to identify opportunities for meaningful engagement and ensure their presence in improvement and redesign work. Then, to be clear that they were more than storytellers or to feed back on their experiences (we had other data for that), they stayed in the room, proving themselves well able to reframe problems, generate new solutions, model collaborative leadership and shift dynamics. Patient partners have been involved in seven major improvement programmes: pain services redesign, fibromyalgia pathways, development of patient reported outcome measures, plans for shared decision-making, administrative systems, support for receptionists and call handlers and integration of physical and mental health provisions.

An early experience helped us to demonstrate benefits. We were discussing how to communicate with patients about booking appointments. We were receiving lots of calls to cancel or change inconvenient appointments that we had booked for people. A woman who had been through our service, told us that our team phoned at inconvenient times to book appointments. She suggested that, instead, we send opt-in appointment letters and put her in the driving seat. Let her phone back when she had her diary in front of her and she could plan out her week. We experimented with the idea and it was successful, with patients and call handlers alike delighted with how it worked. If this approach were rolled out, we would save an estimated 3500 cancelled appointments per year.

Slowly, they have become trusted equals. It has not been easy and is dependent on clarity of role, shared understanding of purpose, demonstrating benefits and the perennial time, money, space, trust... all things the NHS has precious little of. We are ready for the next step – for partners to move from an improvement role into a more steady-state governance role. However, given inevitable resource constraints, we realise that we cannot support two patient partners in each of our eight MDTs. So patient partners have come up with a different approach: the idea of a pilot special MDT. This might model the sort of reflective dialogue they want to demonstrate and focus on issues of quality and patient experience. We would evaluate the work and see whether it could be a model for other pathways. Members of the hip and knee pathway MDT seem keen on the idea, and next month we will be talking to them about how it could work.

We will also discuss whether and how we can ensure that patients are a part of regular MDTs. Several other clinical leads are watching this experiment with interest, and it could pave the way for a different model of reflective governance across the Partnership. It has taken 3 years for this work to take off – the role of patient director is still novel, and this particular model of patient partnership is an experiment. It has taken months of building relationships, doing the ground work and making the case for a different model of engagement.

In the current frenzy surrounding NHS policy and practice, it is worthwhile remembering that long-term improvements take time, space and trust. There are no quick fixes. Our work in Sussex demonstrates one novel approach to the chal-

lenges of rethinking engagement. It is predicated on the four steps necessary to renew engagement – to value what people bring, establish different mechanisms for dialogue, to develop people’s capabilities and provide new opportunities for the new breed of patient (or carer) leaders. Looking back, I now wonder what might have happened if a patient director had been around when I was on the psychiatric unit. Might my three friends still be alive?

David Gilbert is Director of *InHealth Associates* and Patient Director at *Sussex Musculoskeletal Partnership* (Central Sussex), UK.

1.5.55 Adult safeguarding under the Care Act 2014

Katherine Johnson Billy Boland **Correspondence** to Katherine Johnson (katherine.wilson3@nhs.net)

date

2019-2

Abstract

Summary

Safeguarding adults is everybody’s business, and it is now standard practice for clinicians to undertake safeguarding training as part of their mandatory training in the UK. Nevertheless, safeguarding work is complex and can involve significant dilemmas for professionals. The Care Act 2014 has introduced a number of differences in the way safeguarding is approached, emphasising the overall well-being and choice of the patient rather than merely focusing on their safety. This paper sets out to illustrate evolving safeguarding demand and practice, and aid clinicians in protecting people at risk by describing how they can approach challenging presentations.

Declaration of interest

- *Conclusion: implications for patients and carers*

Background

Safeguarding adults in England and Wales is set out in the Care Act 2014.¹ The new law came in to being in April 2015 and superseded earlier documents that sought to protect vulnerable adults,² or ‘adults at risk of harm’,³ from abuse. The Care Act itself brought together a wide range of social care concerns and activities, including personalisation, social care assessment and Mental Health Act 117 aftercare, as well as safeguarding, in a single statute.⁴ This aimed to create ‘a legal framework so key organizations and individuals with responsibilities for adult safeguarding can agree on how they must work together and what roles they must play to keep adults at risk safe’.⁵

In Scotland, the Support and Protection Act 2007 ‘seeks to protect and benefit adults at risk of being harmed’. The Act ‘requires councils and a range of public bodies to work together to support and protect adults who are unable to safeguard themselves, their property and their rights’.⁶ In Northern Ireland, *Adult Safeguarding Prevention and Protection in Partnership* was published in July 2015.⁷ It makes it clear that ‘safeguarding is everyone’s business and that as good citizens we should all strive to prevent harm to adults from abuse, exploitation or neglect’.

Definitions

The term ‘vulnerable adult’ was a term used in *No Secrets* to describe those adults who may need to be subject to safeguarding.² However, in 2011, the Law commission recommended that this concept should no longer be used, as the label of vulnerability was not appropriate and could be ‘stigmatising, dated, negative and disempowering’.³ The Care Act uses the term ‘adult at risk’ and also, at times, ‘adult with care and support needs’.

Most doctors will be used to definitions of abuse from statutory training in child protection and adult safeguarding, which is now a mandatory training requirement. Full details of forms of abuse under the Care Act are included in the Care Act statutory guidance.⁸ It should be noted that services now have responsibilities to ensure that carers are also considered within the safeguarding context. Care Act statutory guidance note 14.45 recognises the circumstances in which a carer could be involved in a situation that may require a safeguarding response and provide information on how to manage these.

A ‘concern’ is used technically in the Act as the point at which the statutory authority is notified by someone that an adult at risk of harm is suspected to be the subject of abuse.

‘Enquiries’ are the investigations that the statutory authority makes in order to determine whether abuse has taken place, and whether the individual would benefit from safeguarding.

Safeguarding activity

Statistics gathered in the first 6 months following the implementation of the Care Act suggest that the number of adult safeguarding cases doubled during this period.⁹ During the year following implementation of the Act, the Local Government Association undertook a series of six Care Act stocktakes to help them to understand the implications of the Act for local authorities. These stocktakes suggested that the rise in safeguarding referrals has continued, with 73% of councils involved in stocktake 6 reporting an increase in the levels of activity, and 34% stating that they had increased greatly.¹⁰ By contrast, figures gathered by NHS Digital in their *Safeguarding Adults: Annual Report* for 2015–2016¹¹ indicate that 102 970 Section 42 *enquiries* were reported for the period 2015–2016, compared with 103 445 *referrals* during the period 2014–2015. It is difficult to directly compare statistics across these two reports in light of changes in terms of reference used within the safeguarding proceedings and therefore the reports. However, it should be noted that a total of 184 860 safeguarding concerns and 8365 ‘other enquiries’ were reported for the 2015–2016 period, suggesting that the rate of overall referral was greater than the recorded number of enquiries given above. When these are considered alongside the ‘referral’ rates from the previous year, it appears that the level of safeguarding concerns

being raised has indeed increased. Statistics for 2016–2017 support this trend, showing 109 145 individuals under a safeguarding enquiry starting during the period measured, an increase of 6% from the previous year.¹²

Guiding principles

As with all aspects of the Care Act, the concept of well-being underpins safeguarding practice, with ‘protection from abuse and neglect’ cited as one of the key elements of promoting individual well-being.⁸ Within this, the Care Act guidance also outlines six fundamental principles for safeguarding (*Box 1*). *Box 1* Six Principles of Safeguarding

Empowerment People being supported and encouraged to make their own decisions and informed consent
Prevention It is better to take action before harm occurs
Proportionality The least intrusive response appropriate to the risk presented
Protection Support and representation for those in greatest need
Partnership Local solutions through services working with their communities; communities have a part to play in preventing, detecting and reporting neglect and abuse
Accountability Accountability and transparency in safeguarding practice

In line with these principles, the Care Act focuses on early identification and prevention of potential abuse and neglect, rather than specifying thresholds for intervention. Any actions proposed should take into account the needs, goals and wishes of the patient, ensuring that their consent is gained before any action is taken. To support this aim, Making Safeguarding Personal (MSP), a sector-led safeguarding initiative, has also been introduced to help develop a more outcome-focused response.¹³

The MSP ‘temperature check’ in 2016¹⁴ recorded a number of positive outcomes in places where MSP was being implemented. Patients reported feeling more in control, with professional meetings declining but smaller patient meetings becoming more common. Overall, the results suggested that while MSP takes no longer than traditional approaches to implement, there is evidence to suggest that it leads to better outcomes and savings in time and resources.

Responsibilities

“*Effective safeguarding cannot be achieved without a large number of organizations and individuals working closely together, and there being an explicit recognition that safeguarding is everyone’s concern.*”¹⁵

The local authority is required under Section 42 of the Care Act to take a leading role in coordinating safeguarding enquiries, and may do this either through making enquiries themselves or by ensuring that others do so. Guidance for carrying out Section 42 enquiries is set out in paragraphs 14.63–14.67 of the Care Act Statutory Guidance.⁸ Section 43 of the Care Act also requires local authorities to establish a Safeguarding Adults Board for its area, with the objective of helping and protecting adults that meet safeguarding eligibility criteria, through coordinating and ensuring the effectiveness of each of its members. A useful diagram showing the simplified responsibilities of key parties can be found in the *Safeguarding Adults* paper produced by the Care Quality Commission (CQC), the Association of Directors of Adult Social Services, NHS England, the Local Government Association and the Association of Chief Police Officers.¹⁶

Alongside local authorities and other partner agencies, individual clinicians should seek to work with individuals at an early stage to promote well-being and independence, with the aim of preventing abuse and neglect from occurring.¹⁵ Further to this, the focus should be upon identifying abuse or neglect early and raising a safeguarding concern. Care Act guidance states: ‘*No professional should assume that someone else will pass on information which they think may be critical to the safety and wellbeing of the adult. If a professional has concerns about the adult’s welfare and believes they are suffering or likely to suffer abuse or neglect, then they should share the information with the local authority and, or, the police if they believe or suspect that a crime has been committed.*’⁸ The safeguarding process can be time consuming, and it is important that clinicians continue to offer appropriate care and treatment to the patient. Where appropriate, clinicians should also attend safeguarding meetings in order to provide a more cohesive and robust plan of support.

Although not all concerns will be escalated to become Section 42 enquiries, this will be decided by the relevant safeguarding team, who will have overall responsibility for the decision on whether an enquiry is required. The team will consider the criteria as outlined in S.42(1) Care Act (*Box 2*). They will also consider issues such as mental capacity¹⁷ and consent, which will be explored in more detail in the case examples below. *Box 2* Care Act Safeguarding eligibility criteria (1) This section applies where a local authority has reasonable cause to suspect that an adult in its area (whether

or not ordinarily resident there);(2)has needs for care and support (whether or not the authority is meeting any of those needs);(3)is experiencing, or is at risk of, abuse or neglect; and(4)as a result of those needs is unable to protect himself or herself against the abuse or neglect or the risk of it.

Where clinicians have concerns that important factors are not being acknowledged, these can be raised with the enquiry officer and through initial strategy discussions and case conferences, which will be held during the safeguarding enquiry process. All individuals involved in the process will be included in determining whether allegations of abuse are substantiated and in developing an appropriate plan with the patient. Whereas under previous guidance, the emphasis was often on taking professionally proscribed measures to ensure patient safety, statutory Care Act guidance states that ‘professionals and staff should not be advocating “safety” measures that do not take account of individual well-being, as defined in Section 1 of the Care Act’.⁸ As in the assessment of social care needs, practitioners should approach safeguarding concerns in an inclusive, outcomes-focused, person-centred manner, and the emphasis should be on ‘sensible risk appraisal, not risk avoidance’.¹⁸ It should be made clear to the individual that they will be included at all stages of the enquiry and that factors such as their wishes, preferences, history and lifestyle will be taken into account throughout the process. Outcomes should be primarily patient determined. While there may be occasions when views of those involved in the process differ, decisions are made in a multidisciplinary manner with the patient’s wishes at the forefront, with overall responsibility for reaching consensus falling to the safeguarding manager.

Safeguarding dilemmas

The case studies below highlight some of the factors and considerations which may be pertinent to safeguarding processes.

Case Example 1: Cheryl – Consent, Coercion and Domestic Violence “Cheryl is a 30-year-old woman with a diagnosis of severe anxiety and depression. She is living with her partner, Julian, and two children, both of whom are under a Child Protection Plan. There have been a number of concerns raised over recent months about Julian, who will often present as verbally aggressive towards professionals. Julian will also ensure that he is present at all of Cheryl’s appointments. Cheryl comes to her out-patient appointment with a black eye which Julian states is due to walking into a door frame. Her psychiatrist manages to speak to Cheryl alone and Cheryl tells her that in fact Julian has hit her the evening before. Cheryl asks her psychiatrist not to tell anyone and says that she does not want police involved or for any action to be taken. Cheryl’s psychiatrist feels that Cheryl has capacity to make this decision, but is concerned about the risks to Cheryl and her children. Cheryl’s psychiatrist raises a Safeguarding Adults concern and also contacts Children’s services to ensure they are aware of the incident.”

Unlike previous guidance, which emphasised the duty to report and act on all allegations of abuse, the Care Act emphasises empowerment and the patient’s right to choice and control over how and with whom information is shared. In this instance, Cheryl is refusing consent to contact police or for a safeguarding investigation to take place. Since Cheryl has capacity to refuse to report abuse to police or for a safeguarding enquiry to be undertaken, a risk assessment will need to be made in regards to whether others are at risk (public interest), a serious crime is taking place (public interest) or Cheryl’s life is in danger (vital interest). In line with principles of protection and proportionality, if there is an identified risk in either of these areas, the investigating team may decide to overrule their consent and continue with the safeguarding investigation, involving only professionals and not friends or family members.

In light of Julian’s behaviour, consideration should also be given to whether Cheryl’s decision is being made under the influence of coercion and control, in which case Cheryl’s consent may be overridden and a safeguarding investigation commenced. This new offence of ‘coercive and controlling behaviour in intimate and familial relationships’ was introduced into the Serious Crime Act 2015 as a way of providing better protection to victims experiencing continuous abuse.⁸ In cases such as these, the individual may present as having capacity in relation to a decision but in fact be unable to make this decision owing to coercion or control. In these cases, the individual will not fall under the auspice of the Mental Capacity Act. This kind of enquiry is often complex and will require a range of professionals to work with the person to identify appropriate safeguarding options. In serious cases, the situation may ultimately require application to the inherent jurisdiction of the High Court,¹⁵ who may legally be able to act against the wishes of the individual to safeguard them from further harm. Similarly, police now have the ability to use a Domestic Violence Protection Order under Sections 24–33 of the Crime and Security Act 2010 to remove an alleged perpetrator from the family home for a period of up to 28 days with or without consent from the person alleged to be experiencing abuse.¹⁹

Should it be decided that safeguarding needs to proceed, with or without Cheryl's consent and involvement, there is a need to undertake 'safe enquiry', ensuring that any investigation does not increase risk to Cheryl. The Local Government Association guide to adult safeguarding and domestic abuse²⁰ provides a useful and comprehensive guide to dealing with these situations within the safeguarding context.

Finally, if Cheryl refuses consent and none of the above risk factors are present, this decision should be respected and Cheryl should be supported in considering other avenues outside the safeguarding agenda. Information may still need to be shared with children's services if there is a perceived risk to the children, which will need to be addressed under child safeguarding procedures.

Case Example 2: Layla – Unintentional Abuse, Carer Safeguarding and Mental Capacity "Layla is a 77-year-old woman with physical mobility difficulties and early symptoms of Alzheimer's disease. She is currently in a relationship with Giles, a 78-year-old man who also has physical mobility issues. Layla and Giles both attend Layla's Care Programme Approach meeting, during which Layla's psychiatrist notices that Layla's hair and clothes are unclean and she has lost weight. He asks Layla about this, who replies that Giles does not help her with her personal hygiene or give her food regularly. Giles explains that he is doing his best but is struggling to care for Layla at the moment owing to his physical health, and that he did not want to contact anyone for help as Layla does not want carers involved. He also discloses that he has found caring for Layla more difficult recently, as on a number of occasions she has lashed out at him and caused him minor injuries. Layla's psychiatrist is concerned that Layla is being neglected and raises a safeguarding concern."

This case study, while on the face of it simple, in fact outlines complex issues around unintentional abuse, carer safeguarding and mental capacity.

In this case study, a safeguarding alert has been raised owing to what appears to be unintentional neglect of Layla, which has arisen because Giles is struggling to care for her. Unintentional abuse is a recognised issue under the Care Act, and guidance is clear that the unintentional nature of this does not change the fact that it is a form of abuse or make the need for action any less important.

In this case example, professionals will need to consider Layla's capacity in relation to a range of safeguarding-related decisions, for example, whether she has capacity to decide whether to allow carers into the home, and whether she can consent to information being shared as part of a safeguarding enquiry.¹⁵ The Care Act works together with the Mental Capacity Act 2005, and if Layla is found to lack capacity, an Independent Mental Capacity Advocate (IMCA) must be made available to her. Unlike most best-interests decision situations, an IMCA may be required even if there is an appropriate friend or family member who could support Layla.

If Layla is found to have capacity in these areas but also appears to have substantial difficulty in engaging with safeguarding processes, it may be appropriate for a Care Act Advocate to be involved. This is a new role under the Care Act which is used where a person with capacity demonstrates substantial difficulty in being involved in decision-making and does not have an appropriate friend or family member to support them. Where there is no appropriate individual, the local authority must provide an independent advocate.²¹

Also pertinent in this case is that one of the major changes to safeguarding processes introduced by the Care Act is the need to provide safeguarding responses for carers who may be experiencing abuse due to their caring role. Since it has been identified that Giles is experiencing physical abuse from Layla in the course of his caring role, this avenue will need to be considered as a framework for providing him with appropriate support. Although the primary focus is likely to remain on safeguarding Layla, consideration will also need to be given to providing a more appropriate package for Giles as carer to help prevent further abuse to both parties.⁸ In this instance, there is no indication that Giles lacks capacity; however, it should be remembered that where an alleged perpetrator lacks mental capacity, they are entitled to support from an IMCA throughout the safeguarding proceedings.⁸

Case Study 3: Alexis – Organisational Abuse "Alexis is a 42-year-old Black British man living in a residential placement owing to his moderate learning disability and physical mobility issues. Alexis attends a routine out-patient appointment, during which he discloses that one of the staff members at the placement has left him sitting in the bath for an extended period of time on a number of occasions. Alexis also shares some racially derogatory names which he says the staff member has been calling him when he asks for help. Alexis's psychiatrist decides to raise a safeguarding concern."

This case example allows us to consider issues round organisational abuse, including neglect and poor practice within an institution or specific care setting, and action which will need to be taken in these instances, as set out in the Care Act statutory guidance.⁸

In situations such as this, the safeguarding investigation will need to include Alexis's residential placement. The placement should be made aware that, as instructed by Care Act guidance, where a complaint or allegation has been made against a member of staff, they 'should be made aware of their rights under employment legislation and any internal disciplinary procedures'.⁸

The local authority does not have the right to direct Alexis' care home as to what actions to take against their staff; however, they should report concerns to the CQC and continue to monitor the situation. Since this is a care setting, the local authority must also advise other placing authorities of the concerns so that appropriate measures can be taken to safeguard all other residents as well as Alexis. Since Section 44 of the Mental Capacity Act makes wilful neglect or mistreatment of an adult who lacks capacity a criminal offence, should Alexis be deemed to lack capacity, police involvement may be required in the safeguarding process.¹⁵

Conclusion: implications for patients and carers

The introduction of the Care Act 2014 has had a number of implications for patients and carers requiring support under the safeguarding framework. One of the positive developments in regards to individual empowerment is that the Act places a greater emphasis on individual self-determination and desired outcomes. Patients now have a more robust framework protecting their rights to make decisions about their lives, with new advocacy requirements ensuring that their voices are heard. Prevention principles have removed some of the previous thresholds which would have prevented those in the early stages of abuse or neglect from being overlooked, and require services to be more proactive in preventing the escalation of abuse.

However, it could be argued that the Care Act's emphasis on patient outcomes and goals could come at the price of leaving some individuals unsafeguarded who would previously have been supported under a less flexible framework. Services may need to develop new ways of responding to these concerns, ensuring that front-line staff across the multidisciplinary team work together to ensure that needs are met and risks are mitigated as far as possible. There are also questions over where this leaves family members, friends and other members of social networks who will continue to worry about the well-being of the vulnerable person. There is scope under Care Act legislation for support to be offered to carers under the safeguarding framework, and it may be that support can be offered to carers in this situation. For example a carer's assessment may be considered to discuss the effects of the caring role, including worry caused by these concerns.

Abstract

Aims and method

The Norfolk Youth Service was created in 2012 in response to calls to redesign mental health services to better meet the needs of young people. The new service model transcends traditional boundaries by creating a single, ‘youth friendly’ service for young people aged 14–25 years. The aim of this study was to investigate the effect of the transition to this new model on patterns of referral, acceptance and service use. We analysed routinely collected data on young people aged 14–25 years referred for secondary mental healthcare in Norfolk before and after implementation of the youth mental health service. The number of referrals, their age and gender, proportion of referrals accepted and average number of service contacts per referral by age pre- and post-implementation were compared.

Results

Referrals increased by 68% following implementation of the new service model, but the proportion of referrals accepted fell by 27 percentage points. Before implementation of the youth service, there was a clear discrepancy between the peak age of referral and the age of those seen by services. Following implementation, service contacts were more equitable across ages, with no marked discontinuity at age 18 years.

Clinical implications

Our findings suggest that the transformation of services may have succeeded in reducing the ‘cliff edge’ in access to mental health services at the transition to adulthood. However, the sharp rise in referrals and reduction in the proportion of referrals accepted highlights the importance of considering possible unintended consequences of new service models.

Adolescence is a high-risk period for the emergence of mental health problems¹ but mental health service provision for this age group is often inadequate.^{2–4} Traditional mental health service models bisect the adolescent period, with young people under 18 (or in some cases 16) years seen by child and adolescent mental health services (CAMHS) and those aged 18 years and over by adult mental health services (AMHS). Consequently, there is often a gap in service provision for young people transitioning to adulthood, meaning that young people are unable to access timely and developmentally appropriate support.^{5–6} In response to these problems, a number of innovative services have emerged that traverse the traditional CAMHS–AMHS divide in an effort to meet the specific needs of young people and reduce the need for disruptive transitions between services.⁶

Norfolk and Suffolk National Health Service Foundation Trust (NSFT) established the Norfolk Youth Service as a pilot in 2012. The pilot service provided mental healthcare for young people aged 14–25 years with severe and complex non-psychotic mental health problems. Following the success of the pilot, the service was expanded to provide staged intervention for all young people aged 14–25 years living in Norfolk and Waveney, replacing the existing traditional CAMHS–AMHS service model. In 2015, Norfolk and Waveney was home to 271 698 children and young people aged under 25 years.⁷ The county is predominantly rural and 86% of residents identify as White British; it has higher rates of looked after children, children in need because of abuse, neglect or family dysfunction, and pupils with behavioural, emotional and social support needs than the average for England.⁷

The new service model was intended to be youth-oriented, non-stigmatising and recovery-focused to maximise access and engagement. The new service kept the same referral criteria, continuing to accept referrals for young people with mental health problems requiring specialist or secondary care interventions. However, young people no longer had to be referred from a CAMHS service into an AMHS service when they reached 18 years old, increasing the continuity of care. The national and local context for this service transformation, and the design of the new service have been described in detail elsewhere.⁸

The empirical evidence of the effect of redesigning mental health services to bridge the CAMHS–AMHS age range on young people's access to mental health services is limited. The aim of this study was to investigate the effect of implementing a youth mental health service model for young people aged 14–25 years, based on patterns of referral, acceptance and service use. The study involved retrospective analysis of service data collected before and after the implementation of the Norfolk Youth Service.

Method

Design

The study used a historical control design. The investigation focused on two 12-month periods, one before and one after the implementation of a specialist youth mental health service for young people aged 14–25 years in Norfolk, UK. The first time period, September 2010 to August 2011, fell immediately before the development of the youth mental health service pilot. The second time period, April 2014 to March 2015, was the second year of operation of the substantive Norfolk Youth Service, chosen to coincide with the completion of the transition to the new service model and embedding of new clinical teams. The service models in operation during these two time periods are outlined in simplified form in

Fig. 1. Pre-existing data on young people referred to secondary mental health services in Norfolk during these two time periods was obtained and analysed. Fig. 1 Service models in operation before and after creation of the Norfolk Youth Service as part of Norfolk and Suffolk National Health Service Foundation Trust's redesign of services for children, families and young people. AMHS, Adult Mental Health Services; CAMHS, Child and Adolescent Mental Health Services.

Data collection

Data on all referrals to NSFT are routinely collected and processed by the Trust's Informatics Department for the purpose of business delivery and development. To meet the aims of our study, the research team requested data held by the Informatics Department on all referrals to secondary mental health services in Norfolk of young people aged 14–25 years during the above 12-month periods. All data was anonymised before being transferred to the research team; the researchers accessed no personally identifiable data. The study was approved by NSFT as a service evaluation and did not require ethical approval.

The data requested included the demographic characteristics of those referred, the outcome of the referral (i.e. whether the young person was accepted into mental health services) and the number of recorded service contacts (i.e. the number of appointments, including both face-to-face and telephone appointments), which served as an indicator of service use.

Analysis plan

The number of referrals received, proportion of referrals accepted, and the age and gender of those referred and accepted were examined for each of the two time periods under consideration. The average number of service contacts per referral by age was also calculated for each time period. These descriptive statistics were used to make comparisons across the two time periods studied, with the aid of tables and figures. The use of inferential statistics to make comparisons between the two time periods was not considered appropriate given that the dataset included all recorded referrals made during the pre-specified time periods of interest, not a sample of such referrals.

Results

Referral and acceptance rates

During a 12-month period before the implementation of the youth service model, from 1 September 2010 to 31 August 2011 inclusive, NSFT received 7476 referrals for young people aged 14–25 years living in Norfolk. Of these referrals, 27.7% were for young people under 18 years of age. Across services, 90.8% of referrals received were accepted. The acceptance rate was higher for AMHS than for CAMHS (95.5 v. 78.5%). During a 12-month period post-implementation of the new service model, from 1 April 2014 to 31 March 2015 inclusive, NSFT received 12 559 referrals for individuals aged 14–25 years living in Norfolk. Of these referrals, 45.8% were for young people under 18 years of age. During this period, the Norfolk Youth Service accepted 68.2% of referrals received. The acceptance rate for adults referred to the service was higher than for young people aged under 18 years (75.8 v. 59.2%). The referral and acceptance data for both time periods are summarised in *Table 1*.

	14–17 years	18–25 years	Total
Pre-implementation	2070	5406	7476
Post-implementation	2070	5406	7476
Referred	2070	5406	7476
Accepted	1624	5162	6786
Percentage accepted	78.5	95.5	90.8

¹

1

Pre-implementation refers to the 12-month period from 1 September 2010 to 31 August 2011. Post-implementation refers to the 12-month period from 1 April 2014 to 31 March 2015 inclusive.

Copyright Notice

Articles published from BJPsych Bulletin are open-access, published under the terms of creative commons Attribution licence (<http://creativecommons.org/licenses/by/4.0/>), which permits unrestricted re-use, distribution, and reproduction in any medium, provided

The majority of those referred during both time periods were female (58.8% pre-implementation and 59.5% post-implementation). For both pre- and post-implementation of the youth service model, the gender disparity in the referrals received was most marked among younger referrals under 18 years of age, with a more even gender split in referrals of those aged over 18 years.

Service contacts

During the 12-month period before the implementation of the new service model, the total number of contacts with young people aged 14–25 years in Norfolk was 56 759. The average number of contacts per referral was markedly higher for young people aged 15–17 years than for young people aged 18–20 years, with a clear disparity between the rate of contacts per referral for those younger than 18 years and those aged 18 years or over. On average, a young person referred at 17 years of age went on to have 11.3 service contacts, whereas a young person referred at 18 years of age went on to have just 5.3 service contacts.

In the 12-month period following implementation of the youth service model, the total number of service contacts with young people aged 14–25 years in Norfolk was 79 659. Although overall the average number of contacts per referral was lower than before implementation of the new model, the average number of contacts received was more equitable across age groups. On average, a young person referred at 17 years of age went on to have eight service contacts, whereas a young person referred at 18 years of age went on to have an average of seven service contacts. The average number of contacts with services during the periods before and after implementation of youth service model by age of referral are presented in *Fig. 2*. *Fig. 2* Average number of service contacts per referral for young people aged 14–25 years pre-implementation (Time 1) and post-implementation (Time 2) of the youth mental health service model.

Discussion

The purpose of this study was to explore whether a change in service structure from a traditional CAMHS–AMHS model with transition at 18 years of age to a youth mental health service model for young people aged 14–25 years was associated with altered patterns of referral, acceptance or service-use.

A number of interesting changes post-implementation were identified. The number of referrals to mental health services for young people aged 14–25 years living in Norfolk increased by 68% following implementation of the new service model: from 7476 before the implementation of the youth service to 12 559 after its implementation. The number of referrals increased most for young people aged 14–17 years: there was a 2.8-fold increase in the number of individuals aged 14–17 years referred but only a 1.3-fold increase in referrals for individuals aged 18–25 years.

The reason for this increase in referrals is unclear. One possibility is that the increase reflects increased local awareness of the support available for young people with mental health problems as a result of the publicity surrounding the new service model. New referral routes (including the option for young people to self-refer) may also have led to an increased volume of direct referrals to secondary mental health services. Previously, these young people might have been referred to primary care or third-sector agencies in the first instance, with only more severe or complex cases being referred on to secondary care. It is also possible that the increase in referrals reflects a wider increase in demand for mental health support for young people, not directly associated with the change in service model. There is some evidence that rates of internalising problems in children and young people have been increasing in recent years,⁹ and a substantial rise in the demand for children and young people's mental health service has been reported nationally.¹⁰

Both before and after the implementation of the youth service model, more females were referred than males, with the gender disparity being more marked among younger referrals. The reluctance of young men to seek care for mental health problems is well documented.^{11–12} The small number of males referred relative to females, both before and after the implementation of the new service model, suggests there is more work to do to encourage young men to access

support. NSFT have recently launched a Men's Wellbeing Project that aims to encourage men and boys to talk more openly about their mental health and increase access to mental health services.¹³

Although the raw number of referrals accepted by the service increased substantially following implementation of the youth service model, the proportion of referrals accepted fell: from 91% pre-implementation of the model to 68% post-implementation. This decrease might be at least partially explained by the increased number of referrals coming into conflict with limited service capacity. As previously reported,⁸ a consequence of improving access to services when resources remain limited has been increased wait-lists and sometimes overwhelming case-loads. Although acceptance criteria were unchanged following implementation of the new service model, it is possible that pressures on service capacity might have led to an upward shift in the threshold for secondary care. However, it is also possible that the fall in the proportion of referrals accepted can be explained by an increase in the number of inappropriate referrals due to the introduction of new referral routes. These referrals are then signposted on to more suitable agencies. The service is in the process of investigating this with a view to developing strategies to further improve access for young people across all agencies, to reduce the number of referrals ending up in the wrong place and subsequently being passed around services.

The number of recorded service contacts was used as a proxy for service use. The overall average number of contacts per referral for those aged 14–25 years decreased following the introduction of the youth service model. Although the service offered by Norfolk Youth Service is not time-limited, there is an emphasis on offering appropriately staged intervention and not retaining individuals within the service for longer than needed.⁸ The reduction in overall average service contacts for young people in this age group might, therefore, reflect this change in service philosophy, toward encouraging flexible re-referral if needed.

Before implementation of the Norfolk Youth Service, young people aged 18 years or over were referred to services in high numbers but received substantially fewer contacts with services relative to those aged under 18 years. This 'cliff edge' in mental health service use at the transition to adulthood has also been reported in the USA,¹⁴ suggesting this problem is not specific to the local context. Following the implementation of the youth service model, the average number of contacts per referral was more equitable across ages, with the cliff edge in service contacts no longer evident. Pre-implementation, the average number of contacts per referral at 18 years of age was less than half that at 17 years of age. Post-implementation, the average number of contacts per referral was just one fewer for 18-year-olds than for 17-year-olds.

It is possible that the new service model simply moved the transition down from 18 years to 14 years. Data for 13-year-olds demonstrated that this was not the case: 574 referrals for 13-year-olds were accepted by the service and they received 5103 contacts. This gave them an average of 8.9 contacts per referral, which is broadly similar to 14-year-olds. This does not support the idea that the previous disparity in contacts per referral has been moved to a transition at 14 years instead of 18 years.

Overall, this study suggests that implementation of the youth service model might have been successful in reducing the disparity between demand for, and access to, service during young adulthood.

Limitations

As the study had a historical control design, it is not possible to know whether the changes in referral, acceptance and service-use patterns observed following implementation of the youth service model were the result of the change in service model. It remains possible that the changes observed resulted from wider factors influencing demand for and/or engagement with mental health services. Further, because the data used were routinely collected service data, it is possible that there were variations in the quality of data collection over time that may have affected the study's findings.

Although moving from separate CAMHS and AMHS to an integrated service for 14- to 25-year-olds removes the service boundary at age 17/18 years, it also creates new boundaries at age 13/14 years and 25/26 years. Arguably, these new service boundaries fit more closely with developmental transitions and coincide less closely with peaks in the incidence of mental health problems. Nonetheless, it will be important for future research to investigate the effect of these new service boundaries on those who fall outside the 14–25 year age range.

We would like to acknowledge the valuable input of Valerie Gage, Kevin Brown (NSFT Informatics Department) and Dr Dickon Bevington.

date

2019-2

Abstract

Aims and method

Recent funding from Welsh Government for mental health has helped to develop liaison psychiatry services in Wales. Systematic data collection was undertaken to map the liaison psychiatry services in Wales in collaboration with the Royal College of Psychiatrists in Wales and Public Health Wales 1000 Lives Improvement. A questionnaire was designed and circulated to all the health boards in Wales to gather information to map liaison psychiatry services in Wales. Up-to-date information was confirmed in January 2018, via email.

Results

Over the past 2 years, liaison psychiatry services have been set up in six out of seven health boards in Wales. Staffing levels have increased and the remit of services has broadened.

Clinical implications

Mapping has highlighted that liaison psychiatry services in Wales continue to evolve. It will be important to continue to monitor these developments and their effects. Comparison with services in England will provide a useful comparison of service provision. A particular challenge will be to establish and monitor liaison psychiatry standards in Wales.

Declaration of interest

- *Liaison psychiatry services in Wales*
 - *Method*
 - *Results*
 - * *Service expansion*
 - * *Staffing*
 - *Discussion*

In 2008, Wales had 2.6 full-time equivalent consultants in liaison psychiatry.¹ Overall, where provided, liaison psychiatry services were not meeting the standards specified in the guidance ‘*Developing Models for Liaison Psychiatry Services*’.² Furthermore, three Welsh National Health Service (NHS) trusts did not provide a liaison psychiatry service.¹ In 2009, 29 NHS organisations merged to form seven integrated health boards, providing all healthcare in Wales.³ Unlike England, there are no separate mental health trusts. Therefore mental health services are part of unified health boards that comprise both mental health and general hospitals. Every health board caters for a number of large and some smaller community hospitals within the geographical area covered by the respective health board.

A policy paper for England, ‘*Achieving Better Access to Mental Health Services by 2020*’,⁴ outlines the need to provide liaison psychiatry cover for all ages in the accident and emergency (A&E) department. In 2012, the Welsh Government published ‘*Together for Mental Health*’, its 10-year strategy to improve mental health services.⁵ Within this document there was an acknowledgement that ‘Improved liaison psychiatry services can ensure that mental health care needs are met for those people on general wards and reduce length of stay’ (p. 65).⁵ The strategy required that all district general hospitals in Wales should have a liaison psychiatry team in place by March 2017.

In response to a request from NHS England, the national surveys of Liaison Psychiatry in England (LPSE) in collaboration with the Liaison Faculty of the Royal College of Psychiatrists charted the extent and growth of liaison psychiatry in England.⁶

In 2015 the Welsh Government allocated more than £8 m of recurrent revenue investment to establish enhanced dementia, liaison psychiatry, psychological therapy and women and perinatal services. Additional funding was also made available to implement the legislative requirements of the Mental Capacity Act 2005.

Method

A collaboration between Public Health Wales 1000 Lives Improvement service, the Welsh Government, the NHS Delivery Unit and the Royal College of Psychiatrists in Wales systematically mapped liaison psychiatry services in Wales. This multi-agency quality improvement project did not require approval from an ethics committee.

A structured questionnaire was designed to gather information on the level of service provision, the make-up of teams by discipline, the type of service provided, the clinical areas and hospitals covered, the hours of working and any plans for further service development. The first draft of the questionnaire was piloted to test for suitability and for ease of data collection. Suggested changes were made to improve the quality of data collection, using Microsoft Excel. A lead clinician or manager (link person) with a remit for liaison psychiatry service was identified within each health board in Wales. The final questionnaire was disseminated electronically by the Public Health Wales 1000 Lives Improvement service to the link person in each health board. The data was collected and analysed with Microsoft Excel.

The collected information was presented in a meeting organised by the Public Health Wales 1000 Lives Improvement service attended by representatives from the liaison psychiatry services in Wales. In January 2018 the level of services across Wales were reconfirmed via email by each health board. This provided an opportunity to confirm or reconcile the information collected in the initial distribution of the questionnaire. The information collected in this mapping exercise is set out below.

Results

The six health boards in Wales with general hospitals responded to the questionnaire. The seventh health board, Powys Teaching Health Board, does not have an acute hospital and therefore did not respond. The liaison psychiatry services for working-age adults and older age adults were the main focus of this mapping exercise. The information gathered is summarised in *Table 1*. *Table 1* Remit of liaison psychiatry services in Wales Health board (geographical areas covered) Notes on service structure and remit Abertawe Bro Morgannwg (Swansea, Neath Port Talbot) Services split geographically. One area has a combined service, the other has services split by age and combined with other teams. Aneurin Bevan (Gwent, Monmouthshire) Services split by age, adult combined with crisis resolution home treatment team. Betsi Cadwaladr (North Wales) Single all-age service, meeting Core 24 criteria. Cardiff & Vale (Cardiff and Vale of Glamorgan) Services split by age, Poisons Unit linked with the adult service. Cwm Taf (Merthyr Tydfil, Rhondda Cynon Taf) Single all-age service. Hywel Dda (West Wales) Older adult service in place. Adult being set-up. *Table 2* Staffing establishment comparison by health board between 2007 and 2018

Service expansion

There has been a significant increase in the availability of psychiatric liaison services in Wales in the past 10 years. Six Welsh health boards now provide a liaison psychiatry service for older adults, and all but one provide a working-age adult service. All services now operate in A&E departments.

Table 1 shows the variation in the structure and remit of psychiatric liaison services across Wales. Some health boards have combined services covering working-age adults and older adults whereas others were split by age. One health board provides distinct geographical services. Two health boards have combined the crisis resolution home treatment team with the adult liaison psychiatry team. *Table 2* identifies the total number of general hospital beds in each health board and the number of major general hospitals that make up each health board.

Betsi Cadwalder University Health Board provides a 24 hour liaison psychiatry service. This service meets the requirements of the Mental Health Partnerships' Core 24 model and is accredited by the Psychiatric Liaison Accreditation Network (PLAN)⁷ service. Other services provide a broadly '9 to 5' service, although in many cases, this includes weekends and some services provide extended 12 or 14 hour cover of A&E departments. Two health boards, Cardiff & Vale University Health Board (C&V UHB) and Abertawe Bro Morgannwg University Health Board, provide liaison psychiatry out-patient clinics. The liaison psychiatry service in Betsi Cadwalder University Health Board provides follow-up out-patient review appointments.

Dedicated intellectual disability liaison services (also known as learning disability in UK health services), substance misuse liaison services and child and adolescent liaison services were not the main focus of this survey. Some information was included in some of the responses. Two health boards have substance misuse liaison services as a stand-alone service.

Staffing

Table 2 summarises the staffing levels for the liaison services by discipline, together with total staffing levels in Wales in 2007.¹ The table also identifies variation in the staffing levels between health boards; however, direct comparison is not possible given the different structures and remits of services. At this stage service provision cannot be explained by level of need or referral numbers in each health board as this information is only collected on a local level. To present the mapping more clearly and allow easier comparison, the data is set out by health board rather than by individual liaison teams or hospitals covered by the teams. In the two health boards where age-specific liaison teams operate, we have included the breakdown of these teams.

We identified that in the past 2 years there has been a considerable overall increase in the level of staffing within liaison psychiatry services in Wales. No health board has a liaison service comprising only nursing staff, whereas in 2007, this was the case in three out of eight liaison psychiatry services. Dementia support workers have been included in two old-age liaison psychiatry services. Five health boards include the provision of occupational therapy services. One old-age service includes support from a pharmacist. C&V UHB previously established a nurse-led substance misuse liaison service consisting of three nurses. The health board also has a dedicated service for people presenting to the A&E department with alcohol-related issues, which was developed with separate public health funding. Betsi Cadwalder University Health Board provides two nurses dedicated to an alcohol misuse service within its liaison psychiatry service.

Discussion

This is the first survey of liaison psychiatry services in Wales since additional funding was provided by the Welsh Government in 2015. At a national level, medical staffing has trebled and nurse staffing has doubled since 2007. This mapping process identified the progress in establishing multi-disciplinary services with an increase in the number of nurses, dedicated psychology support, the inclusion of occupational therapists and dementia support workers with additional consultant posts. This mapping exercise was undertaken using the available resources, with no additional funding for this work. We achieved this through multi-agency collaborative work between the Public Health Wales 1000 Lives Improvement service, NHS Wales Delivery Unit and the Royal College of Psychiatrists in Wales.

Historically some health boards had no specific liaison psychiatry teams and relied on community mental health teams and duty psychiatrist cover. In some areas a collaborative 'goodwill' arrangement existed between consultant colleagues to provide cover for the mental health needs of patients in acute hospitals where no specific cover for liaison psychiatry teams was in place. For these health boards, the new funding from the Welsh Government for liaison psychiatry has been of particular significance. In certain instances, the duty system and crisis teams continue to provide cover to A&E departments out of hours. In addition to government-funded developments, locally funded initiatives have also enhanced these services. This survey did not collect detailed information on these local arrangements or the division of government funding for setting up these services, which is a potential limitation.

The health boards in Wales had autonomously established services according to local needs and requirements. Wales is diverse in its geography and demography, with a mix of rural and urban centres, and the size of geographical areas covered by the individual health board varies. These factors could have influenced the manner in which liaison psychiatry teams have been established by health boards.

The previous survey undertaken in 2008 reported that, in total, there were only two relatively well-established services in Wales: Cardiff and Swansea.¹ In North Wales, a service delivered by a less than full-time consultant with some nursing support existed. Before funding from the Welsh Government becoming available, Cardiff and Swansea had set up old-age liaison psychiatry services. Aneurin Bevan University Health Board piloted the old-age Rapid Assessment, Interface and Discharge⁹ model in the Royal Gwent Hospital and this is now also the model used by the old-age liaison service in C&V UHB.

A liaison psychiatry team should include a consultant psychiatrist, mental health nurses and a psychologist as a core part of this team. Recommended minimum staffing numbers vary with the size of the hospital and type of service.² Published models of liaison psychiatry are named Core, Core 24, Enhanced 24 and Comprehensive. For example, the minimum numbers for a Core liaison psychiatry service covering around 500 beds are two whole-time equivalent consultant psychiatrists and eight whole-time equivalent nurses, in addition to other staff.

The PLAN⁷ has provided quality standards for liaison psychiatry services. Since LPSE-1 was undertaken, there have been two further surveys of liaison psychiatry in England, with response rates of 100% and 97%, respectively. The LPSE has charted the growth of liaison psychiatry in England against the government commitment to establish liaison psychiatry in every acute hospital with an A&E department in England by 2021, with half of these meeting the Core 24 specifications. A fourth survey, LPSE-4, is planned for 2018.

The challenge within Wales will be to evaluate the effect of the newly established liaison psychiatry services. Information currently available suggests that different health boards have invested in developing services in line with their local vision and perceived requirements. Within the relatively small sample of Welsh health boards, there is diversity in the type of liaison psychiatry services provided.

We recommend that information for the next logical phase should be obtained on referral rates to these services. Furthermore, it would be prudent to set standards for liaison psychiatry services in Wales. These standards could be similar to the standards that have evolved in England or bespoke liaison psychiatry standards could be developed for Wales. Hence, further work might also involve assessment of adherence to the agreed standards.

There is an opportunity to learn from the experiences in England. An important lesson from the experience of the LPSE process in England is the need to repeat the mapping exercise over a period of time to assess progress. Moreover, comparison with services in England may emphasise the need for future funding to develop liaison psychiatry services in Wales.

There is an opportunity to gather further data on referrals, standards, patient experience, outcome measures and the evolution of services. There is also an opportunity for health boards to learn from services with a well-established substance misuse liaison service and intellectual disability liaison service.

Liaison psychiatry for children and adolescents in Wales, as in England, is less well developed. Furthermore, investment in a liaison psychiatry service for the specialist Velindre Cancer Centre will need to be considered, as will the arrangements in Powys Teaching Health Board, which does not have any acute general hospitals.

It is anticipated that the development in Welsh liaison psychiatry services will attract trainees to liaison psychiatry for foundation, core and higher training. Previously there were only two services in Wales that provided higher training leading to endorsement in liaison psychiatry.

In conclusion, liaison psychiatry services in Wales are developing and evolving. It would be prudent to monitor this evolution with a view to setting standards, surveying adherence to the standards and monitoring the referrals for an outcome-oriented evaluation of these services. Already, in collaboration with Public Health Wales and the NHS Delivery Unit, plans are in place for developing the governance to address the recommendations discussed in this paper.

We are grateful to all the liaison psychiatry teams in the health boards who contributed to information for this paper.

1.5.58 Night-time confinement is an unacceptable hospital practice

Abstract

Night-time confinement, currently imposed as a blanket restriction on all patients on wards in UK high secure hospitals, constitutes an arbitrary restriction of liberty, not being based on any therapeutic purpose for those so restricted, nor serving a need for the protection of others. Its imposition constitutes a form of 'degrading' treatment as well as an unjustified restriction of 'residual' liberty. Persons who are vulnerable, especially those who are involuntarily detained as in this case, are particularly at risk of suffering human rights abuses. A compelling case can be made, based on ethics, law and accepted practice standards, for ruling out night-time confinement as an acceptable measure.

 - *Conclusion*

Night-time confinement (NTC), currently imposed as a blanket restriction on all patients on wards in UK high secure hospitals (see Silva & Shepherd and Thomson this issue), represents an arbitrary restriction of liberty, not being based on any therapeutic purpose for those so restricted, nor serving a need for the protection of others. Its imposition, I propose, constitutes a form of ‘degrading’ treatment as well as an unjustified restriction of ‘residual’ liberty. This is especially troubling when occurring in a hospital, not a prison. Treating patients with respect for their dignity is a fundamental principle of medical care. Persons who are vulnerable, especially those who are detained as in this case, are particularly at risk of suffering human rights abuses.

While there is a duty on those working in the healthcare system to optimise the use of resources, there are ‘red lines’ limiting what actions can be justified. Locking all patients in their rooms from 9:15 pm to 7:15 am in order to save money on nursing costs crosses such a ‘red line’.

Treating patients in this manner cannot be seen as therapeutic or as facilitating recovery; if anything, the reverse. It has been argued that NTC is welcomed by some patients because they feel safer at night. My reaction to this is one of disappointment that wards cannot be made safe using other means. For example, NTC confinement of an individual patient assessed as presenting a risk to others can be acceptable. Further, if patients feel safer when locked in their rooms, they could be offered this option on a consenting, voluntary basis. A valid consent would make the action not a restriction of the person’s liberty.

Degrading treatment

A good case can be made that NTC constitutes a form of ‘degrading treatment’.

A definition of ‘degrading treatment’ can be difficult to establish. Before considering legal aspects, it is helpful to examine, as Waldron¹ suggests, the ordinary meaning of ‘degrading’. The word ‘degrading’ in everyday language connotes treatment of a person that significantly diminishes their normally accepted rank or status. In this sense, NTC can be seen as degrading the status of ‘patient’ when set against all other patients (as opposed, say, to prisoners). A further ethical argument is that in NTC patients are being instrumentalised, used as ‘means to an end’, the ‘end’ being the saving of money (albeit with the claimed aim of enhancing therapeutic possibilities during the day).

Article 3 of the European Convention on Human Rights (ECHR)² says that ‘no one should be subjected to torture or to inhuman or degrading treatment or punishment’. While the European court concedes there is a threshold of severity to be met, the fact that a person is held in control by state agents, for example in detention, will influence that decision. As a rule, the threshold depends on a number of factors – including the vulnerability of the person, as well as the duty of care owed by the authorities towards persons held in their care.

The approach of the European court has been to assign the terms ‘inhuman’ or ‘degrading’ to an accumulation of particular kinds of practice in particular settings.¹ The meaning of the terms is then read back from the list of particular practices ruled prohibited and identified descriptively. Until a case of NTC, or one relevantly similar to it, is considered, it is not clear whether the European court would regard NTC as constituting ‘degrading’ treatment.

The Equality and Human Rights Commission (EHRC)³ states that ‘degrading treatment’ means treatment that is extremely humiliating and undignified. Whether treatment reaches a level for such an ascription depends on a number of factors. These include the duration of the treatment, its physical or mental effects, and the vulnerability and health of the victim. In NTC the duration is long-term, perhaps lasting years, and a health problem is the reason for the person being in a hospital. Presumably, the hospital is intended to offer a therapeutic environment for persons with a mental disorder, one that, for example, enhances a sense of agency or self-worth. It is hard to see how NTC encourages, rather than impedes, such progress.

The recognised defence of ‘medical necessity’⁴ for what may on the surface appear to be degrading treatment, it can be argued, cannot be applicable in NTC: there simply is no medical purpose.

It is commonly stated that the right not to be treated in a degrading way is ‘absolute’. The EHRC notes that ‘it must never be limited or restricted ... For example, a public authority can never use lack of resources as a defence against an accusation that it has treated someone in an inhuman or degrading way.’³

Waldron poses the question whether treatment can be ‘degrading’ even if the person subject to it is unconscious of it.¹ He proposes that we may judge the treatment as objectively degrading even if the victim accedes to it. A decision in the High Court⁵ supports this contention: “Treatment is capable of being ‘degrading’ within the meaning of article 3, whether or not there is awareness on the part of the victim. However unconscious or unaware of ill-treatment a particular patient may be, treatment which has the effect on those who witness it of degrading the individual may come within article 3 [ECHR]. It is enough if judged by the standard of right-thinking bystanders it would be viewed as humiliating or debasing the victim, showing a lack of respect for, or diminishing, his or her human dignity.”

This view comports well with the results of a survey of patients and staff concerning their ‘agreement’ or ‘disagreement’ with NTC.⁶ This showed that while the majority of the small number of patients (comprising fewer than 50% of eligible participants) were not in disagreement with NTC, 100% of staff were.

Deprivation of ‘residual liberty’

Thus far, English law has not recognised the concept of ‘residual liberty’. However, the European court following the case of *Munjaz v UK*⁷ now does. While the residual liberty of *Munjaz* was ruled not to have been infringed, the validity of the concept was confirmed by the Court – there can be a further deprivation of one’s liberty under Article 5 of the ECHR, even if already detained. The Court held that whether there was a further deprivation of liberty of someone already detained depended on their concrete situation, for example, the type of measure used, and its duration, effects and manner of implementation. In fact, the Court stated, the criteria for a further deprivation ‘must apply with greater force’ when the person is already detained.

The grounds given for the Court’s negative decision in *Munjaz* offer reasons why NTC, by contrast, might well be considered as a deprivation of residual liberty. The court recognised that Mr *Munjaz* was secluded when already in a high secure hospital where he was already subjected to greater restrictions on his liberty than a normal mental health patient. However, reasons for a rejection of his claim were: his seclusion was ‘to contain severely disturbed behaviour likely to harm others’; the length of the seclusion was ‘foremost a matter of clinical judgment’; and great store was placed on ‘the manner of implementing the seclusion policy’ – the hospital’s approach was ‘to allow secluded patients the most liberal regime that was compatible with their presentation’, and seclusion was being ‘flexibly applied’. Behind each reason lay a critical assumption: that the deprivation of liberty served the fundamental purpose of protecting other patients from the harm that might have been caused specifically by Mr *Munjaz*. The problem with NTC is that its purpose is not therapeutic, nor an individually planned response to the risk of harm to others by the person deprived of their liberty. Furthermore, NTC is clearly not ‘the most liberal regime compatible’ with the person’s presentation, nor is its consistent application for 10 h each night ‘flexible’.

The case for a violation of the patient’s ECHR Article 8 right to a ‘private life’ was also considered. Mr *Munjaz* argued that the hospital’s seclusion policy was not in accordance with the law as it lacked the necessary foreseeability and procedural safeguards. The European court affirmed the presumption that those deprived of their liberty will continue to enjoy all of the other fundamental rights and freedoms guaranteed by the Convention. It stated: ‘the importance of the notion of personal autonomy to Article 8 and the need for a practical and effective interpretation of private life demands that when a person’s personal autonomy is already restricted, greater scrutiny be given to measures which

remove the little personal autonomy that is left ... [Mr Munjaz's periods of] seclusion must be regarded as additional interferences with the private life of the applicant, which were distinct from the inevitable interference with his private life that arose from his detention in high security conditions'.

NTC offers little evidence of the kind of additional 'greater scrutiny' demanded by the court. Furthermore, the court stated that any potential breach of Article 8 must be in accordance with the law requiring the impugned measure both to have some basis in domestic law and to be compatible with the rule of law consistent with the object and purpose of Article 8. 'The law must thus be adequately accessible and foreseeable, that is, formulated with sufficient precision to enable the individual – if need be with appropriate advice – to regulate his conduct'. In NTC, on the other hand, the patient's conduct is irrelevant to the deprivation of liberty and thus represents 'arbitrary interference'.

I suggest that NTC would be very unlikely to meet criteria for a lawful restriction of persons' residual liberty or interference with their private life.

Mental Health Act Code of Practice 2015

NTC is furthermore inconsistent with 'guiding principles' expressed in Chapter 1 of the Mental Health Act Code of Practice (MHA CoP) 20158 – 'the least restrictive option and maximising independence'; 'respect and dignity'; 'purpose and effectiveness ... clear therapeutic aims, promote recovery ...'.

The MHA CoP (26.7) states that restrictive interventions, when required, 'should be planned, evidence based, lawful, in the patient's interests, proportionate and dignified'.

And later: "26.20 ... service providers should avoid blanket restrictions that apply to all patients; interventions should always be individualised, and subject to discussion and review by the whole clinical team. The individual's consent to the intervention should always be sought where the individual has capacity to consent or refuse the intervention, even if a refusal may be overridden ..."

Under the section entitled 'Respecting human rights': "26.45 Any use of restrictive interventions must be compliant with the Human Rights Act 1998 (HRA), which gives effect in the UK to certain rights and freedoms guaranteed under the European Convention on Human Rights (ECHR).26.47 No restrictive intervention should be used unless it is medically necessary to do so in all the circumstances of the case. Action that is not medically necessary may well breach a patient's rights under article 3, which prohibits inhuman or degrading treatment.26.48 Article 8 of the ECHR protects the right to respect for private and family life. A restrictive intervention that does not meet the minimum level of severity for article 3 may nevertheless breach a patient's article 8 rights if it has a sufficiently adverse effect on the patient's private life, including their moral and physical integrity."

These statements are clearly relevant to the earlier discussion.

I note 26.105 '... Seclusion does not include locking people in their rooms at night in accordance with the High Security Psychiatric Services (Arrangements for Safety and Security) Directions 2013'. Locking patients in their rooms at night is not seclusion; seclusion is justified by clinical considerations of the risk of harm to the patient or to others. Locking all patients on a ward in their rooms at night as a money-saving measure involves no therapeutic purpose.

Conclusion

A case, based on ethics, law and accepted practice standards, for ruling out NTC as an acceptable measure is compelling. It should cease as soon as possible.

I thank to fellow members of the Special Committee on Human Rights of the Royal College of Psychiatrists for their helpful comments on the manuscript.

1.5.59 The assertive approach to clozapine: nasogastric administration

Alex Till James Selwood Edward Silva

Correspondence

Dr Edward Silva

(ed.silva@merseycare.nhs.uk)

date

2019-2

Abstract

Aims and method

An ‘assertive approach’ to clozapine, where nasogastric administration is approved, is assessed through a case-load analysis to provide the first systematic description of its use and outcomes worldwide.

Results

Five of the most extremely ill patients with treatment-resistant schizophrenia were established and/or maintained on clozapine, resulting in improvements to their mental state; incidents were reduced, segregation was terminated and progression to less restrictive environments was achieved.

Clinical implications

Despite being underutilised and rarely enforced, in extreme circumstances, an assertive approach to clozapine can be justified. Nasogastric clozapine can be safely delivered and the approach itself, rather than actual nasogastric administration, may be enough to help establish and maintain patients with treatment-resistant schizophrenia on the most effective treatment.

Declaration of interest

E.S. has received speaker fees from Jansen Pharmaceuticals and Novartis.

- *The assertive approach to clozapine: nasogastric administration*
 - *Methods*
 - *Results*

– Discussion

* Conclusion

The efficacy of clozapine in treatment-resistant schizophrenia is well established.¹ Compared with alternative antipsychotics, clozapine provides superior symptom control, longer duration of treatment, shorter lengths of stay and reduces violence.² Although enforced antipsychotic treatment is generally widespread, clozapine is both underutilised³ and rarely enforced, with only a handful of case reports worldwide reporting the use of nasogastric^{4–6} and intramuscular^{7–9} clozapine.

With injectable clozapine unavailable in the UK until very recently, when presented with a crisis,¹⁰ nasogastric clozapine was successfully used for the first time at Ashworth high-security hospital in 2010 and has been used subsequently to help establish and maintain treatment with clozapine. We now present the first systematic description of the ‘assertive approach’ to clozapine via nasogastric clozapine, which commences not on the first administration of nasogastric clozapine, but on its approval for use; this in itself is often enough.

Methods

A retrospective case-load analysis of E.S.’s patients was conducted on an intent-to-treat basis, defined by the presence of a Second Opinion Appointed Doctor (SOAD) request for the authorisation of nasogastric clozapine, from the first case in 2010 through to 2016. This provided a minimum 12-month follow-up period. Clinical records were reviewed to identify patient demographics and clinical details including medication compliance and response to treatment, which was determined by Clinical Global Impression (CGI) scores¹¹ combined with segregation use and incident frequency for 12 months before and after SOAD approval for nasogastric clozapine.

The method used to deliver nasogastric clozapine is outlined within *Box 1*. **Box 1** How to deliver nasogastric clozapine. Clozapine preparation Although several brands of clozapine are available and unlicensed ‘special’ oral suspensions can be prepared (including crushed tablets), we advocate the use of Denzapine as this is currently the only licensed oral suspension in the UK. If an alternate clozapine provider is currently in operation, then registration of the hospital and prescribing psychiatrist with a second supplier are necessary before transferring the patient’s registration. This risks using two clozapine monitoring systems in one hospital, with possible confusion regarding dispensing medication and liaising with different clozapine-monitoring services as well as the potential of having to switch providers once the patient is established on tablet medication. **Restraint** A thorough risk assessment is required to ensure adequate numbers of trained, competent and resilient staff are present and it is essential they are well supported by the leadership team; consultant presence was initially provided, being replaced by more junior medical staff when confidence grew. At least one member of Resus Council (UK) ‘Immediate Life Support’ trained member of staff must be present. Throughout every intervention, patients should be repeatedly given the option of taking oral clozapine. Mechanical restraint was considered as an option but, even with our most difficult patients, was neither planned nor used. Manual restraint was sufficient with between two and six members of staff; in the most extreme cases one member of staff was allocated to each limb, with two controlling the head. Patients were usually seated upright on the edge of their bed, with their neck in line with their back. Precautions may be required to mitigate risks of spitting and biting, including lightweight disposable face visors and gloves. **Nasogastric tube placement** Appropriate training for both medical and nursing staff can be arranged with a general hospital clinical skills team. Fine bore feeding tubes should be used. The first-line, gold-standard method of confirming placement in the stomach is by demonstrating a gastric pH of 5.5.¹⁴ Acid-inhibiting medication reduces the sensitivity but does not alter the specificity or render the method unsafe¹⁴; actions to reduce this risk should be considered. Radiological confirmation is not required.¹⁴ Once placement is confirmed, nursing staff can administer the clozapine, which varies in volume (50 mg/ml) throughout titration. Unless safe to leave *in situ*, the nasogastric tube should be removed immediately after clozapine administration. **Legal authority** In England and Wales, incapacitous or non-consenting patients detained under the Mental Health Act 1983 may be administered drug treatments for mental disorders for longer than 3 months only if a Second Opinion Appointed Doctor (SOAD) approves the treatment, including the route of administration. Personal communication from the principal SOAD has indicated that the oral and nasogastric routes are equivalent: both are enteral. **Ethical dilemmas** Explored by Silva *et al*¹⁰, there are ethical dilemmas with administering nasogastric clozapine. These involve balancing the risks and benefits of an unacceptable status quo against the uncertainties of the possible risks and benefits of intervention, alongside contain-

ing and resolving the emotions of the team when using a novel, restrictive and coercive treatment on a vulnerable and incapacitous patient.

Results

E.S. had cared for five patients, whose demographics can be seen in *Table 1*, where a SOAD approved the administration of clozapine via a nasogastric tube. All were diagnosed with treatment-resistant schizophrenia (ICD-10 code F2012), all were confined in their rooms because of risk to others (long-term segregation¹³) and all were considered to be among the most extremely ill patients encountered within this particular population (CGI score of 7 for severity of illness). *Table 1* Patient demographics Patient Age at first episode of psychosis Age at admission to high-security services Age at SOAD approval of nasogastric clozapine Duration of illness at SOAD approval of nasogastric clozapine Length of stay in high-security services at SOAD approval of nasogastric clozapine Primary diagnosis Admission source Mental Health Act section on admission 11943432498 days F20.3 Medium-security hospital 322127432216 years F20.0 Prison 47/493213335142 years F20.0 Prison 47/494193945265 years F20.0 Medium-security hospital 37/415152533188 years F20.3 Medium-security hospital³

For all patients, their families, advocates and/or legal team were consulted. None objected.

At the time the assertive approach to clozapine was initiated (i.e. SOAD approval for its use was gained), two patients had not started clozapine and three patients had started clozapine but were not reliably compliant (median duration of 31 days); ultimately, only three patients received nasogastric clozapine and other than the use of restraint, no adverse incidents occurred.

Patient 1 commenced clozapine after SOAD approval and received four doses of nasogastric clozapine on non-consecutive occasions over a period of 3 weeks, before being established on oral clozapine. Patient 2 only commenced oral clozapine after SOAD approval for nasogastric clozapine, but nasogastric administration itself was never required. Patient 3 commenced oral clozapine after persuasion, but threatened to stop and SOAD approval was enough to maintain compliance without nasogastric administration being necessary. Patient 4 took oral clozapine for 1 month but then repeatedly threatened to refuse. SOAD approval was sought and nasogastric clozapine was administered once, which was enough to maintain compliance thereafter. Patient 5 maintained erratic compliance with oral clozapine and despite taking it for 617 days, was approved for nasogastric clozapine because of life-threatening clozapine withdrawal catatonia that had previously been unresponsive to benzodiazepines or electroconvulsive therapy (ECT). In the 12 months after SOAD approval for nasogastric clozapine, he received it four times on non-consecutive occasions over the first 6 months.

All five patients were considered to have shown a global improvement on CGI scores after the initiation of an assertive approach to clozapine, with the drug efficacy index showing that, for the majority of patients, clozapine had resulted in a 'vast' or 'decided' improvement in their condition (*Table 2*). Across all five patients, incidents reduced from an average of 72 over the 12 months before SOAD approval to 29 in the 12 months after SOAD approval. No patients were unchanged or worse, and only patient 5 remained in segregation beyond 12 months (terminated on the 476th day). Therefore, despite a significant reduction in incidents (*Fig. 1*), they were registered as having only minimally improved according to their CGI score. *Fig. 1* Incident frequency in the 12 months pre- and post-SOAD approval for an assertive approach to clozapine. SOAD, Second Opinion Appointed Doctor. a. Incident data for patient 1 was unavailable beyond 3 months before SOAD approval as they had not been admitted. *Table 2* Patient outcomes, including Clinical Global Impression scores, time in segregation and referral/transfer status Patient Clinical Global Impression scores (>12 months post-SOAD) Days in segregation (total pre-SOAD) Days in segregation (12 months pre-SOAD) Days in segregation (12 months post-SOAD) Transfer out of high-security services high dependency unit Referral out of high-security services Transfer out of high-security services Severity of illness Global improvement Efficacy in-

¹ Age and duration of illness is presented in years. Primary diagnosis is given by ICD-10 code (see ICD-10 for full definitions). SOAD, Second Opinion Appointed Doctor.

dex172069898133NoYesYes27102104628094YesYesYes37206373798aYesNoNo472062094365287NoYesYes573092492365365NoYes

Our most recent data (with a minimum follow-up of 2 years after SOAD approval for nasogastric clozapine) demonstrates that none of the five patients required clozapine re-titration, and that all are now compliant with clozapine (although patient 5 did require a nasogastric tube to be passed on one occasion before accepting clozapine orally nearly 2 years (626 days) after it was last administered nasogastrically).

Discussion

The majority of patients are transferred to high-security hospitals in the UK because the severity of their psychotically driven violence is considered to be uncontrollable elsewhere, and a large proportion of the patient population already complies with clozapine without using what we can only describe as a highly assertive approach.¹⁵ This is reserved for those with the most severe and debilitating conditions. They have often been detained for decades, with some spending years in segregation despite persistent attempts at engagement in psychological work and/or numerous trials of both evidence-based and/or other none or weakly evidence-based treatments (including failed attempts on clozapine secondary to poor compliance), commonly including treatment with high-dose and/or multiple antipsychotics, which are both unlikely to work and hazardous to the individual.¹⁶⁻¹⁷

Although all health professionals prefer to initiate treatments with patients who fully understand and actively consent and cooperate, in these rare cases, the status quo is clearly unacceptable and the ethical argument for this very assertive approach to clozapine, once conceived of, is not hard to make to establish and maintain patients on clozapine.¹⁰

However, a survey of psychiatrists working in psychiatric intensive care units in the UK found that even restraint to take bloods for clozapine was very rarely reported and attitudes towards it were variable, with a significant minority describing it as never appropriate.¹⁸ The same author's description of an approach to enforcing clozapine, including taking bloods in restraint,¹⁹ resulted in critical responses: one expressing dismay that the article was published at all,²⁰ and the other setting out why it would not work.²¹

Our results demonstrate that simply accepting refusal of clozapine from a patient with treatment-resistant schizophrenia can deprive them of the benefits that this significantly superior (compared with all other antipsychotics²²) and recommended treatment of choice provides, and how an assertive approach to clozapine, rather than actual nasogastric administration, can help initiate and maintain treatment leading to improvements in mental state, reductions in incidents, terminations of seclusion and transfers to less restrictive environments.

These results were not unexpected, given the unique properties of clozapine on treatment-resistant schizophrenia and violence.² Neither was the sometimes significant period of decompression before segregation was stopped, as despite some patients having a rapid improvement and almost immediate cessation of incidents of aggression or violence, they had significant histories of being involved in dramatic and disabling assaults against staff and therefore extreme caution was exercised.

What was clinically unexpected, given the individual patient histories, was the surprising level of cooperation. There were fewer restraints and enforced nasogastric clozapine administrations than had been expected, and one patient who had repeatedly refused oral clozapine for years cooperated without nasogastric administration at all, although this was also a finding when intramuscular clozapine was enforced in the Netherlands.²³

It is possible that teams redoubled their efforts, that patients were aware of the possibility of restraint and were coerced by the prospect alone or that patients regained a level of insight, or even a combination of the three; it is difficult to tell.

2

Fourteen additional episodes of seclusion totalling 80 days.

As Silva *et al*¹⁰ discuss, teams that embark on this approach are faced with very difficult decision-making, such as how long to persist with one attempt at passing a nasogastric tube? When is a patient's distress at the procedure too great? And how many times should clozapine be administered via a nasogastric tube before accepting that oral compliance will not be maintained? These questions are not easy to answer, and the judgements can only be made by individual teams and will vary on their own capacity to maintain treatment and a relationship with a patient in very difficult circumstances.

For some patients their previous refusals will be based on psychotic motivations and it is hoped that these patients may quite rapidly respond. Others may have a combination of psychotic, personal and possibly comorbid motivations that may not be remedied by either clozapine or this assertive approach. For these patients, we would not advocate the regular use of nasogastric administration of clozapine as a long-term solution. We know, particularly when huge effort and resources are expended on initiatives, that there can be a tendency to get stuck in a persisting course of action or to fail to consider alternative approaches²⁴ (although in this case many of these are less likely to work²²), and teams must be careful not to fall into this trap.

One good alternative, with local guidelines emerging,²⁵ is the option of trying to establish patients on clozapine by an assertive approach with intramuscular injections. Having recently become available again, intramuscular clozapine may be preferred to nasogastric clozapine, given the less intrusive and unpleasant method of administration. However, unlike nasogastric clozapine, intramuscular clozapine is limited by the deliverable dose and therefore duration of treatment, with large volumes required (25 mg/ml) as the titration increases toward the average UK dosage of around 450 mg/day.²⁶ Intramuscular clozapine also remains an unlicensed product, with an increased likelihood of prone restraint and a theoretical risk of accidental intravenous administration. Therefore, although intramuscular clozapine provides an additional treatment option, nasogastric clozapine can continue to have an important role to prevent re-titration and administer clozapine when the maximum deliverable dose of intramuscular clozapine is insufficient.

Another alternative, where an assertive approach to clozapine fails or for the significant number of patients who do not respond to clozapine monotherapy or clozapine augmentation strategies, is the more restrictive treatment of ECT, which may well be the most appropriate next step.²⁷ However, for the cohort we describe, this intervention is particularly difficult to deliver and maintain the safety of both staff and patients.

Ethically, what remains is a real argument about the wrongs of a failure to treat the most severely ill patients with treatment-resistant schizophrenia against the perceived wrongs of nasogastric clozapine. Clearly, this approach can never be a panacea: clozapine can often not be used (because of adverse effects) and nearly 50% of patients fail to achieve a satisfactory therapeutic response.²⁸ However, for those who have suffered with the most debilitating conditions imaginable, clozapine can result in dramatic and seemingly unexpected improvements in mental state and function. Accepting a patient's refusal of treatment and failing to offer them that chance of improvement via an assertive approach to clozapine through nasogastric administration seems, in our opinion, cruel and unnecessary.

Conclusion

Our case series shows that nasogastric clozapine can be safely delivered and that the approach itself, rather than actual nasogastric administration, may be enough to establish and maintain treatment with clozapine.

An assertive approach to clozapine can therefore play an important role in managing patients with treatment-resistant schizophrenia. It can be justified to help reduce patients' extreme suffering and distress as a result of their psychosis, can be expanded in a variety of psychiatric in-patient settings and can help reduce the usually disappointing outcomes seen with other drugs or drug combinations.

This is the first systematic description of the assertive approach to clozapine and helps counter likely objections regarding the efficacy and risk of administering nasogastric clozapine that might otherwise prevent or delay patients with treatment-resistant schizophrenia receiving the recommended treatment of choice.

Saeed Farooq (Sfarooqlrh@yahoo.com)

date

2019-2

Abstract

Aims and method

To systematically review the literature on barriers to the use of clozapine and identify any interventions for optimizing clozapine use in treatment-resistant schizophrenia. Journal databases were searched from 1972 to March 2018. The following search terms were used: treatment-resistant schizophrenia, clozapine, barriers, use, prescription rates, implementation, clozaril and prescribing practices. Following a review of the literature, 15 papers were included in the review.

Results

The major barriers that were identified included mandatory blood testing, fear of serious side-effects and lack of adherence by the patients, difficulty in identifying suitable patients, service fragmentation, and inadequate training in or exposure to using clozapine.

Clinical implications

In view of consistent evidence across the studies on inadequate knowledge and skills as a significant barrier, we suggest that a certification requiring competence in initiating and managing side-effects of clozapine becomes a mandatory requirement in training programmes.

Declarations of interest

None.

Clozapine use in schizophrenia

Clozapine is the only medication licensed for treatment-resistant schizophrenia (TRS), which affects about one-third of those suffering from the disorder. Recently, there has been increased interest in redefining the role of clozapine in the treatment of schizophrenia in view of the evidence of superior efficacy and safety, despite serious side-effects.¹ Meta-analyses have demonstrated that clozapine is significantly better at treating symptoms than first-generation antipsychotics and some (but not all) second-generation antipsychotics.² This superior efficacy was also supported by two large, independently funded studies.^{3,4} Clozapine also appears to have broader effects, with evidence for efficacy in suicidality, aggression and substance misuse.¹ In the USA, clozapine is approved by the Food and Drug Administration for the management of suicidality in people with schizophrenia or schizoaffective disorder. In addition, clozapine has been shown to have anti-aggressive properties⁵ and may also be effective in diminishing substance misuse.^{6,7} Tiihonen *et al*⁷ found, using a large database, that people regularly taking clozapine had the lowest risk of premature mortality compared with both those on other antipsychotics and those not taking regular medication, despite the fact that the drug is associated with a number of serious adverse side-effects.⁷

Potential barriers and delays in clozapine use

Despite the evidence of superior efficacy and recommendations by different treatment guidelines, the drug is grossly underutilised.⁸ Studies based on prescription patterns in routine practice almost universally show lower prescriptions of clozapine in individuals with Schizophrenia, even after taking into account potential barriers such as inadequate service provision.⁹ There is also substantial evidence that the use of clozapine is delayed for several years, which may result in less than optimal efficacy for the drug. A study by Howes *et al*¹⁰ showed that the mean theoretical delay from meeting the National Institute for Health and Care Excellence (NICE) criteria for TRS and starting clozapine was about 4 years. In New Zealand the theoretical delay was almost 10 years.¹¹ In the USA, only six states reported that more than 10% of Medicaid-eligible patients with schizophrenia had received a prescription of clozapine.¹²

The reasons for such suboptimal use of clozapine remain obscure, and may include several factors related to patients, carers and clinicians. These may include the perception of the drug as a dangerous medicine¹ or difficulties associated with initiating and maintaining the treatment. The life-threatening side-effects of clozapine and mandatory requirement for white blood cell (WBC) counts may partly account for the less than optimal use of the drug in clinical practice. Experience in using clozapine may be an important factor. A study by Nielsen *et al*¹³ of the attitudes and knowledge of 137 psychiatrists in Denmark, including 100 consultant psychiatrists, revealed that some had never prescribed clozapine despite having worked for over 5 years. The barriers to effective use of clozapine have not been reviewed systematically.

We therefore aimed to review the literature on barriers to the effective use of clozapine in clinical practice for TRS. We also wanted to identify any interventions that could potentially improve the use of clozapine. This systematic review aimed to answer the following questions. •What barriers or factors have been identified that prevent the optimal use of clozapine in TRS, based on the current literature?•What strategies have been explored to promote the effective use of clozapine in TRS?•What is the methodological quality of the evidence that is available exploring the barriers to optimal use of clozapine?

Method

We followed the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) statement guidelines.¹⁴ A protocol defining the key methodological parameters was developed prior to the literature search and was registered at the International Prospective Register of Systematic Reviews (PROSPERO).¹⁵

Search strategy

Electronic databases (PsycINFO, Medline, PubMed, AMED, CINHALL and EMBASE) from 1972 onwards were searched, followed by a search of the reference lists of the full texts of the retrieved articles for further relevant articles. The following search terms were used: treatment-resistant schizophrenia, clozapine, barriers, use, prescription rates, implementation, clozaril and prescribing practices. These keywords were searched for in the title, keywords, or abstract. Truncations and related terms were used as appropriate based on individual database procedures. The search was last updated in March 2018.

All study types (intervention, observational and descriptive) were included in the review if the following inclusion criteria were met. •Adult populations with a diagnosis of TRS for whatever indication. Clozapine has been used for other diagnoses; however, we limited our present review to TRS. •Included primary research information on the outcome variables, i.e. barriers or factors associated with low use or implementation strategies. •Published between 1972 and 2018.

Studies that examined the pattern of use of clozapine, the rate of prescriptions, or its efficacy and effectiveness were excluded, unless these provided data on the barriers or factors associated with low or high use of clozapine.

There is no agreed definition of the 'optimal use' of clozapine. However, a number of studies^{9-11,16} indicate that the optimal use is determined on the basis of time since the start of the first antipsychotics (considering that clozapine is used after failure to respond to two antipsychotics) and the prevalence of clozapine prescription relative to total antipsychotic prescriptions (based on fact that about 30% of those suffering from schizophrenia develop TRS). These provide useful guidance but do not take into practical factors such as patient willingness to start clozapine or non-availability, or the cost of clozapine in low- and middle-income country settings. We used these parameters as a broad guideline for our review, but we will also report clozapine use and how it is defined as adequate or optimal by different studies.

Data extraction

The screening for searches examining the relevant abstracts, examination of full-text articles and data extraction were done by two reviewers independently, as outlined in the protocol.¹⁵ Any disagreements were resolved by consensus and, where appropriate, by consultation with the third reviewer. A data extraction sheet was developed based on the pre-specified outcomes and relevant data were extracted on to this sheet. We planned a meta-analysis of primary and secondary outcomes, but it was not possible to statistically summarise the data owing to the heterogeneity of studies, lack of adequate data and low quality of studies. We instead provide a descriptive summary of main findings.

Results

The electronic searches returned 253 relevant abstracts and titles; no further articles were identified from the other sources. We screened the titles and abstracts, and excluded any studies that were not directly relevant to the objectives of the review. After screening these titles and abstracts and removal of duplicates, we further examined 47 full-text papers. Finally, we included 15 papers in the review. The details of the search yield and reasons for excluding full-text articles are provided in *Fig. 1*. *Fig. 1* Summary of the abstracts reviewed to identify papers relevant for the review.

Characteristics of included studies

The studies were conducted in a number of different populations, settings and periods, and also used diverse methodologies. Owing to the diverse methodologies and number of variables examined across studies, it was inappropriate to pool the data to produce a statistical summary. We therefore describe the main findings and produce a narrative summary of results.

Fifteen studies met the inclusion criteria. Twelve of these studies focused on barriers or factors associated with clozapine use. These comprised surveys ($n = 5$), case note reviews ($n = 4$), and semi/structured interviews and consultations with stakeholders ($n = 3$). The majority of these studies ($n = 8$) involved eliciting views from clinicians, particularly consultant psychiatrists. Three studies described interventions or quality improvement initiatives to facilitate the use of clozapine. These are described separately.

In survey-based studies, response rates varied from 8.8 to 76%. The mean response rate from the papers which had figures available ($n = 5$) was 52.3%. The total number of males from the studies providing this information ($n = 6$) was 608, and the number of females was 402. The populations in these studies comprised 902 psychiatrists, 68 trainees, 49 pharmacy staff and 15 nursing staff or staff in mental health leadership positions. One database study reviewed the Medicaid patients on antipsychotic medication using records of 629 800 patients in the analysis.

In the three intervention studies, 158 participants were involved. One study did not provide details of sample size.

Barriers to the use of clozapine in TRS

It was possible to classify the barriers in three groups with some overlap: •barriers related to patients and the drug;•clinician-related barriers;•health system-related factors.

Patient- and drug-related barriers

Five studies commented on patient-related factors affecting the use of clozapine in TRS. The complete refusal of blood tests was considered a major barrier, with patients delaying the initiating of clozapine (56%, $n = 72$).¹⁷ This was replicated by Kelly *et al*,¹⁸ who surveyed psychiatrists in Maryland, USA, and found that the main barrier, ranked highest on the Likert scale (1–5), was patient non-adherence with blood work (3.7 ± 1.1) and the burden of blood work on the patient (3.6 ± 1.2).¹⁸ In a survey of patients, Swinton and Ahmed (1999)¹⁹ reported that almost two-thirds of participants did not want the burden of regular blood tests. This was replicated in a survey of staff, with 65% ($n = 83$) reporting that patients did not want the burden of regular blood tests and that frequent blood tests were considered a major barrier to initiating clozapine.¹⁷

Concerns about tolerating clozapine were considered to be fairly or very frequently related to delays in clozapine use by 46% ($n = 59$) of clinical staff.¹⁷ Complications related to clozapine, such as constipation, hypersalivation, myocarditis and neutropenia, can inhibit clozapine use; a survey of clinical staff found that 37% ($n = 76$) felt that these potential medical complications frequently restricted the use of clozapine.¹⁷

Najim *et al*²⁰ reviewed 42 case notes of patients on clozapine and found that there were significant delays in commencing clozapine in patients aged over 30.²⁰ This was replicated by Grover *et al*,²¹ who carried out a case note review on 200 in-patients from a tertiary care centre in North India. A greater delay in initiating clozapine was noted in the older age group (over 20) compared with those under 20 (mean 0.91 v. 2.05; s.d. 1.05 v. 1.86).²¹ In addition, they found a significant delay in patients prescribed polypharmacy compared with non-polypharmacy (mean 2.58 v. 1.68; s.d. 2.06 v. 1.67), and delays were also associated with being in an urban locality (mean 2.11 v. 1.37; s.d. 1.98 v. 1.11).²¹

Clinician-related factors

Inadequate knowledge of or experience in clozapine use. Fifty-two per cent ($n = 75$) of staff surveyed in South London Maudsley NHS Foundation Trust¹⁷ reported not being familiar with initiation of clozapine. In another large survey, 74% ($n = 136$ total 184) of psychiatrists working in the UK also highlighted a lack of knowledge or experience amongst consultants, leading to delays.²² A significant number of consultants (42%; $n = 96$) had fewer than five patients on clozapine, despite half of these consultants working in trusts with a dedicated clozapine service and having been in-post for 7 years.²² This was replicated by Nielson *et al* (2009), who found that 48% of psychiatrists surveyed had treatment responsibility for fewer than five patients treated with clozapine.¹³ In Mexico, Apiquian *et al*²³ reported that fewer than half of the 200 surveyed psychiatrists in Mexico knew the recommended average dose of clozapine.²³

The fear of side-effects or lack of knowledge in dealing with these were considered to be serious hurdles in initiating clozapine. Sixty per cent ($n = 70$) of practitioners surveyed in South London and Maudsley NHS Foundation Trust

raised concerns about tolerability and side-effects that delayed the initiation of clozapine.¹⁷ Nielson *et al*¹³ reported that in terms of side-effects and knowledge, only 33% ($n = 33$) knew that the risk of agranulocytosis was highest in the first 6 months and 23% ($n = 23$) overestimated this risk of agranulocytosis.¹³

The majority of the clinicians in a survey (78%; $n = 105$) said they would support clozapine initiation after a trial of two antipsychotics.¹⁷ However, Nielson *et al* (2009) found that only 44.9% ($n = 44$) would go to clozapine after two antipsychotics,¹³ and about a third 30.6% ($n = 30$)¹³ of clinicians in one survey and 14% ($n = 19$) in another would wait until three adequate trials of antipsychotics prior to initiating clozapine, while 18.4% ($n = 19$)¹³ would wait until more than three failed adequate trials of antipsychotics. In another survey, 28% ($n = 51$, total 184) of consultants said they would trial at least another antipsychotic before going to clozapine after a failed trial of two antipsychotics,²² and 40.5% ($n = 92$) preferred to use several other antipsychotics before clozapine.¹⁹ Nielson *et al*¹³ found that 64.7% of psychiatrists surveyed ($n = 64$) would rather combine two antipsychotics than prescribe clozapine, and 15.2% ($n = 15$) would augment with a mood stabiliser before using clozapine in a non-schizoaffective state.¹³

Difficulty in identifying suitable patients and unclear diagnosis were highlighted by 12% of consultant psychiatrists ($n = 22$) in a survey conducted by Tunganaza & Farooq.²² Although consultants felt they had good exposure to clozapine as trainees, 36.2% ($n = 83$) felt it was not easy to identify suitable patients for clozapine.²²

Need for intense monitoring

Forty-two per cent ($n = 77$) of psychiatrists in a UK-wide survey felt it was complex and cumbersome to initiate and manage clozapine, which led to delays in starting the drug.²² In a survey of consultants based in child and adolescent psychiatry, 29% ($n = 17$) reported that they did not prescribe clozapine owing to the need for intense monitoring.²⁴ Tunganaza & Farooq²² found that 74% ($n = 136$) of clinicians felt there were delays owing to refusal of patients to have blood tests.²²

Serious side-effects

In a survey of consultant psychiatrists, 105 out of 231 respondents (45.5%) acknowledged that their patients experienced untoward side-effects while on clozapine, which was considered to be major factor in delaying clozapine use.²²

Staff in child and adolescent services highlighted unfamiliarity with clozapine (41%; $n = 4$) and side-effects (41%; $n = 4$)²⁴ as major factors in delaying clozapine initiation. Swinton & Ahmed¹⁹ reported that 22% ($n = 7$) of the clinical staff in their study believed that the risks associated with clozapine outweighed the benefits of starting clozapine.¹⁹

Perception that patients may not adhere to treatment

Clinical staff surveyed at a high-secure hospital reported likely poor adherence by the patients as a reason for not prescribing clozapine in 53% of cases ($n = 17$).¹⁹ Other clinical staff reported that patients were likely to refuse blood tests 43% ($n = 13$).¹⁹ Tungaraza & Farooq²² reported that 54% ($n = 99$) of practicing psychiatrists felt that likely poor adherence to the drug was a reason for delays.²²

Health system-related barriers

Studies based on clinician surveys identified the following health system-related barriers. (a) Difficulties in obtaining baseline bloods and the time taken to register patients for blood monitoring were considered as major factors in initiating clozapine by 22% ($n = 26$) clinicians.^{17(b)} Staff resources, including inadequate staff to monitor clozapine initiation, were a major factor for 22% ($n = 26$) of clinicians in delaying clozapine initiation.^{17(c)} The need for admission as required by some health providers to initiate clozapine and a shortage of beds were highlighted by 20% ($n = 23$) of clinical staff.¹⁷ In another survey, 32% ($n = 40$) of clinical staff felt that a lack of resources in the home treatment team led to frequent delays in commencing clozapine.^{17(d)} Service fragmentation owing to separate teams providing community and in-patient services and a lack of community support were cited as major barriers ($n = 39$) by clinicians in one study.²² A survey of staff at Ashworth high-secure hospital also revealed that clinicians felt that a lack of resources was responsible for delays or non-prescription of clozapine in 16% ($n = 5$) of cases.¹⁹

Stroup *et al*²⁵ conducted a retrospective study using Medicaid claims data from 45 states in the USA. It was found that among 629 809 unique antipsychotic treatment episodes, 79 934 showed service use patterns consistent with treatment resistance. Clozapine accounted for 2.5% of starts of antipsychotic medication among patients in the overall sample, and 5.5% of starts among patients with treatment resistance. Clozapine initiation was significantly associated with male sex, younger age, White ethnicity, more frequent out-patient service use for schizophrenia, and greater prior-year hospital use for mental health.²⁵ Patients residing in counties with historically high clozapine usage were almost twice as likely to start clozapine as patients residing in historically low-use counties (adjusted odds ratio (AOR) 2.03; CI 1.75–2.30).²⁵ A high concentration of psychiatrists (>15 per 100 000 residents) was also associated with a greater likelihood of clozapine initiation (AOR 1.17; CI 1.03–1.33).²⁵ However, there were no significant effects of population density or measures of poverty or income on clozapine initiation.

Goren *et al*²⁶ carried out 70 semi-structured interviews with stakeholders such as psychiatrists, mental health nurses, and pharmacy and laboratory staff at five sites with high clozapine use and five low-utilization sites. Low utilization of clozapine was associated with a lack of champions to support the clozapine process. Some of the barriers highlighted included the complex and time-consuming paperwork.²⁶ Lack of transport, particularly for rural patients, inability by disorganised patients to navigate public transport, paranoia around travelling by public transport and the cost of transportation²⁶ were reported as major barriers. Patients living far away from clinics were not considered suitable for clozapine owing to their inability to attend for regular blood tests.²⁶

Kelly *et al*¹⁸ elicited the views of psychiatrists using an anonymous survey questionnaire. The questionnaire consisted of 56 questions to be scored on a five-point Likert scale (1 = strongly disagree, 5 = strongly agree) regarding the barriers related to clozapine, and the physician's interest and willingness to use point-of-care (POC) devices. The survey was sent to 860 psychiatrists, of whom 277 (32%) responded. Among the 28 listed barriers (clinical, nonclinical, and side-effects) to more frequent use of clozapine, the two highest ranking barriers were: (a) the likely non-adherence of patients to blood work (score 3.7 ± 1.1) and (b) the burden of ongoing blood monitoring for the patient (score 3.6 ± 1.2). Among nine potential solutions for increasing the use of clozapine, the use of POC devices was the highest ranked. The physicians agreed that a POC device would improve care and that it would increase their clozapine use with a mean score of 3.9 ± 1.0 .¹⁸

The National Association of State Mental Health Program Directors (NASMHPD) in the USA formed a working group to identify barriers to clozapine underutilization and interventions to overcome these at a national level.²⁷ The initial work group included 11 clinicians and researchers and consulted a wide range of stakeholders and existing literature on the subject. They identified 14 major barriers, which included all the factors mentioned above, as well as benign ethnic neutropenia (BEN), which occurs among people of African or Middle Eastern ancestry. The lack of a definition for BEN in product labelling and clear guidance on monitoring requirements may be responsible for the low use of

clozapine in this population. A lack of standardised materials for shared decision-making, complex protocols for treatment monitoring and management of side-effects, formulary issues and costs of ancillary services such as transportation and service coordination were also identified as barriers (*Box 1*).²⁷ *Box 1* Barriers to clozapine use and strategies to overcome these

Barriers to clozapine use

- Patient/drug-related barriers
 - Refusal of blood tests^{17–19}
 - Tolerating clozapine and side-effects¹⁷
 - Age > 20^{19,20}
 - Patients prescribed polypharmacy²¹
 - Benign ethnic neutropenia²⁷
- Clinician-related barriers
 - Inadequate knowledge of or experience in clozapine use^{17,22–24}
 - Fear of side-effects for patient/lack of knowledge about clozapine side-effects^{13,17,19,22,24}
 - Lack of adherence to guidance^{13,17,22}
 - Difficulty identifying suitable patients and unclear diagnoses²²
 - Need for intense monitoring^{22,24}
 - Perception that patients may not comply with treatment^{19,22}
- Health system-related barriers
 - Not enough resources, including not enough staff resources to monitor clozapine initiation¹⁷
 - Shortage of beds¹⁷
 - Service fragmentation²¹
 - Lack of champions to support the clozapine process²⁶
 - Complex and time-consuming paperwork²⁶
 - Lack of standardised shared decision-making²⁷
 - Complex protocols for treatment monitoring²⁷
 - Formulary issues and costs of ancillary services such as transport and service coordination²⁷

Strategies to overcome barriers to clozapine use

- Use of POC devices²⁹
- Support for prescribers and decision-aid tool for consumers grounded in principles of shared decision-making²⁷
- Internet-based educational programmes to provide information for consumers, family members and clinicians²⁷

Interventions to overcome the barriers

Three studies described interventions that could help to overcome the barriers identified above. These included a training initiative²⁸ and two studies describing the use of POC devices.^{28,29} As these studies employed different methodologies and interventions, the results are briefly summarised here.

Bogers *et al*²⁹ compared a POC device using capillary blood sampling with a finger prick that provided WBC counts with conventional venous sampling. An open-label randomised cross-over trial design was used to compare the two procedures. The main outcome measure was the subjective experience of various aspects of blood sampling, as measured by a visual analogue scale (VAS). A consistent pattern in favour of capillary blood sampling was found (total perceived burden blood sampling: capillary 5.79 *v.* venous 13.4 ($P < 0.001$)). Both patients and practitioners showed preferences for the capillary blood sampling.²⁹

Similarly, Nielsen *et al*³⁰ evaluated a POC using a randomised cross-over trial design. Patients were randomised to one of two blood monitoring sequences. The first group underwent venous sampling followed by capillary sampling in a twice-repeated procedure (venous–capillary–venous–capillary); in the other, the sequence was reversed (capillary–venous–capillary–venous). Eighty-five patients were included in the study using a VAS; patients indicated that they found capillary blood monitoring less painful than venous sampling (VAS ratings: 0.55 *cm* 25–75th percentiles: 0.1–1.4 *cm* *v.* 1.75 *cm* 25–75th percentiles: 0.7–2.6, $P < 0.001$). They also felt less inconvenienced by the POC method than by traditional blood sampling.³⁰

Carruthers *et al*²⁸ described an educational intervention to promote the evidence-based use of clozapine in New York,²⁸ consisting of support for the prescriber and a decision aid tool for consumers grounded in the principle of shared decision-making. A manual for clinicians was developed and academics presented a series of state-wide grand rounds presentations to provide information on clozapine prescribing. Internet-based educational programmes and a telephone consultation service by experts to support the prescribers were also provided. A key component of the programme was testimonials from patients, who described personal benefits alongside the challenges.²⁸ The programme was evaluated using Medicaid data on the pattern of new antipsychotic start-ups. The number of new starts amongst all antipsychotic trials increased from 1.5% in 2009 to 2.1% 2013.²⁸ The greatest change was seen in state-operated facilities, where the rate of clozapine new starts per quarter increased compared with all new antipsychotic starts. The change in the rate of clozapine new starts in these facilities was three times higher than in other settings (3.77% *v.* 1.13%).²⁸

Quality assessment of included studies

The published protocol outlined separate quality assessments for qualitative and quantitative studies, using appropriate checklists for different study designs.¹⁵ However, after examining the included studies, it was felt that only two trials²⁹⁻³⁰ could be assessed for quality using the risk of bias tool, as per protocol. These randomised cross-over trials compared capillary blood sampling using a POC device with traditional venous blood sampling. Patients were randomised to two sequences, starting with either capillary or venous blood sampling, followed by a repeated sequence. Neither of these trials provided details of how participants were randomly allocated to the two sequences, and the outcome assessments did not appear to have been done by blind assessors. Both studies had high risk of bias.

Other studies did not use appropriate study designs, which could be evaluated using the checklists we proposed in the protocol for observational studies. These studies were mostly surveys and provided little information on how the samples were selected and the validity or reliability of the questionnaires/instruments used, or any information on non-responders. All these studies were considered to be of low quality.

Discussion

This was the first systematic review aiming to examine the barriers to effective use of clozapine. The following major barriers or factors related were identified: the mandatory blood testing requirement; fear of serious side-effects, lack of familiarity in use of clozapine; lack of clarity in diagnosis and difficulty in identifying suitable patients; service fragmentation; and lack of adequate training in or exposure to using clozapine. Only one educational intervention was available that showed some effect on clozapine prescription rate. POC testing using capillary blood was more acceptable to patients than traditional blood sampling, being less painful and less time consuming, but no studies tested whether it increased the uptake of clozapine.

A conservative estimate suggests that TRS adds more than \$34 billion in annual direct medical costs in the USA.³¹ In the UK, NICE has included the extent and the degree of clozapine use in the quality criteria for commissioners when commissioning services for mental health.³² However, initiatives to overcome this major service need are rare.

Almost all studies highlighted routine blood monitoring as the top-ranking barrier to initiating and maintaining clozapine treatment. Two randomised cross-over trials showed that blood testing using a simple finger prick that was undertaken as part of routine assessment by psychiatric staff, either in the patient's home or at a psychiatric out-patient clinic, was feasible and convenient for patients. However, none of these trials looked at the effect of POC testing on prescription rates. The POC devices will also need to comply with regulatory requirements for monitoring blood counts.

It appears that there is a common perception amongst clinicians that clozapine is a dangerous drug, and that patients will not adhere to it or would not like to consider it as a treatment option. The findings in this review suggest that these negative beliefs about clozapine result from a lack of experience and knowledge, owing to the current limited use of clozapine. A self-perpetuating cycle can ensue, as practitioners do not see the benefits of clozapine, and thus do not develop confidence in its use.¹ This is consistent with the study by Stroup *et al* which showed that higher clozapine initiation was significantly associated with patients residing in areas associated with historically high clozapine usage and higher concentrations of psychiatrists (>15 per 100 000 population).²⁵

The NASMHPD published 36 recommendations on its website for expanding the use of clozapine.³³ One important recommendation included improving residency trainee standards. Considering the disease burden resulting from TRS and the central role of clozapine in its treatment, we suggest that training in the use of clozapine becomes a mandatory requirement for all psychiatry residence and continuing professional development programmes. A certification requiring competence in initiating, maintaining and managing side-effects of clozapine is required, based on clinical experience, similar to the certification that is now required for electroconvulsive therapy.

The use of clozapine is alarmingly low in many developing countries. In Pakistan, for example, about 1300 patients were receiving clozapine as recorded in the Clozaril Patient Monitoring System. Although generic clozapine has become available recently, numbers are still very low, considering that the country has a population of about 200 million (R. U. Rahman, personal communication, 2016; data available from the authors on request). To put this prescription rate into perspective, The Netherlands, with a population of about 17 million, has over 12000 patients on clozapine, which

is 0.07% of the population (<https://www.gip databank.nl/>). This means that, at current rates of use, there is a more than 100-fold difference between the two countries. This situation requires a public health intervention to improve access to clozapine in certain countries.

The major limitation of the review was the low quality of the included studies. Studies were based on surveys, which are prone to a number of biases, including selection bias of respondents, and lacked control groups. The low numbers of studies from a few countries also limit the generalisation of results. None of the studies defined the optimal use of clozapine. The lack of patient perspectives is striking, considering that a number of studies suggested patient-related factors as major barriers.

Despite these limitations, this systematic review indicates that there is broad agreement on the major barriers that hinder the effective use of clozapine. There is certainly a need to improve the methodological quality of studies and the way these are reported, but the present study identifies gaps in clinical practice and health services that can be addressed in intervention studies. Use of POC devices, educational interventions targeting clinicians and shared decision-making involving patients need to be evaluated using controlled study designs. Future research should be guided by the implementation science methods and behaviour change principles that have successfully been used in implementing and evaluating evidence-based interventions in medicine.

Formerly Consultant Psychotherapist and Consultant Psychiatrist, Royal Edinburgh Hospital, and Honorary Professor, Queen Margaret University, Edinburgh

2018/S2056469418000189_inline1.jpg

Christopher (Chris) Paul Lindsay Freeman, who recently died at the age of 70, had an unusually bright and enquiring mind and loved challenging existing orthodoxies. In 1978, while still a junior academic, he carried out a double-blind trial of the effectiveness of electroconvulsive therapy (ECT) — then, as now, a controversial intervention. The trial, which found ‘real’ ECT to be superior to ‘sham’ ECT, was published in *The Lancet*, a remarkable achievement for such a young researcher. Subsequently, he published a number of other key research papers, almost 150 publications in total. He also contributed substantially to the teaching of a generation of psychiatrists, personally writing chapters on neuroses, personality disorder and ECT for the *Companion to Psychiatric Studies*. In addition, he was co-editor of the 7th and 8th editions of this textbook, required reading for those studying for the MRCPsych qualification.

Despite his academic productivity, Chris was more interested in developing and improving services than in pursuing an academic career. His considerable energies went especially into his areas of expertise: psychotherapy as it relates to eating disorders, post-traumatic stress disorder and ECT. It is an indication of his breadth of knowledge that he chose to focus on opposite ends of the psychiatric treatment spectrum. Although his influence on psychological therapies in the treatment of eating disorders and trauma-related morbidity was broad, the most tangible evidence of his efforts was the establishment of the Cullen Centre at the Royal Edinburgh Hospital, the Anorexia Nervosa Intensive Treatment Team and the Regional Unit at St John’s Hospital that provide, respectively, out-patient, community-based and in-patient treatment for people with eating disorders.

When he recognised the increasing number of referrals his service was receiving for the assessment and treatment of traumatic stress disorders, Chris took practical steps to meet the changing needs. He ensured that specialist services for people suffering from these disorders were available by establishing the Rivers Centre, together with Claire Fyvie. This centre was named after W. H. R. Rivers, the psychiatrist who worked at Craiglockhart Hospital during the First World War, and among whose patients were the poets Siegfried Sassoon and Wilfred Owen. Chris also undertook much related medico-legal work that ensured the condition was better understood by the courts and, where appropriate, that sufferers were compensated. He broadened his influence in this field by establishing the Scottish Trauma Advisory Group with direct links to the Scottish Government. He also served as President of the UK Psychological Trauma Society.

Chris had a strong interest in maintaining high standards in the quality of psychiatric care. In Scotland, he established the ECT Accreditation Service and later chaired a similar body for the Royal College of Psychiatrists. He also chaired the Ethics Committee of the College and most recently was its Clinical Lead for Quality Improvement.

After a childhood in York, Chris studied medicine at Edinburgh University Medical School, from where he graduated in 1971. He trained in psychiatry at the Royal Edinburgh Hospital, obtaining the Membership of the Royal College of Psychiatrists in 1976. Three years later, he was awarded the Gaskell Gold Medal. He was appointed Senior Lecturer at Edinburgh University Medical School and Honorary Consultant Psychiatrist at the Royal Edinburgh Hospital in 1980, but in 1984 surprised many with a move to a National Health Service Consultant post in Psychotherapy. Exploring new territory in psychotherapy, he changed the focus of the department from traditional psychoanalytically based psychotherapy to cognitive-behavioural therapy (CBT). He was able, with colleagues, to develop a training course in CBT for doctors, psychologists, nurses and other professionals. This grew to become the South of Scotland CBT course. The emphasis in therapy was on a positive collaboration with the patient, with the aim of developing the patient’s motivation to change.

Chris’s personality was characterised by his infectious enthusiasm, coupled with an eager willingness to take on new challenges. On occasion, his reluctance to turn down opportunities resulted in serious overload and a need to ‘wing it’. When his ‘just in time’ approach became ‘just too late’, colleagues could be left spinning or catching falling plates. This sometimes led them to feel frustrated with him, but there was never any lasting animosity.

Although he placed great importance on getting personally involved with patients, carers and colleagues, he was never happier than when working with his hands in his garden or workshop. He was fascinated by new technology and its

accompanying gadgets, but also spent a great deal of time and effort gathering an extensive collection of old children's toys.

At an extremely well-attended memorial service for Chris held at the University of Edinburgh, Playfair Library, on 13 October 2017, colleagues from many different disciplines paid tribute to his massive contributions to the field. Chris was devoted to his family. At the service, his wife and two sons described his role as a family man whose happiest times in his later years were spent playing with his grandchildren. A quotation from John Buchan on the cover of the order of service eloquently summed up his life.

'His presence warmed and lit up so big a region of life that in thinking of him one is overwhelmed by the multitude of things that he made better by simply existing among them.'

Born on 21 April 1947, Chris Freeman died of cancer of the prostate at home in East Lothian on 20 August 2017. He is survived by his wife Katherine, his sons Paul and Robin, and his grandchildren.

date

2018-8

Abstract**Aims and method**

A national survey investigated the implementation of mental health crisis resolution teams (CRTs) in England. CRTs were mapped and team managers completed an online survey.

Results

Ninety-five per cent of mapped CRTs ($n = 233$) completed the survey. Few CRTs adhered fully to national policy guidelines. CRT implementation and local acute care system contexts varied substantially. Access to CRTs for working-age adults appears to have improved, compared with a similar survey in 2012, despite no evidence of higher staffing levels. Specialist CRTs for children and for older adults with dementia have been implemented in some areas but are uncommon.

Clinical implications

A national mandate and policy guidelines have been insufficient to implement CRTs fully as planned. Programmes to support adherence to the CRT model and CRT service improvement are required. Clearer policy guidance is needed on requirements for crisis care for young people and older adults.

Crisis resolution teams (CRTs) are multidisciplinary, specialist mental health services that offer brief intensive home treatment to people experiencing a mental health crisis, with the aim of averting hospital admission wherever possible.¹ CRTs for working-age adults have been implemented nationally in England since the National Health Service (NHS) Plan of 2000,² and elsewhere in Europe and Australasia.³ The English national mandate for CRTs was accompanied by policy implementation guidance⁴; the CRT model it specified has been endorsed in numerous subsequent policy guidelines.⁵ Trials suggest that CRTs can reduce in-patient admissions and increase patients' satisfaction with acute care.⁶⁻⁷ However, when scaled up to national level, the implementation of CRTs has been highly variable,⁸⁻¹⁰ and their effects on admission rates have been disappointing.¹¹ In England, improving access to and quality of mental health crisis care across the age range has been identified as a priority by expert bodies and policy makers.¹²⁻¹⁵ To inform

future mental health workforce planning, in 2016 Health Education England commissioned a team from University College London to conduct a national survey of CRTs.

Method

Aims

The nationwide implementation of CRTs for working age adults in England mandated by the NHS Plan² represents an unusually prescriptive attempt to implement a new mental health service model on a national scale. In this paper, we aimed to investigate the consequences of this national implementation, through addressing two main research questions. First, to what extent do CRTs adhere to the implementation guidance for CRTs⁴ that accompanied the national mandate? Second, how has the implementation of CRTs changed, compared with results from a similar CRT survey⁹ conducted in 2012? Secondary aims were to map the provision of CRTs in England for working-age adults, children, and older adults and people with dementia; to explore variation in the local acute care system contexts in which CRTs operate; and to describe the staffing and access arrangements of CRTs.

Setting

We sought to map and include all CRTs in England. CRTs were defined as mental health services that exclusively provided brief, intensive home treatment for people in mental health crisis with the aim of averting hospital admission. Services that provided longer-term intensive home treatment (e.g. assertive community treatment teams) or intensive home treatment as part of a broader community service (e.g. within the context of a community mental health team) were excluded.

Participants

Team managers of each identified CRT were invited to participate in the survey. Where the manager was unavailable, an alternative senior CRT staff respondent was sought.

Measures

The study team developed a 91-item questionnaire, informed by the measure used in a previous CRT survey.⁹ This included a mixture of quantitative questions and questions requiring brief free-text responses. Questions covered: current CRT staffing and caseload size; referral and access arrangements, including opening hours, eligibility criteria, referral routes and response time; working arrangements with other acute services; the role of the CRT in decision-making regarding hospital admission ('gatekeeping'); staff training; and team philosophy of care.

Procedures

CRTs were mapped by multiple means, including registers of adult and older adult CRTs from two research studies and a national quality improvement network, and through the websites of all mental health NHS trusts in England. CRT managers were asked to identify other CRTs in their area (including teams for young people or older adults) when contacted about the survey, in order to identify any CRTs previously missed.

The survey met Health Research Authority criteria for a service evaluation¹⁶ and was approved as such by the North London Research Consortium. Local processes for approving the service evaluation were followed by the study team wherever required.

Details of mapped CRTs were entered into Opinio,¹⁷ UCL's secure online survey system. Team managers were then automatically invited to complete the survey by email, through Opinio, and were also contacted by researchers, sent an

information sheet about the study and given the opportunity to ask any questions. Following three, weekly automatic Opinio email reminders, researchers contacted remaining non-responders by phone. The option of completing the questionnaire as a telephone interview was offered. Respondents consented to take part by completing the survey: those who completed the survey online entered their own data directly into Opinio; researchers entered the data into Opinio for phone respondents.

The survey took place from September to November 2016. At the beginning of December 2016, the online survey was closed and the data were downloaded from Opinio into SPSS for Windows for data analysis. Data files were stored on the secure, password-protected UCL IT system.

Analysis

Data were analysed in SPSS and descriptive statistics were presented separately for adult, older adult/dementia, and children and young people's CRT teams. Survey questions which directly mapped on to national policy implementation guidance for adult CRTs⁴ were identified, and the proportion of adult CRTs meeting each policy recommendation was reported. For variables where comparable data were available from both our survey and the 2012 national CRT survey,⁹ differences in responses between the two time points were explored using bivariate statistics.

Results

Overall, 198 adult CRTs, 15 CRTs for children and young people, and 31 CRTs for older adults and/or people with dementia were mapped. (One adult CRT originally mapped in error was excluded.) Survey responses were obtained from 190 adult teams, 13 children and young people's teams, and 30 older adult teams: an overall response rate of 95%. Two administrative health regions (NHS trusts) had no adult CRT services: in these regions, crisis response was organised within broader community mental health teams.

Adult CRTs' adherence to policy recommendations

Table 1 summarises how far adult CRTs were adhering to the recommendations of the influential Mental Health Policy Implementation Guide⁴ which accompanied the national mandate for adult CRTs in England. Only one team was fully adherent in all respects; recommendations for having a multidisciplinary staff team and for accepting referrals directly from general practitioners (GPs) and patients were most frequently unmet. Regarding staffing levels, 76% of teams met the minimum recommended staffing level of 14 full time equivalent staff for a caseload of 30 patients, based on their current caseload on the day of the survey. However, this figure dropped to 55% of teams, based on their reported highest typical caseload. *Table 1* Adult CRTs' adherence to national policy implementation guidance regarding access and staffing

Department of Health 2001 policy implementation guidance requirement for CRTs	Proportion of CRTs for working age adults implementing this guidance	n/N (%)
The CRT can provide home treatment 24 h a day, 7 days a week	[Coded as: the CRT can provide home visits to patients on its caseload at any time of the day or night]	132/190 (70%)
The CRT has easy referral processes including accepting direct referral from GPs and patients/families		78/185 (42%)
The CRT will work with adults aged 16–65 years		42/190 (22%)
The CRT should act as gatekeeper to in-patient services	[Coded as: does the CRT always assess voluntary patients in person before hospital admission?]	92/185 (50%)
Adherence to all the above access requirements		33/185 (18%)
The CRT includes a psychiatrist	[Coded as: the CRT includes a consultant or staff grade psychiatrist]	173/185 (94%)
The CRT team should be multidisciplinary	[Coded as: the CRT includes psychiatrist, nursing, social work, psychologist and occupational therapist staff and support workers]	27/185 (15%)
The CRT should include at least 14 full time equivalent staff for a team caseload of up to 30 patients	[Coded based on current caseload from survey responses]	137/180 (76%)
Adherence to all the above staffing requirements		17/180 (9%)
Adherence to all staffing and access requirements		1/180 (1%)

Changes to CRT implementation 2012–2016

Table 2 summarises recent changes in adult CRT implementation, based on a comparison of results from this survey with those from a previous national survey conducted in 2012.⁹ Overall, adult CRTs appear to be more accessible in 2016: compared with 2012, significantly more CRTs accept self-referrals, provide a 24 h service, and work with people with personality disorders and with older adults. An exception to this trend is that fewer CRTs in 2016 accepted young people aged 16–17 years. More CRTs in 2016 were able to access non-hospital crisis beds, compared with 2012, and more teams in 2016 fulfilled a full ‘gatekeeping’ function and assessed all patients before voluntary hospital admission. Changes in CRTs’ staff mix were less marked, although social workers were less well represented and psychologists were better represented in CRTs in 2016 than in 2012. The proportion of teams meeting recommended minimum staffing levels fell from 87 to 76%. Table 2

Service domain	2012 CRT survey	2016 CRT survey	Characteristic	n/N (%)	Significant differences
Eligibility (diagnosis)	The CRT will accept people with dementia	39/192 (20%)	32/190 (17%)	n/s	
Eligibility (age)	The CRT will accept people with personality disorder	151/192 (79%)	187/190 (98%)	$\chi^2 = 36.6, P < 0.001$	
Access (hours of service)	The CRT will accept people age 16+	99/192 (52%)	60/190 (32%)	$\chi^2 = 15.7, P < 0.001$	
Access (referrals)	There is no upper age limit to the CRT service	110/191 (58%)	137/190 (72%)	$\chi^2 = 8.8, P = 0.003$	
Access (gatekeeping)	The CRT provides a 24 h telephone response	138/171 (81%)	176/190 (93%)	$\chi^2 = 11.3, P = 0.001$	
Access (referrals)	The CRT accepts referrals from GPs	147/190 (77%)	148/184 (80%)	n/s	
Access (gatekeeping)	The CRT accepts self-referrals from known patients	106/191 (55%)	127/184 (69%)	$\chi^2 = 7.4, P = 0.007$	
Access (gatekeeping)	The CRT accepts self-referrals from new patients	40/191 (20.9%)	79/184 (43%)	$\chi^2 = 20.9, P < 0.001$	
Access (gatekeeping)	The CRT assesses all patients in person before voluntary hospital admission	62/187 (33%)	92/185 (50%)	$\chi^2 = 10.5, P = 0.001$	
Staff mix	The CRT includes consultant psychiatrists	148/171 (87%)	163/185 (88%)	n/s	
Staff mix	The CRT includes nurses	171/171 (100%)	182/185 (98%)	n/s	
Staff mix	The CRT includes social workers	122/171 (71%)	105/185 (57%)	$\chi^2 = 8.2, P = 0.004$	
Staff mix	The CRT includes occupational therapists	72/171 (42%)	88/185 (48%)	n/s	
Staff mix	The CRT includes psychologists	50/171 (29%)	73/185 (39%)	$\chi^2 = 4.1, P = 0.04$	
Staffing level	The CRT has at least 14 full time equivalent staff for a caseload of 30 patients (based on current caseload)	116/134 (87%)	137/180 (76%)	$\chi^2 = 5.4, P = 0.02$	
Crisis alternatives	The CRT has access to a crisis house	65/184 (35%)	85/185 (46%)	$\chi^2 = 4.3, P = 0.04$	
Crisis alternatives	The CRT has access to an acute day hospital	41/184 (22%)	40/185 (22%)	n/s	

CRTs within the acute care system

Table 3 shows the different acute care contexts within which CRTs operate. While all NHS trusts include acute in-patient wards, there was wide variation in the availability of other crisis services within local acute care systems. About half of adult CRTs were supported by a separate, staffed crisis phone line, and had access to residential, non-hospital crisis beds. About one-fifth of adult CRTs could access places for patients at an acute day hospital. Three innovations in acute care systems are highlighted by the survey. First, there is a split between crisis assessment and crisis home treatment functions: nearly one-third of adult CRTs are now supported by a separate triage/crisis assessment service. Second, 15% of adult CRTs are supported by non-residential crisis drop-in services, which typically function at evenings and on weekends, and can signpost elsewhere or refer individuals to CRTs. Third, specialist CRTs for young people and older adults, which were not nationally mandated, have been developed: these typically have less access than adult CRTs to other supportive crisis services. Table 3

Variation in the acute care systems within which CRTs operate	Acute care system characteristic	CRTs operating within this type of acute care system	n/N (%)
Adult CRTs	Children and young people’s CRTs	Older adult/ dementia CRTs	
A separate, 24 h crisis line is provided			106/184 (58%)
A separate crisis assessment/triage service is provided			59/184 (32%)
The CRT has access to residential crisis beds (non-hospital)			85/185 (46%)
The CRT can access an acute day hospital			40/185 (22%)
A separate sanctuary/crisis drop-in service is provided			28/185 (15%)

Staffing and access: adult CRTs

Full descriptive results from the survey are provided in the supplementary data (File DS1) available at <https://doi.org/10.1192/bjb.2018.19>. Adult CRTs exhibited wide variation in staffing and access arrangements. While most teams included nurses (98%), psychiatrists (94%) and support workers (88%), whether teams included social workers (57%), occupational therapists (48%) or psychologists (39%) was much more variable. Current team caseloads varied from 5 to 144 patients; current staffing varied from 3 to 69 full time equivalent staff. A typical adult CRT, based on median scores, comprised 21 full time staff for a caseload of 29 patients.

Eligibility criteria for adult CRTs also varied. Most teams (72%) accepted patients over the age of 18 with no upper age limit, but only a third of teams (32%) would support young people aged 16–17. This was in the context of 13% of adult CRTs reporting that there was a local children and young people's CRT which operated 24 h a day, and 6% of adult CRTs with a local older adults' CRT operating 24 h a day. Half of adult CRTs (50%) reported that they would accept patients with comorbid learning difficulties, and only a minority (17%) supported people with dementia. Referrals from GPs were accepted by 80% of teams; self-referrals were accepted by two-thirds of teams (69%) if the patient was already known to services, but by fewer than half (43%) if the person was not previously known.

Most teams (93%) provided a 24 h telephone response, but just over two-thirds (69%) operated a full 24 h service, including capacity to make home visits. Half of adult CRTs (50%) reported that they always assessed patients in person before hospital admission was arranged, but only 19% of teams reported always attending Mental Health Act assessments, which precede compulsory hospital admissions. Eighty-six per cent of adult CRTs set a target response time for starting an assessment, having accepted a referral for a patient in crisis, but these targets varied from 1 h to 1 week. In 45% of teams, this target response time was 4 h or less.

Staffing and access: children and young people's and older adult CRTs

While nurses were represented in all teams, only a minority of children and young people's CRTs (46%) and older adult CRTs (38%) included medical staffing. Occupational therapists were included in a majority of older adult teams (55%), and social workers in a majority of children and young people's teams (61%). For children and young people's teams, current caseload size ranged from 3 to 49 patients, and 59% of teams met a minimum staffing level benchmark of 14 full time equivalent staff for a caseload of 30 patients. For older adults, current caseloads ranged from 8 to 226 patients; 59% of these teams also met the minimum staffing level.

All but two of the children and young people's CRTs accepted all ages up to 18 years the other two had lower limits of 11 and 12 years, respectively. Of the 30 older adult teams included in the survey, 11 were exclusively for people with dementia, while the other 19 also accepted older adults with mental illness. Compared with adult CRTs, fewer CRTs for older adults (30%) and for children and young people (46%) offered a full 24 h service, including capacity to provide home visits. While most teams would accept direct referrals from GPs (69% of children and young people's teams; 76% of older adult teams), fewer than half would accept any referrals directly from patients or their families (46% for people already known to services in children and young people's CRTs; 45% in older adult CRTs). Target response times for starting an assessment following a new referral were very varied, as in adult CRTs: the response time target was 4 h or less for 64% of children and young people's teams which set a target, and for 33% of older adult teams. Only about a third of older adult and children and young people's teams (31% for each) reported always assessing patients in person before hospital admission.

Philosophy of care and staff training

Forty-four per cent of adult CRTs and 52% of older adult CRTs reported having any philosophy of care or theoretical model which underpinned their service, with the recovery model being by far the most common response in each case. Only three of 13 children and young people's CRTs reported any underpinning philosophy or model – either a 'psychosocial' model or a dialectical behaviour therapy approach. Fewer than half of CRTs for adults (41%), older adults (28%), or children and young people (31%) reported providing any CRT-specific training for the whole staff team.

Discussion

The survey findings show that current implementation of the CRT model is highly variable. Almost no adult CRTs adhere fully to the model recommended in policy guidance. This is consistent with the findings from previous surveys.⁸⁻⁹ Adult CRTs appear to have become more accessible since 2012. The finding that fewer adult CRTs met recommended staffing levels in 2016 compared with 2012 should be treated with caution: it may be an artefact of a better response rate to the relevant questions in the 2016 survey, and may also reflect the proliferation of separate crisis assessment services, which, where present, reduce the workload for CRTs in responding to new referrals.

While adult CRTs remain almost universal in England, CRTs for children and for older adults are comparatively rare. The teams which do exist may serve larger geographical areas than adult CRTs, but in most areas of England, neither children nor adults with dementia can access crisis support from a specialist CRT team. Children's and older adult CRTs are typically less well staffed and less likely to be organised to provide easy-access, 24 h intensive home treatment, compared to adult CRTs.

Strengths and limitations

The very high response rate provides confidence that this survey is representative of CRTs in England. As a self-report questionnaire, it is vulnerable to social desirability bias and to the possibility that respondents do not all interpret questions in the same way. It provides only a cross-sectional snapshot of CRT implementation at one moment in late 2016, although the comparison with results from a similar survey in 2012 allow some assessment of changes over time. Our survey did not ask about the types of intervention provided by CRTs.

Implications for research

Four priorities for future research can be identified from this service evaluation. First, there is a need to evaluate mental health crisis care systems, not just individual service models. *Table 3* showed that CRTs are operating in extremely variable acute service contexts; these contexts – both the configuration of crisis services and the continuity of care among them – are likely to influence outcomes for CRT patients and the overall effectiveness and costs of acute care. The separation of crisis assessment and home treatment teams in many areas represents a major change in acute care in England, which appears to have occurred in response to perceived local need rather than policy guidance or supporting research evidence. We lack evidence about optimal acute service system models. Second, a systematic review¹⁸ has highlighted the lack of high-quality evidence regarding older adult CRTs, and evidence is equally lacking for effective models of crisis care for younger people. It is unclear whether an adult CRT model is also appropriate for these client groups, or how the model should differ: specification and evaluation of CRT service models for children and older adults is required. Third, our survey suggests that CRTs may be improving access to care without increased staffing resources. This may be occurring in the context of increased demand for CRT services and reduced budgets.¹⁹ The effects of absorbing these pressures on the quality of care delivered to CRT patients are unknown. The need to understand the relationships between CRT resources, service organisation and access, and the quality of care provided to patients is therefore of high importance. A recently developed fidelity measure for CRTs²⁰ offers a means to assess the organisation and delivery of care in CRT services rigorously and reliably, which could help to address this need. Fourth, the lack of adherence to best practice recommendations in adult CRTs indicates a need to develop resources to

support CRTs in achieving high model fidelity and service quality. A current nationally funded study²¹ is evaluating a service improvement programme for CRTs in a cluster randomised trial, which, if effective, should help to address this need.

Implications for practice

A generalisable implication of this service evaluation is that a policy mandate and guidelines are insufficient to achieve complete and consistent implementation of a desired service model. Active monitoring and support has been shown to be essential for the successful implementation of complex interventions in mental health in international contexts.²² Clear specification of desired service standards for CRTs, with audit and service improvement support to identify and address difficulties with implementation, is required for CRTs at local and national levels. For example, there is a huge difference for someone in a mental health crisis between waiting an hour for CRT support and waiting a week – yet this is the range of local response time targets reported by CRTs. This survey provides benchmarking data, which can inform the setting of feasible national standards for CRTs and assessment of future changes in CRT implementation. The apparent recent improvements in the accessibility of CRTs suggested by our survey may indicate that recent national policy campaigns in England to achieve better access to mental health crisis care¹⁵⁻²³ have had some positive effect. Notwithstanding the need for more research evidence about effective service models, the current ‘postcode lottery’ found by our survey regarding the availability of specialist crisis services for children and older adults indicates a need for action from policy makers and service planners to ensure appropriate services are provided in all areas for these vulnerable groups at times of crisis.

I am a big fan of short books and, at around 100 pages, this is a remarkably short book. The authors outline the debate between autonomy and paternalism, and also aim to demonstrate where philosophy can be useful to psychiatry and medicine. The book succeeds in both areas, although in places it could have benefited from further elaboration and exposition.

Part 1 summarises the arguments for personal autonomy, defined as ‘acting on one’s own reasons, not on those of other people’. The authors outline why this is valued as a good in its own right, only to be interfered in with significant moral justification. Paternalism is shown generally to act to undermine individual autonomy (although it can be justified e.g. for public health). Medicine is defined ‘not as a science but an interpretive practice relying on clinical reasoning’.

The patient–doctor consultation is rightly situated as the ‘central act of medicine’. The way people make decisions is considered: not as isolated units but in dialogue with their significant others.

The best section is on Miranda Fricker’s concept of epistemic injustice. Fricker has highlighted two types of injustice: testimonial and hermeneutical. Testimonial injustice refers to a speaker being awarded less credibility owing to prejudice on the listener’s part, e.g. a woman speaking in a male-dominated boardroom. Psychiatric patients are particularly susceptible to this *credibility deficit*. The authors cite Elyn Saks’s account of attending the accident and emergency department with a brain haemorrhage. When doctors heard of her history of schizophrenia, they stopped diagnostic investigations and sent her home. Hermeneutic injustice occurs when an individual/group does not have access to, or is not represented within, the shared generation of meaning. Here the injustice is often to the subject who questions the credibility of their own testimony. An example is a depressed new mother trying to make sense of her feelings without any knowledge of postnatal depression.

Part 2 addresses specific problems: mental health legislation, do-not-resuscitate orders, and assisted dying. These are condensed and well-written, but there is nothing new for anyone working clinically in these specialties.

Overall, this is a clear and concise introductory work useful for anyone interested in this area.

Aims and method

Following the introduction of new standards for early intervention in psychosis (EIP) in England, EIP services are accepting referrals for people aged 35–65. The Cambridgeshire and Peterborough EIP service (CAMEO) aimed to explore the immediate implications for the service, especially with regards to referral numbers and sources. Data were collected from April 2016 to June 2017.

Results

Referrals for over-35s represented 25.7% of all new referrals. Fifty per cent of referrals for over-35s were accepted onto caseload (40.2% for under-35s). The over-35s were more likely to be referred from acute and secondary mental health services ($P < 0.01$) and had longer durations of untreated psychosis than the under-35s ($P = 0.02$).

Clinical implications

CAMEO has received a significantly higher number of referrals as a result of age inclusivity, with an increased proportion of patients suffering from severe, acute psychotic presentations and existing mental health difficulties. This has implications for service planning.

Declaration of interest

None.

 - *Discussion*

In April 2016, a new Access and Waiting Time Standard for early intervention in psychosis (EIP) services in England¹ came in to force. At least half of all referrals to EIP services should have access to and commence a National Institute for Health and Care Excellence (NICE)-concordant package of care for psychosis within 2 weeks of referral. Although EIP services had promoted easy access and prompt responses to new referrals since their inception, the new policy offered detail on how to achieve and report the Standard. In addition, the policy, in accordance with NICE recommendations,² provided information about the need to expand current care provision in order to treat those individuals that might be at risk of developing psychosis, and to ensure prompt access and treatment for people with a first-episode psychosis regardless of their age. The effect of age inclusivity on the *modus operandi* of previously youth-oriented services was unknown. In fact, those EIP services that adhered to the new policy in full entered an uncharted territory that, inevitably,

would require cultural and structural changes. However, the magnitude of these changes was unclear and not fully informed by previous evidence. For instance, the paucity of studies on the administrative incidence of first-episode psychosis in people aged over 35 assessed in early intervention settings^{3–5} complicated new workload calculations and commissioning decisions.

The CAMEO EIP service in the Cambridgeshire and Peterborough NHS Foundation Trust (<http://www.cameo.nhs.uk>) decided to conduct a service evaluation to determine the initial effects of this policy change and assess how well it was achieving its intended aims with this population. In the first instance, CAMEO managers and clinicians were particularly keen to explore the immediate implications for the clinical service, especially with regards to referral numbers and sources for individuals aged over 35 with a suspected first-episode psychosis. This would help generate meaningful information that could drive local decision-making.

Method

Setting and data collection

CAMEO is an EIP service that offers management for people aged 14–65 years suffering from first-episode psychosis across Cambridgeshire and Peterborough, UK. CAMEO serves a very diverse population of around 870 000, from the international scientific community in Cambridge city and multicultural population of Peterborough to a large rural base in the Fens.⁶ Referrals of suspected psychosis are accepted from multiple sources, including general practitioners, other mental health services, the third sector, school and college counsellors, relatives and self-referrals.^{7,8} CAMEO started accepting referrals of people aged over 35 from 1 April 2016.

Data on referral numbers and sources for people aged over 35 were collected over 15 months, from 1 April 2016 to 30 June 2017. Additional personal information was de-identified and did not contain sensitive details. It included data available from the Cambridgeshire and Peterborough NHS Foundation Trust electronic clinical records, such as demographic information (age, gender, ethnicity and marital status) for all referrals, and duration of untreated psychosis (DUP) and working diagnosis (usually based on the clinical judgement of two senior clinicians, including a senior consultant psychiatrist, and discussions at multidisciplinary team meetings) for those referrals accepted onto the CAMEO case-load. For comparative purposes, we also collected some information for under-35s referred to our service during the same period. This included referral numbers and sources, age, gender and DUP for those accepted to case-load.

Data analysis and publication followed the guidelines established by the *Anonymisation Standard for Publishing Health and Social Care Data*.⁹ Raw data were not shared with any third party.

Statistical analysis

All analyses were performed using version 20 of SPSS (SPSS, Inc., Chicago, Illinois). Comparisons were made using the χ^2 test for categorical variables and *t*-test or Mann–Whitney U-test for continuous variables. A *P*-value of less than 0.05 represented a significant difference.

Results

Referral numbers and characteristics

One hundred and sixty-two referrals for individuals over 35 were received during the 15-month evaluation period; 458 referrals were recorded for people under 35. Thus, referrals for over 35s represented 25.7% of all referrals.

50% of referrals for patients over 35 were accepted onto the CAMEO case-load ($n = 81$). Based on the population aged 35–65 in Cambridgeshire and Peterborough,¹⁰ this represented an administrative incidence of approximately 25 per 100 k per year for this group. Notably, a lower proportion of the total number of referrals for individuals aged under 35 were accepted onto case-load (40.2%) (*Fig. 1*). *Fig. 1* Flow chart for referrals received by CAMEO from April 2016 to June 2017.

Of the referrals for over-35s, 21.7% ($n = 35$) were not assessed and 28.3% ($n = 46$) were assessed but not accepted onto case-load. Reasons for those over 35 referred but not assessed or taken onto CAMEO were: (a) absence of psychotic symptoms and/or diagnosis of non-psychotic disorder, usually anxiety disorders, after assessment ($n = 55$); (b) evidence of a first-episode psychosis in the past ($n = 12$); and (c) psychotic symptoms in the context of neurodegenerative disorders, i.e. dementia ($n = 3$). The rest were not taken onto case-load for a variety of reasons, such as change of residence to outside CAMEO's catchment area, disengagement during the assessment period or cancellation of referral.

The mean age for all referrals for this group was 47.66 (s.d. = 8.44, range = 36–66.5 years). Fifty-one per cent of referrals for over-35s were female *v.* 38% for under-35s ($\chi^2(4) = 420.55, P < 0.01$). Forty-four (54.3%) out of the 81 referrals for over-35s finally accepted onto case-load were women.

Approximately one-third of over-35s referred to CAMEO were married or cohabiting, 16.3% were divorced or separated, and 34.7% were single (15.6% not known/recorded). The majority (60.5%) considered themselves White British (the remainder were White other (11.1%), Asian British (1.2%), Asian other (6.8%), African–Caribbean British (1.2%), African–Caribbean other (2.5%), other (3.1%) and not known/recorded (13.6%)).

Referral sources

A higher proportion of referrals for over-35s were received from acute (acute psychiatric wards and crisis resolution home treatment teams) and secondary (community mental health teams) mental health services in comparison with under-35s, who were referred from primary care more often. Differences in referral sources between the two groups were statistically significant ($\chi^2(5) = 27.84, P < 0.01$). Also, self-referrals from over-35s were less common (2 *v.* 39 individuals) (Fig. 2). Notably, 45.9% of all over-35s referred to our service had a confirmed previous history of mental health problems. Fig. 2 Percentage of referrals for over- and under-35s by referral source.

Duration of untreated psychosis

DUP for over-35s accepted onto case-load ranged from 2 days to 20 years (median 2.6 months, mean = 1.88 years; s.d. = 4.32; $n = 68$, 13 not known). Five patients had a DUP of more than 10 years, and another six of more than 3.5 years. Under-35s had a mean DUP of 8.5 months (s.d. = 1.76 years, median = 1 month, range 1 day to 12 years; $n = 157$, 27 not known). The difference in DUP between under- and over-35s was statistically significant ($u = 3129.5, P = 0.02$).

DUP was longer than 3 years for 13.5% of patients over 35 accepted onto case-load ($n = 11$), compared with 3.8% for patients aged under 35 ($n = 7$).

Working diagnosis

Working diagnoses for the over-35s accepted onto case-load were as follows: unspecified nonorganic psychosis (22.2%, $n = 18$), psychotic depression (16.0%, $n = 13$), delusional disorder (14.8%, $n = 12$), bipolar disorder (12.3%, $n = 10$), schizophrenia (11.1%, $n = 9$) and acute and transient psychotic disorder (8.6%, $n = 7$), with a further 6.2% ($n = 5$) having other diagnoses, including schizoaffective disorder and drug-induced psychosis, and 8.6% ($n = 7$) not known/recorded. Differences in diagnoses by gender were statistically significant ($\chi^2(7) = 14.30, P = 0.05$); women were more likely to suffer from affective psychoses, such as psychotic depression.

Discussion

Our findings contribute to a sparse research landscape looking into the administrative incidence of first-episode psychosis in people aged over 35 assessed in EIP settings. What little is so far known has been gathered from services already offering a broader EIP service in predominantly urban areas prior to 2016.³⁻⁵ By collecting data after the introduction of the new Access and Waiting Time Standard,¹ we were able to evaluate the effects of these changes in existing EIP services, such as CAMEO, and anticipate further challenges and opportunities.

Following the changes to our service, almost 26% of new referrals were for patients over 35 years old. This confirms previous evaluations in early-adopter services, which suggested that patients over the age of 35 would make up a significant proportion of referrals, ranging from 25 to 33%.³⁻⁵ A higher proportion of patients over the age of 35 were referred from secondary and acute care in comparison with those aged under 35; the over-35s were more likely to have existing mental health issues.

Since referral processes may differ across EIP services, data from early-adopter services are difficult to compare with ours; however, they also suggested relatively few referrals from primary care for this older group. This might reflect lack of awareness in the wider health system, but, for some patients, it may well be related to psychosis developing as a secondary feature of depression and other conditions for which they had already received some support.¹¹ Interestingly, 50% of referrals for over-35s were taken on by our early intervention service, whereas only 40.2% of referrals for under-35s were accepted to case-load. This would also support the idea of those aged over 35 suffering from a longer history and higher burden of mental health issues.

Previous studies suggested a different distribution of diagnoses for older *v.* younger patients, with an increased proportion of primarily affective psychoses in over-35s.³⁻⁴ Our results reaffirm these findings, with 16% of over-35s suffering from psychotic depression. The proportion of our patients aged over 35 with non-affective psychosis, approximately 55–60%, is similar to that found by previous evaluations and lower than would be expected in younger patients, where non-affective psychosis is usually reported in approximately 75% of cases.⁴ This is consistent with the natural course of mood disorders, such as resistant depression, which becomes progressively more prevalent in older patients, some of whom may have suffered hypomanic episodes for which they did not seek treatment. Non-affective psychotic disorders are less likely to present for the first time over the age of 35.¹¹ Also, the higher representation of females in our over-35s sample and those of other studies may reflect a bimodal pattern of psychotic disorders in women, with an first peak at around the same age as in men (18–25 years) and a further peak, usually of an affective nature, in the 40s.¹² A willingness to treat these older female patients would support age inclusivity across EIP services.

Selvendra *et al*¹³ showed that older patients referred to their mental health service in Italy had been unwell for significantly longer than younger patients. Our results, from an EIP context, also found a statistically significant difference in DUP between over- and under-35s. This indicates the need to continue to enhance outreach approaches to detect emerging psychotic symptoms earlier,⁸ or to consider different approaches for a group of patients whose illness may have become more chronic by the time they are assessed by EIP services.

Although only three referrals were not taken on by CAMEO owing to comorbid dementia in our evaluation, other studies have shown a steady increase in transition to organic pathology in older patients. In fact, neurodegenerative diagnoses creep into the fold as the upper age limit increases above 35.¹⁴ Accordingly, follow-up studies of over-35s treated in EIP services under the new Standard¹ will be required in order to evaluate this potential clinical issue and the subsequent effects on services that are not designed to treat such conditions.

In summary, our evaluation has begun to unfold the practical challenges that the implementation of the new Access and Waiting Time Standard¹ brings to established EIP services with regards to age inclusivity. The CAMEO service received a significantly higher number of referrals as a result of this, with an increased proportion of patients suffering from severe, acute psychotic presentations and with existing mental health issues for which they had already received treatment. These patients were more likely to be referred from secondary mental health services after an acute crisis, and to have longer DUP and psychotic symptoms in the context of other conditions, such as mood disorders.

The main limitation of this evaluation pertains to the collection of data from electronic records routinely employed in clinical practice; some clinical information was missing and working diagnoses were not confirmed with structured diagnostic questionnaires. However, data on referral numbers and sources, which represented the main purpose of this work, were complete and will aid future analyses on clinical and functional outcomes after completion of the early

intervention care pathway. This should help to determine whether EIP services, as currently implemented, achieve the required standards with a group of patients whose characteristics clearly differ from those traditionally treated in what used to be exclusively youth-oriented clinical services.

We thank all members of CAMEO services for their help and support with this evaluation.

Formerly Consultant Psychiatrist, Claybury Hospital, Woodford Bridge, and Chase Farm Hospital, Enfield, UK

2018/S2056469418000244_inline1.jpg

Emanuel Moran, known to many of his Maudsley colleagues (though not to family and friends) as Gus, died on 18 August 2017, aged 89. He had become the UK's foremost authority on the psychiatric and social aspects of pathological gambling. His interest had developed during his time as a psychiatric registrar at the Maudsley. He had seen patients who had attempted suicide when they were in difficulties resulting from their gambling dependence. Over the next few years, he accumulated a series of 50 such patients and published his findings in 1970 in the *British Journal of Psychiatry*.¹ He proposed a definition of pathological gambling and put forward a tentative typology. He concluded that gambling was due to a complex interaction between personal factors and social pressures. Among the latter, he noted that the gambling urge would be triggered by new opportunities, such as the opening of a licensed betting office near the person's home or place of work.

It is striking that among the 50 subjects there were no women, a finding probably due to the limited opportunities at that time for women to indulge in serious gambling. They seldom frequented betting shops or casinos and confined themselves to bingo halls, playing that sedate game in the company of friendly neighbours. It was only in the late 1980s that fruit machines were introduced into bingo halls and there was a rapid increase in more active gambling among women. Even more pernicious was the advent of online gambling, attracting young women in particular.

A similar increase in pathological gambling occurred when regulations on gambling were relaxed. Warning signals were sounded following the 1960 Betting and Gambling Act, which had resulted in increased gambling facilities. In more recent years, Emanuel campaigned tirelessly against any further relaxation of restrictions on gambling. He was the first chairman of the Society for the Study of Gambling and insisted that no funding was received by the Society from the gambling trade. Subsequently, he founded the National Council on Gambling.

The Gambling Act, which was passed in 2005 and became effective in 2007, had as one of its stated objectives the protection of children and other vulnerable persons from being harmed or exploited by gambling. This laudable aim has been somewhat undermined by the acceptance of an elastic definition of 'responsible gambling'. From 1974 to 2010, Emanuel was the specialist adviser on gambling to the Royal College of Psychiatrists. Under his guidance, the College submitted crucial advice on restricting the more harmful 'remote gambling' (including mobile phones and the internet). He recognised that the regulation of online companies was only possible when these were based in Britain, but, in fact, most internet companies promoting gambling are now based abroad. Towards the end of his life, Emanuel felt that his efforts to reduce the dangers of gambling had been of no avail, a source of considerable distress to him. Yet his efforts had been determined and valiant.

Emanuel was born in Charlottenberg, Berlin, in 1928. His parents originally came from Kiev. His father, a Baptist minister, moved to Berlin to run a Christian mission. Emanuel was evacuated to England on his 10th birthday, where he was quite alone and knew no English, yet he pursued his schooling with ease. His parents and two younger siblings joined him in London a few months later. His further education took him to Fitzwilliam College, Cambridge, and Guy's Hospital to study medicine. After a period in neurology at the Whittington Hospital, he trained in psychiatry at the Maudsley Hospital under the influence of the formidable Professor Aubrey Lewis. From 1966 to 1980, he was a psychiatrist for Gamblers Anonymous. Through his work, gambling came to be recognised as an addictive disorder. His definition of gambling disorder was adopted by the World Health Organization. Throughout the 1970s, he worked closely with the Home Office. He advised Parliament through the Royal Commission chaired by Lord Rothschild, opposing the deregulation of gambling laws.

Emanuel was an extremely kind and considerate colleague. As a junior consultant, I had admitted a not-so-young lady who became depressed when her engagement to marry was broken. She disappeared from the ward and, justifiably, I feared the worst. The Thames River Police asked me to identify the body. Witnessing my dismay, Emanuel offered to accompany me to the mortuary, an offer I gladly accepted.

In 1965, he was appointed Consultant Psychiatrist to Claybury Hospital, Woodford Bridge, and Chase Farm Hospital, Enfield, where he worked for almost 30 years. He was clinically responsible for one of the busiest general adult sectors in north London, a role which consumed a great deal of his time and energy

In the early 1970s Emanuel began to suffer from severe ill-health, and in 1974 his wife was told that he had only weeks to live because of a bladder cancer. He survived for another 40 years, for which he felt indebted to two urosurgeons, but his illness greatly affected his subsequent quality of life. He took delight in his family. Jane was his wife for 51 years. His elder son, Paul, became a psychiatrist, and his younger son David was active in education. He leaves five grandchildren.

2018-8

Contents

- *Profile: David O'Flynn*

Julia Bland meets Dr David O'Flynn, the insider of 'outsider' art, Chair of The Adamson Collection Trust and Consultant Rehabilitation Psychiatrist in Lambeth.

Dr O'Flynn contains within himself some of the contradictions of 'outsider' art. On first meeting, I unthinkingly proffered my right hand to shake his right hand, and then kicked myself as he offered his left hand: he has a right-sided hemiplegia. I don't think he was remotely bothered by the momentary awkwardness. From the beginning he exudes a joyous, almost boyish, enthusiasm; both for the works of The Adamson Collection and for his work on the Tony Hillis Unit, a 15-bed locked ward in Lambeth Hospital for men with chronic psychosis, behavioural problems and addictions. His sparky nature seems paradoxically linked to a very unfunny situation. Living with a terminal illness for much of his 30s, he has developed a sense of proportion about what really matters: 'I shouldn't really be here it's all extra'.

He enthuses about his work with intractable, sometimes violent, patients with psychosis, many of which have substance misuse problems in the mix. The atmosphere on the ward is calm and the patients are friendly, albeit with intense psychopharmacological treatment. They have an inside gym, an outside area and art sessions on the ward. 'It's really a therapeutic community, exactly what I always wanted.' The mean length of stay is 15 months. He remembers learning a slow, thoughtful approach to crisis on the ward from a consultant when he was a trainee. There had been a fight between five patients and 'he taught me to go slowly, considering each patient, one by one.'

How did Dr O'Flynn get involved with The Adamson Collection?

He continued working in the emerging field of rehabilitation psychiatry, in spite of his poor health, and went to a psychiatric conference in Delphi where – by chance – he met a trustee of The Adamson Collection. O'Flynn was subsequently co-opted onto the committee that was planning Edward Adamson's legacy. Through this work, he became a personal friend of Adamson's surviving partner, John Timlin.

What is The Adamson Collection?1

Edward Adamson (1911–1996) was an artist who was employed at Netherne Hospital to run an art facility for the patients from 1946 until his retirement in 1981. Before he started, some psychiatrists had set up the art studio as a kind of experimental laboratory, for example to compare a patient's work pre- and post-lobotomy.

Adamson had a very different approach. He created a calm place, with classical music in the background, where patients could produce whatever they liked and there was no interpretation. He believed that making illustrations of any kind had a healing effect. As Anthony Stephens the Jungian analyst wrote: 'Adamson enabled them to formulate the meaning of their predicament; and by mobilising the creative resources latent within their own personalities, he assisted them to heal themselves.'

He even managed to arrange separate spaces for patients who couldn't tolerate the studio with other people. He also enacted respect for each patient by providing a chair, an easel and a small table for paints and brushes so that each person

had a distinct individual space within the room. This was in contrast to the uniformity of the institutional regime: beds lined up in a ward with no privacy.

Adamson was a trained artist and not a therapist; although he was influenced by Jungian ideas, regularly visiting the Jungian art therapy community Withymead in Oxfordshire. He had been a conscientious objector during the war and trained as a chiropodist. He established the British Association of Art Therapists in 1964, as well as the first art therapy training programme in 1969.

Particularly remarkable artists in The Adamson Collection (see below) include J. J. Beegan, who poignantly drew on lavatory paper with burnt matchsticks, and Mary Bishop, who expressed her utter despair and frustration with psychiatrists in paintings such as *Cri du Couer* and *Sadist in a White Coat*. Other notable workers in Adamson's studio include William Kurelek, a Canadian of Ukrainian origin who went on to be a successful, recognised artist later in his life. Rosanda Polonska spent 35 years in Netherne, producing drawings, poetry and sculpture, including the *Stations of the Cross* which were put up in the Netherne Hospital chapel. In 1982 she left hospital to live with her sister in Paris. Gwyneth Rowlands was completely original, making painted sculptures out of flints and pebbles she found. Some of these are permanently on display in Lambeth Hospital. Other Rowlands flints, pottery and other sculptural works are kept in The Adamson Collection Trust at the Bethlem Royal Hospital, and another 6 are in the Reading Room of the Wellcome Collection. Fig. 1 *Key Centres* by Martin Birch, date currently unknown. Pencil on paper. Courtesy of the Adamson Collection/Wellcome Library.

The thousands of works produced at Netherne underwent complicated selection processes. Adamson himself organised a group exhibition as early as 1947; and in 1956, 500 works were chosen by Adamson for the gallery he had established at Netherne. After he retired this became a physiotherapy room.

In 1981 Adamson and Rudolph Freudenberg selected several thousand works for storage and display at the entomologist Miriam Rothschild's Ashton Wold estate in Northamptonshire. When they later returned to Netherne, the rest of the works had disappeared.

In 1997 the whole collection was moved to Lambeth Hospital, which didn't have an adequate storage facility, and pieces were stored on open shelves and even in a disused shower cubicle! Fig. 2 *Graffiti on Lavatory Paper 2: 3 Lions* (detail) by J. J. Beegan, c. 1946. Match char on Izal medicated toilet paper. Courtesy of the Adamson Collection/Wellcome Library.

Finally, the works on paper were accepted into the Wellcome Library in 2013, where they are now stored and curated.

In what ways does David O'Flynn think art therapies help? Is it an expression of distress and frustration without violence, respect for the production process or do the boundaries of the therapeutic group make it a safe place? Is it a validation of experience? Is it that the act of concentrating on producing an external concrete object, e.g. a painting, relieves the mind of tormenting internal preoccupations, allows distancing and an objectification of thoughts and feelings and thus provides a positive relief? Could engagement with the medium in a quiet place, with a soothing but non-judgemental parental presence, perhaps allow some reworking or reawakening of childhood playfulness?

In 1996 the Hayward Gallery exhibited 'psychotic art' from the German Prinzhorn Collection; the art consisted of poignant pieces by long-term institutionalised patients.² Like The Adamson Collection, there are recurrent themes of fear, disintegration, fragmentation, feeling observed (multiple eyes), loss of control/being controlled (e.g. rays, pursuing objects, etc.), magical creatures and variable and multiple perspectives. The artworks feel like attempts at mastery of internal chaos. Fig. 3 *The Sadist in the White Coat* by Mary Bishop, date currently unknown, probably late 1950s. Poster paint on paper. Courtesy of the Adamson Collection/Wellcome Library.

The past decade has brought a newer phenomenon of 'community arts': public arts associated with well-being that include drama as well as painting. This phenomenon seems to be targeted at a different patient group, i.e. people that are managing in the community, rather than the long-stay asylum population that Adamson was catering for.

David O'Flynn seems like an ideal fit for The Adamson Collection: interested in art, he used to escape the claustrophobic suburb as a child to look at pictures. When he was at school at Westminster, he often dropped into the Institute of Contemporary Arts, where he spotted his first punk. He lives with his husband in a not-yet-gentrified part of West London in a house full of reggae. He describes the area as 'a real mix ... there are old ladies who still go to the shops in slippers and a dressing gown ...'

He was brought up in respectable Blackheath, the son of a dedicated surgeon at Guy's Hospital. His brother is also a psychiatrist and is married with children. The young David was sent to Dulwich Preparatory School and then went on to Westminster from 1974–1978, an institution he appreciates for giving him 'confidence without arrogance'. And for a final irony, long before he was aware of Adamson, he had a Jungian analysis with someone who was also an art therapist. Fig. 4 and 5 *Self-portrait: Skull Head* by Gwyneth Rowlands, date currently unknown. Vault and underside. Indian ink, watercolour and varnish on flint. Courtesy of the Adamson Collection Trust.

Abandoned Goods is a film that has been made about The Adamson Collection. It powerfully illustrates how the meaning of the works is radically altered by their location. Probably the most extreme example of this is how the work of J. J. Beegan, on lavatory paper, came to be the centre of an exhibition in Paris while on loan from the Wellcome Collection.

Within the film there is a marvellous vignette of a conversation between two (male) psychiatrists. First psychiatrist: 'We haven't got a clue why they get ill, why they get better or what causes them to relapse.' Second psychiatrist: 'So we don't know anything about ourselves?' First psychiatrist: 'Yes that's probably true.'

I think that the works of The Adamson Collection challenge us as contemporary psychiatrists. When Adamson was working at Netherne, many patients were there for 30 years or more. They were subjected to physical restraint, overcrowding and neglect in many cases. Adamson's work was about respecting the individual as the author of the meaning of their experience.

Modern psychiatrists try to respect each individual but we have created the organisation of mental healthcare in such a fragmented fashion: the patient moves from team to team and sees different mental health professionals each time. We risk losing sight of the importance of the long-term, one-to-one relationship where patients feel respected rather than pushed from pillar to post.

Interestingly Dr O'Flynn's approach in the Tony Hillis Unit does allow time for each patient to be treated as an individual. So who better to be Chair of The Adamson Collection?

Julia Bland is an honorary consultant psychiatrist for South London and Maudsley National Health Service Foundation Trust and a consultant medical psychotherapist at DocHealth, British Medical Association, UK. Email: julia.bland@hotmail.co.uk

1.5.66 Peter Sykes MB, ChB, FRCPsych, DPM

Emma Savin

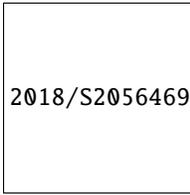

date

2018-8

Contents

- *Peter Sykes MB, ChB, FRCPsych, DPM*

Formerly Consultant Psychiatrist, Greaves Hall Hospital, Banks, Southport, UK.

Peter Sykes, who died aged 86 in March 2017, was a pioneer in the field of the psychiatry of learning disorders. After postgraduate training, he held consultant posts in the north of England and in Scotland. He then spent 2 years in Canada from 1969 to 1971, where he was appointed Director of Mental Health Services for the Province of New Brunswick. He carried out a complete reorganisation of the mental health and mental subnormality services. The new service was based on community involvement and divisional responsibility. Throughout his working life, he championed a person-orientated approach to the care of patients with severe mental health problems and learning difficulties, moving away from the ‘asylum’ principle of care towards a more integrated, community-based approach that still recognised the important role of residential units.

On returning to England, he took up a post in Peterborough and Cambridge, where he again set up services in a general hospital unit rather than the then traditional model based on subnormality hospitals. On appointment to the Greaves Hall Hospital, Southport, in 1973, he provided a model for community-based services that was influential both locally and nationally. He was widely involved in the planning and design of new hospitals in the north of England and Scotland, always working in close association with the charity MIND.

Throughout his career, he carried out a considerable amount of forensic work. He also lectured widely, having, at various times, honorary lecturer appointments at the Universities of Liverpool and Aberdeen.

At the end of his clinical training in the Medical School of the University of Sheffield, he was the prize medallist in both clinical medicine and surgery. After psychiatric training, he was appointed to his first consultant post at the age of 29, being at that time the youngest doctor in England to be appointed as a consultant.

Peter saw medicine as an art rather than a science and had an open mind about new approaches to psychiatric care. Colleagues would often refer their complex patients to him, and he would use new techniques such as hypnotism to bring about dramatic improvements.

Always a practical man, as well as a plain-speaking Yorkshireman, Peter loved to find out how things worked and would spend hours tinkering with his old Morris Minor. His approach to these endeavours is best summed up by his motto ‘when all else fails, read the instructions’. As an example of his practical skill, while working in Scotland he devised a means of stopping bulls from falling over (a catastrophic event) and shared his technique with the local farmers.

He leaves his wife Jean, four daughters, seven grandchildren and five great-grandchildren.

According to Dr Lee personality disorder is ‘not your fault’ and is a treatable ‘disorder’ for individuals that are both able and willing to become involved with available therapeutic programmes. This book immediately highlights the importance of responsibility, not only on the part of clinical staff, but also for the person engaging with services, and as someone who has lived with the diagnosis of borderline personality disorder for many years, I was pleased to find that a key theme was one of empowerment.

The format and content allows a wide reach in terms of audience, being accessible to both clinicians and those with lived experience, their families and others with whom they may come into contact. The author utilises well the fictional character Nina to portray real-life examples, while not apportioning blame, nor attributing her difficulties to one particular aspect of her life. Although the focus is mainly on borderline personality disorder, the use of case examples in a chapter dedicated to other personality disorders gives an excellent insight into how these may present. Indeed, within this, is also the notion of the enduring and pervasive nature of personality disorder, how it affects lives, and the ability to question whether a label is indeed always helpful or necessary.

Lee uses the term ‘personality configurations’ to describe individual differences and how carers may adapt to a role which enables the individual. The label of personality disorder is often perceived as stigmatising and, therefore, reframing how this is presented to others can be significant in accepting both the diagnosis and how to manage it. Overall, he attempts to reduce stigma and the feeling of being stigmatised, while retaining an honest approach to how negative perceptions can influence relationships of all levels. This notion of relationships is also addressed, being key to personality disorder and to therapeutic alliance.

The information on the differences between borderline personality disorder and other psychiatric diagnoses may help to dispel some myths. For example, Lee suggests that clinical depression and depressive symptoms of borderline personality disorder are not the same. Although this comes across as a medicalised view, it fits well with my personal experience where unnecessary pharmacological treatment pathways were the only option given, rather than an effective therapeutic management of negative emotion.

The chapter on treatments provides a comprehensive overview of evidence-based therapies for borderline personality disorder and indirectly highlights the paucity of evidence-based options for other personality disorder classifications. From the range of treatment options available, albeit limited, the information given is easy to digest, providing key concepts and a tabulated summary of areas such as goals and the all-important patient-therapist relationship.

At one point Lee outlines the role of choice in finding a treatment programme and therapist. In an ideal world, the choice of therapist can be an essential aspect of engagement in services but in reality this is not always the case – this is perhaps an area towards which health care services can move their focus.

I would have welcomed discussion around the role of gender in personality disorder, in relation to both diagnosis and treatment outcomes, as well as a more explicit and detailed examination around the role of emotion (and how this underlies relationships and day-to-day or even minute-to-minute interactions). Although this idea is present in the examples used, further elaboration may be helpful.

For me, the book summarises a positive approach to understanding and helping individuals with personality disorder without leaving the reader feeling helpless; this is achieved not by changing who we are but, as the author suggests, by building on the positive qualities we already have. I liked the idea that the final chapters provide an ending, not just for Nina but for the reader.

Taking a collaborative approach to treatment goals and enabling individuals to have a sense of agency in their passage to self-discovery is an essential aspect of the book – and a way of working that I found to be imperative to discovering a way through what for me was a confusing, frustrating and distressing journey.

date

2018-8

Abstract

Aims and method

The clinical utility of the multidimensional Framework for Routine Outcome Measurement in Liaison Psychiatry (FROM-LP) has not previously been examined. We sought to establish whether referral accuracy and ability to achieve the reason(s) for referral to our liaison service improved after incorporating the Identify and Rate the Aim of the Contact (IRAC) scale of this tool into our referral process. We carried out a retrospective analysis of electronic case notes of all appropriate referrals to the team before and after this adaption.

Results

Accuracy of referrals to our team improved from 73.8 to 93.7% following intervention. Referral requests that were fully achieved improved from 57.4 to 77.8%, and referral requests that were not achieved decreased from 26.2 to 6.4%.

Clinical implications

The IRAC component of the FROM-LP measures what it was developed for, and thus has clinical utility supporting its widespread adoption across liaison services in the National Health Service.

Declaration of interest

None.

* *Conclusion*

The value and cost-effectiveness of an adequately funded and organised mental health liaison team (MHLT) have been demonstrated and promoted in national policy documents and economic analyses over the past 5 years.¹⁻⁴ Although the economic benefits of a MHLT have been established, there is a lack of evidence relating to clinical (and other) outcomes.⁵ Measurement of clinical outcomes is essential for clinical teams to evaluate their work and enable ongoing service development. A Centre for Mental Health (CMH) report highlighted the challenges associated with measurement of outcome across MHLTs, which are operating in a number of different settings and carrying out a wide range of clinical activities in support of patients with many different types of clinical problems.⁵ A systematic review on the effectiveness of liaison psychiatry found that many studies had disparate results and were methodologically flawed.⁶ The CMH report proposed the use of a framework for measurements based on a logic model approach which took into account structure (inputs), process (activities) and outcomes (outputs) and suggested using a combination from each, 'the so-called Scorecard approach'.⁵

Development of the FROM-LP

In response to these recommendations, in 2015 the Faculty of Liaison Psychiatry of the Royal College of Psychiatrists produced the Framework for Routine Outcome Measurements in Liaison Psychiatry (FROM-LP).⁷ The authors, after further describing its development, proposed that it was adopted across all MHLT's in the National Health service (NHS).⁸ Their aim was to enable consistency of data collection and effective reporting of outcomes such that patients, referrers, the NHS Trust providing the service and commissioners could all understand and have confidence in the beneficial effects of their MHLT. The authors acknowledged that rolling out this tool quickly across MHLT's nationwide meant that it was potentially an imperfect tool; however, they recognised that it could be refined over time.⁷

Implementation of the FROM-LP

Until recently, our MHLT had been measuring a number of outcomes; however, these were not based on national guidelines and therefore could not be directly compared with other MHLTs across the NHS. In addition, our in-patient team were assessing patients and finding that the reason for referral documented on the e-referral form was not always accurate. In April 2017, we adapted our routine data collection to include the FROM-LP outcome measurements. As shown in *Table 1*, there are three broad outcome categories. For the purposes of this evaluation, we focused on the *Process* section, which includes the 'Identify and Rate the Aim of the Contact' (IRAC) scale, comprising ten aims of contact (*Table 1*). We replaced the four referral options on the e-referral form with the ten IRAC categories (*Table 2*) and then evaluated whether this: (a) improved the *accuracy* of reason for referral to our service (b) in turn, improved our *ability* to fully achieve those reasons for referral, i.e. with this analysis could we determine the construct validity and thus the clinical utility of this component of the FROM-LP? *Table 1* Framework for Routine Outcome Measurement in Liaison Psychiatry (FROM-LP) content. Method

Our MHLT is adult ageless and is based in a large 800-bed teaching hospital in Bristol. It is composed of doctors, nurses and social workers, and is split into an emergency department team and an in-patient team. This paper focuses on the in-patient, which received an average of 106 referrals per month during the period October 2016 to September 2017, often involving a series of patient contacts. The referrer has to complete an e-referral form which consists of a drop-down menu and free-text boxes. Once the referral form has been accepted and opened by administrative staff, it is then triaged by the shift coordinator. The clinical information provided by the referrer enables the shift coordinator to determine the urgency of the referral, and can also help facilitate decisions such as which member of staff might be most appropriate to see the patient.

The e-referral form includes a 'reason for referral' section, which has a drop-down menu from which the referrer can select more than one option. *Table 2* shows the original e-referral form, which had four categories (left column), and the e-referral form adapted for our team by the Trust IT department, which has ten categories based on the IRAC scale. All the other information on the e-referral form remained unchanged.

Following the launch of the modified e-referral form, when a clinical member of our team closed a case, they were asked to record the reason for referral (categories 1–10, *Table 2*) and whether the reason for referral was fully achieved (2), partially achieved (1) or not achieved (0) in accordance with FROM-LP guidance. As the in-patient team did not collect these data prior to modification of the e-referral, our researcher (S.C.) rated whether the team had met the reason(s) for referral before and after the intervention so that a more direct comparison could be made.

Data collection

Our researcher (S.C.) retrospectively reviewed the electronic healthcare records of patients referred to the in-patient team before and after the intervention. The initial group consisted of all appropriate referrals to our team from 3 to 16 Oct and 24 Oct to 6 Nov 2016. The comparison group consisted of all appropriate referrals to our service from 24 Apr to 7 May and 15 May to 28 May (2017). The electronic records were scrutinised for each patient referred to determine whether the reason for referral on the e-referral form was accurate (i.e. by probing the content of the assessments). If the reason for referral stated on the e-referral form was established as accurate, the researcher then further reviewed the electronic records to determine whether the in-patient MHLT had fully achieved, partially achieved or not achieved the reason(s) for referral. If the reason for referral on the e-referral form was not accurate, it was recorded as 'did not achieve the reason(s) for referral' (because it would not have been possible to meet the reason for referral if we had been given inaccurate referral information from the outset).

The Authors own the copyrights to the individual articles.

Statistical analysis

The following outcomes before and after modification of the e-referral form were compared using Fisher's exact test: (a) accuracy of the reason for referral (b) referral outcome – did the in-patient MHLT fully achieve, partially achieve or not achieve the referral request?

The effect estimates are reported as odds ratios with 95% confidence intervals, and all the *P*-values reported are two-tailed.

Results

A total of 124 cases were analysed; 61 were referred prior to the modification of the e-referral form and 63 were referred after. Comparison of the accuracy of the reason for referral before and after modification of the e-referral form (Table 3) demonstrated a statistically significant difference. Referrals were assessed as accurate in 73.8% of cases when using the previous referral system, compared with 93.7% when using the new referral system ($P = 0.0030$). Table 3 Referral accuracy

	Before ($n = 61$)	After ($n = 63$)	Odds ratio (95% CI)	<i>P</i> -value
Yes, n (%)	45 (73.8)	59 (93.7)	5.24 (1.53–22.76)	0.0030
No, n (%)	16 (26.2)	4 (6.4)		

Comparison of whether the reason(s) for referral were met before and after modification of the e-referral (Table 4) also demonstrated a statistically significant difference. The referral request was assessed as fully achieved for 57.4% of referrals when using the previous referral system, and for 77.8% of referrals when using the new referral system ($P = 0.0210$). There were no significant differences identified between the two referral systems when the referral request was assessed as partially achieved (16.4 v. 15.9%, $P = 1.0000$). The percentage of referral requests assessed as not achieved decreased significantly when using the new system, from 26.2 to 6.4% ($P = 0.0030$). Table 4 Referral outcomes

	Before ($n = 61$)	After ($n = 63$)	OR (95% CI)	<i>P</i> -value
Fully achieved, n (%)	35 (57.4)	49 (77.8)	2.60 (1.11–6.16)	0.0210
Partially achieved, n (%)	10 (16.4)	10 (15.9)	0.96 (0.33–2.82)	1.0000
Not achieved, n (%)	16 (26.2)	4 (6.4)	0.19 (0.04–0.65)	0.0030

Discussion

The adapted e-referral form went live in March 2017. A retrospective analysis of the electronic healthcare records demonstrated that, following this intervention the reason, for referral was five times more likely to be accurate and the team was 2.6 times more likely to fully achieve the reasons for referral. The results suggest that improving the accuracy of the referrals improved the team's ability to achieve the reasons for referral.

Following the intervention, 6.4% of the referrals (compared with 26.2% before the intervention) were inaccurate. Periodic review of inaccurate referrals may help to determine why they were inaccurate. One possible explanation might be that the referrals to our team are generally made by the most junior doctor on the team, and the reason for referral may not have been made clear to them by the senior doctor asking for the referral. Another possibility is that none of the ten referral options adequately covered the reason for referral.

Following our intervention, the referral request was achieved (fully or partially) in 93.7% of referrals. In liaison work, it is not unexpected to partially achieve a referral request. Many patients might only be seen briefly prior to discharge from hospital, requiring handover to community teams or health professionals to complete the work. Despite this, further in-depth exploration as to the reasons would be useful.

An accurate referral to the MHLT is important because it enhances triage, so that patients can be prioritised accordingly and assigned to an appropriate member of staff (i.e. doctor or nurse, consultant or trainee doctor). It also potentially enables a more focused assessment based on the referrer's expectation; this could improve time efficiency, which in itself is important for a variety of reasons, such as when the patient is very unwell, or to facilitate financial savings and flow through the acute hospital. In addition, by outlining very specifically the referral categories to the referrers, it highlights exactly what type of work the MHLT can do and encourages referrers to consider the objectives of their referral, which in turn improves general efficiency.

We are aware that our evaluation, by embedding the IRAC scale into the referral form and asking the referrer to select the aim of contact, is in contrast to many other MHLT around the country, who tend to complete both the aim of the

contact and achievement of the contact themselves. However, there were several reasons behind this process variance: (a) it was in alignment with the way many other specialties designed and operated their e-referral pathways in our trust, and so was not too dissimilar when making a referral to, e.g. respiratory or cardiology; (b) based on our experience, we felt that referrers often have a reasonably good idea of what they want assistance with in managing their patient, and it is then for us to be able to achieve that as providers of the service; and (c) it made data collection and measuring a much more reliable, more consistent and simpler process.

A number of limitations with this evaluation are worth commenting on. The number of patients involved in the retrospective analysis was small, and the confidence intervals were relatively wide as a consequence. A single researcher examined the electronic healthcare records for each referral, determining the accuracy of a referral based on the available clinical information and whether the reason for referral had been fully achieved, partially achieved or not achieved. This introduces the possibility of observer bias. If the researcher found the reason for referral to be inaccurate, then it was recorded as 'not meeting the reason for referral'; this may have introduced exclusion bias.

In this evaluation, we did not measure or comment on referrer satisfaction, but we can predict that if there was an improvement in the team's ability to fully meet the reasons for referral, there would also be an associated improvement in referrer satisfaction. Using all the FROM-LP outcome measurements, our MHLT will be able to capture this information in the future. Our MHLT now routinely measures the IRACs for all referrals made to our service. Our results show that the main reasons for referral were: (a) assessment & diagnosis (37.5%) (b) medication management (11.8%) (c) assessment and management of risk (12.5%) (d) providing guidance and advice (16.5%).

This type of information can be used (alongside the structure and outcomes measurements in FROM-LP) to gain a clearer understanding of the work that the in-patient team are routinely carrying out, as described in the paper by Guthrie *et al.*⁹ This can then guide service development; for example, do our staff have all the necessary skills to manage the referrals, or do they require training in specific areas?

In the future, our team plan to incorporate the structure, process and outcomes data into a mental health dashboard on the Trust IT system, which will provide live up-to-date performance data, allowing our MHLT to anticipate trends quickly and respond in a timely fashion. This information will also be made available to our various 'customers' (commissioners, patients, carers, and referring staff).

Conclusion

Since the launch of FROM-LP, there has been encouraging feedback based on opinion and observation, and numerous MHLT's have already implemented it.⁸ However, the developers acknowledged that rolling out this tool quickly across MHLTs nationwide meant that it was potentially imperfect.⁷ Tadros's commentary¹⁰ further encouraged MHLTs to develop a positive approach integrating the collection of outcome measures into everyday clinical practice, and found the FROM-LP a very useful tool to measure service quality and clinical effectiveness. To date, however, there has not been an actual appraisal of the tool or any part of it.

Through our evaluation of the IRAC scale of the FROM-LP, we have demonstrated an improvement in the accuracy of the referrals to our service. In turn, this has helped our team's ability to achieve the referral request and we have therefore been able to establish the instrument's construct validity. We conclude that the IRAC composition of FROM-LP does indeed measure what it was intended for, and we thus have demonstrated the clinical utility of the IRAC scale, which hopefully has reinforced its recommended incorporation into MHLTs across the NHS.

Dr Caroline Guest is a specialty doctor in Liaison Psychiatry in the North Bristol NHS Trust Mental Health Liaison Team, Bristol, UK; **Dr Stephen Crockett** and **Dr Patrick Little** are both Foundation Year 2 doctors in Liaison Psychiatry in the North Bristol NHS Trust Mental Health Liaison Team, Bristol, UK; and **Dr Anish Patel** is a Consultant Liaison Psychiatrist in the North Bristol NHS Trust Mental Health Liaison Team, Bristol, UK, and part of Avon and Wiltshire Mental Health Partnership NHS Trust, Chippenham, UK.

Still Down by Dean F. MacKinnon, a US-based psychiatrist, is a patient-centred guide written primarily for patients – and their families – seeking effective management for treatment-resistant depression.

The book begins with a revision of the symptoms of major depressive disorder and a summary of how treatment has developed to include a wide range of antidepressant medications that allow patients to be trialled on alternative

treatments when any one agent is unsuccessful. The author explains treatment-resistant depression – where patients fail to respond to antidepressant therapy – using nine case studies that suggest reasons for treatment failures, starting with relatively straightforward cases and ending with more complex scenarios. Scenarios include patients who have been inadequately treated or misdiagnosed as well as patients who are ‘treatment resistant.’ Strategies, both biological and psychological, based on the author’s own clinical experiences are suggested as ways to overcome antidepressant failure. These are summarised in a table towards the end of the publication.

MacKinnon presents cases concisely, in an engaging and conversational style. Each presentation ends with a summary of the key (general) clinical points and case notes which highlight diagnostic features specific to the patient’s individual presentation.

The main strength of this work is its clarity of information. Easy-to-read prose, bullet-points and tables help break up the text in ways that aid comprehension. Explanation of medical jargon where used and the relative absence of jargon ensures suitability to the target audience. Limitations include its focus on treatments approved by the U.S. Food and Drug Administration, which may be less relevant in countries other than the USA. Furthermore, the book does not include novel evidence on pharmacological or psychological treatments. Irrespective of this, it remains a valuable commodity for healthcare professionals, offering a general revision of the topic and inspiring an individualised approach to managing patients.

In summary, this is a well-written and helpful resource for patients and relatives seeking to gain a better understanding of depression and its management.

1.5.68 Doctors, suicide and mental illness

Clare Gerada

Correspondence

Clare Gerada (clare.gerada@nhs.net)

date

2018-8

Abstract

This article focuses on doctors and suicide. It provides real examples to illustrate why doctors die by their own hand. These reasons are replicated in the general population, but also include a host of additional risk factors related to being a doctor. In each case, information about the doctor is in the public domain or, as in one case, consent from the next of kin has been obtained for a detail not in the public domain. The author is a doctors’ doctor, heading up a confidential health service for doctors with mental illness or addiction, the National Health Service Practitioner Health Programme. Mortality data from the programme (January 2008–January 2017) will also be included. For the sake of confidentiality, data is collated and details regarding age and gender have been approximated.

Declaration of interest

None.

In most healthcare systems (whether privately or publicly funded), and across all ages, genders, specialties and seniority, doctors have higher rates of depression and anxiety compared with the general population and other professional groups.¹ This is counterintuitive given that doctors have a host of apparently protective attributes, including career and financial security, high status and a generally rewarding job. However, doctors are as exposed as anyone else to risks associated with genetic predisposition, early traumatic life events, later bereavements, illnesses or relationship breakdowns. Doctors also have additional risk factors. They are chosen for personality traits that predict good doctoring – perfectionism, obsessiveness and even elements of martyrdom – traits that can act against them. From an early age they are driven, competitive, compulsive, individualistic and ambitious – features that can go into overdrive when stressed. As doctors work harder, they blame themselves for not being able to deliver the care required by their patients, and feel guilty for events beyond their control. Consequently, doctors can suffer from a triad of guilt, low self-esteem and a persistent sense of failure.² To survive a lifetime in medicine, doctors also have to develop psychological defences that include depersonalisation and dissociation. This can make it harder to create attachments to others or to recognise when the emotional burden of their work becomes too much, and thus contributes to the spiralling of discontent and increased risk of suicide.

Doctors and suicide

In the UK, around one in five adults has considered suicide and one in 15 have attempted it. Very few attempts result in death, estimated to be about 1 in 10 000 per annum.³ The suicide rate for doctors have been variably estimated at between two and five times the rate of the general population.^{4,5} In a systematic review, Lindeman *et al.* estimated physicians' relative suicide risk at 1.1–3.4 for men and 2.5–5.7 for women compared with those for the general population, and at 1.5–3.8 for men and 3.7–4.5 for women compared with those for other professionals.⁶ Anaesthetists, general practitioners and psychiatrists appear to be associated with higher risk. In an Australian survey, approximately a quarter of doctors reported having had thoughts of suicide prior to the past 12 months (24.8%), and 10.4% reported having had thoughts of suicide in the previous 12 months. Thoughts of suicide are significantly higher in doctors compared with the general population and other professionals (24.8 v. 13.3 v. 12.8%).⁷ In a 2008 study, members of the American College of Surgeons were sent an anonymous survey with questions on suicidal ideation and use of mental health services, and questionnaires for depression, burnout and quality of life.⁸ Of 7905 participating surgeons (a response rate of 31.7%), 501 (6.3%) reported suicidal ideation during the previous 12 months (more common in older surgeons). These levels of suicidal thoughts were between 1.5 and 3.0 times more common among surgeons than the general population. Importantly, only 26.0% of the surgeons with suicidal thoughts had sought help, whereas 60.1% (301) were reluctant to seek help because of concern that it could affect their medical license. This study shows the high rate of mental health distress accompanied by low use of treatment services.

Suicide and mental illness

Major risk factors for completed suicide across all populations are depression and substance misuse, both of which are also common in doctors who take their own life. For example, Dr Louise Tebboth, a gifted south London general practitioner, was only 40 years old when she killed herself. Her husband Gary Marson, in his book *Carry on Breathing*,⁹ describes in poignant detail the first year of his bereavement, starting on Friday 23 January 2015 when he found her hanging from the bannisters in their home. She fought a long battle against bipolar disorder. She had survived a near fatal overdose in her late 20s but decades later, despite the intervention of psychiatric services and daily monitoring by her husband, and an intensive regime of activity to keep her occupied and safe, she killed herself.

Deaths of doctors attending the National Health Service Practitioner Health Programme

As well as being a local general practitioner colleague, Louise was a patient of the National Health Service Practitioner Health Programme (PHP) when she died. Of the approximately 3500 doctors who have presented between 2008 and 2017, 80% have done so with mental health problems (mainly depression, anxiety and symptoms indistinguishable from post-traumatic stress disorder). Another 15% have predominantly suffered from alcohol or drug misuse (mostly alcohol dependence) or a mix thereof; the service also has a number of doctors with personality disorder, bipolar disorder, physical health problems affecting their mental health and a small number with undiagnosed schizophrenia or psychosis. During this period, 21 patients of the service have died; approximately 6 times as many men died as women. The average age at death was 44 years, ranging from under 30 to over 65 years old, and from early on in training to senior consultants near retirement. General practitioners accounted for 7 out of 21 (33%) of the deaths; the remainder were drawn from different medical, surgical, anaesthetic and emergency specialties in almost equal numbers. Six doctors died from suicide. A further ten died from accidents where the cause of death was not given as suicide, but which could be considered to be part of a suicidal act or from fatal overdoses of drugs/alcohol (not classified as suicide). Five were from either natural causes or the doctor died overseas and we have been unable to find the cause of death.

Doctors, suicide and barriers to care

It is not just mental illness that predisposes doctors to killing themselves. Suicide is also linked to how doctors are treated, how they treat themselves, unique issues related to their job and a system where doctors with mental illness are handled through an adversarial rather than treatment system. This equates to personal, professional and institutional stigma, which doctors face when trying to access care and also once in treatment. Stigma is one of the most important barriers for doctors trying to be treated, illustrated by the next doctor. Daksha Emson was a young psychiatrist. On 9 October 2000, when her first child, Freya, was 3 months old, she stabbed her baby, poured accelerant on them both and set it alight. Both died. Daksha had written in her diary, just before her death, about her feelings of hopelessness. What follows is an abridged extract from that diary entry:

'Feel useless as a mother as a wife as a woman.

See no hope for the future.

sleep unrefreshing food forced down because my baby needs nourishment. Focusing on my precious baby Freya – she means everything to me, I desperately want to be a good mother to her but I'm starting to feel I'm failing her in a big way, that everyone can see I'm a useless mother that I'm no good.

... hits me in early hours of morning – thoughts churn round and round.

Finding it difficult to hang on to reality - am I bad and wicked? I don't deserve good things, is there really hope for the future?'

Extract from the last diary entry of Dr Daksha Emson, published in *Report of an Independent Inquiry into the Care and Treatment of Daksha Emson and her Daughter Freya*.¹⁰

The subsequent inquiry identified stigma as a major factor in her and her daughter's deaths. Daksha, like many doctors, felt that she had failed by becoming mentally unwell. The study by Henderson *et al.*¹¹ of doctors out of work with

mental illness found that most felt guilty, shamed and fearful. Doctors feel a dreadful sense of personal failure and inadequacy if they struggle to keep working and despair can be sudden and overwhelming. The researchers describe an overwhelming stigmatisation that mentally ill doctors were exposed to by friends, family and peers, which left them isolated and sad. Some sick doctors deliberately concealed their problems, and this resonates with doctors attending PHP who will pretend to go to work each day rather than admit to their families that they are unwell. In the Henderson *et al.* study, doctors described a lack of support from colleagues and feared a negative response when returning to work. Self-stigmatisation was central to the participants' accounts and several doctors appeared to have internalised the negative views of others. Stigma was also a key feature of a survey conducted by Cohen *et al.* of almost 2000 doctors.¹² Cohen *et al.*'s view is that fewer professions stigmatise mental health disorders more prominently than medicine, a conclusion supported by the finding that 41% of doctors with mental illness said that they would not disclose it. Garelick *et al.*,¹³ reporting on the service for doctors with mental health problems, also cites stigma as a major barrier to receiving appropriate care.

Daksha was concerned about the stigma of her mental illness and its effect on her career progression; she mentioned this fear to her best friend several times. Even if, as with Daksha, doctors present for help, it is difficult for caregivers to see beyond the professional to the patient and treat the sick doctor as the frightened, vulnerable individual they are. Doctors tend to treat sick doctors differently from other patients. They engage in medical talk, discuss academic papers or the latest research and go way beyond what the sick doctor really wants or needs. The PHP discourages shared decision-making until the sick health professional begins to improve. Daksha's untimely death led to funding for PHP, with which thousands of doctors with mental illness have been helped.

Doctors, suicide and complaints

Dr Wendy Potts was a 46-year-old mother of two and a general practitioner in Derbyshire. She also suffered from bipolar disorder. Dr Potts wrote about her experience with depression on an online blog. In it, she wrote openly on how fluctuations in her mood affected her and her life in general. It is reported that a patient complained after reading her blog, questioning whether she should be able to practise as a general practitioner. She was suspended by her practice and National Health Service (NHS) England, and referred to the General Medical Council (GMC). In November 2015, Dr Potts hung herself. Dr Potts' case incorporates both stigma and mental illness, but also the additional burden that weighs heavily on doctors and adds to their risk – complaints and disciplinary processes. Bourne *et al.*¹⁴ conducted a study of doctors comparing the mental health (using standardized tools) of those who had and had not received a complaint. A total of 10 930 out of 95 636 (11.4%) responded, and 7926 (8.3%) completed the full survey and were included in the complete analysis. Of those who completed the survey, 16.9% of doctors with current or recent complaints reported moderate/severe depression (relative risk 1.77; 95% CI 1.48–2.13) compared with doctors with no complaints (9.5%). A total of 15% reported moderate/severe anxiety (relative risk 2.08; 95% CI 1.61–2.68) compared with doctors with no complaints (7.3%). The authors found that distress increased with complaint severity, with highest levels after a GMC referral (26.3% depression, 22.3% anxiety). Doctors with current or recent complaints were 2.08 (95% CI 1.61–2.68) times more likely to report thoughts of self-harm or suicidal ideation. This analysis illustrates how damaging complaints and regulatory processes are to doctors' health and job performance. Similar findings of the negative effect of disciplinary processes on the mental health of doctors were found in a study from the Netherlands.¹⁵ Analyses of the deaths of doctors at PHP show a significant correlation between mortality and involvement of the regulator. Among PHP patients who have not died, the GMC is involved in around 10% of cases, compared with 11 out of 21 (52%) of patients who have died and 9 out of 16 (56%) patients who died from accidents, suicide or overdoses (Table 1). Table 1 Analysis of patients seen at the National Health Service Practitioner Health Programme who have died, and their involvement with General Medical Council (GMC) procedures

Cause of death	Number of patients	GMC involvement
All deaths	21	11
Overdose drugs/alcohol or accidents	10	9
Suicide	6	6

In response to concerns about high numbers of deaths among doctors, the GMC commissioned an independent study examining 28 deaths of doctors due to suicide (or suspected suicide) where the doctor was also involved in fitness-to-practise processes between 2005 and 2013.¹⁶ The case reviews of doctors during this period showed that many of the doctors who died by suicide suffered from a recognised mental health disorder or had drug and/or alcohol addictions. Other factors that often followed from those conditions may have also contributed to their deaths. These include marriage breakdown, financial hardship and in some cases, police involvement, as well as the stress of being investigated by the GMC. Of course, correlation between death and regulatory involvement does not equate to causation, as the GMC

review found. The interaction between complaints and mental illness is complex, with many possible issues to take into account (*Table 2*). *Table 2* Relationship between regulatory processes and mental illness in doctors Relationship between suicide in doctors and complaints/regulatory or disciplinary processes •A complaint may lead to a doctor becoming depressed or worsen a pre-existing mental illness. •Mental illness can lead to cognitive impairment, which can lead to a boundary transgression or inappropriate behaviour such as bullying or acting inappropriately with a patient or work colleague. •Mental illness might lead to out-of-character criminal behaviour (such as shoplifting), which itself can lead to worsening of the mental illness. •Mental illness might involve criminal activity; for example, drug use. •Drug use can lead doctors transgressing good medical practice, such as stealing drugs, self-prescribing or prescribing in a patient's name for the doctor's own use. •Mental illness in itself might be considered counter to fitness-to-practise; for example, bipolar disorder, schizophrenia, personality disorder or schizoaffective disorder. •The very act of trying to kill oneself might lead to criminal or professional sanctions where the means of the suicide attempt involves obtaining drugs illegally or via self-prescription.

At Dr Potts' inquest, the coroner commented that the system had lost sight of the fact that there was a human being behind the complaint and investigation.¹⁷ It is indeed common to underestimate the effect that complaints can have on doctors, and to lose site of the severe pain this causes to the doctor and how a complaint can threaten a doctor's sense of self. A complaint challenges a doctor's values. It is a catastrophic personal event, described by one doctor at PHP as akin to a diagnosis of cancer. The overwhelming feeling (once the anger and shock has subsided) is that of shame: shame of disclosure, of appearing in front of the regulator, of having to face the gauntlet of the press and the shame brought on their families, friends and colleagues. All too often, their shame becomes exaggerated and they begin to feel responsible for the entire profession's values and future.

Prevention

Preventing a very rare event (completed suicide) and identifying those who will go on to complete a suicide act from those who express suicidal thoughts is extremely difficult, if not impossible. A systematic review of risk assessment for suicide by Large *et al.*¹⁸ concluded that the overwhelming majority of people who might be viewed as high risk for suicide will not kill themselves, and about half of all suicides will occur among people viewed as low risk. Carter *et al.*¹⁹ found similar results in their systematic review of instruments aimed at predicting high risk of suicide and concluded that no high-risk instrument was clinically useful. This is what we have found among our doctors at PHP. PHP risk-assesses all patients at first assessment and reviews thereafter as required. Patients are risk-assessed depending on the perceived risk to self, service/institution or their own patients. This assessment forms part of the weekly multidisciplinary team meeting. Only 3 of the 21 doctors who died were assessed as being high risk (red) (recent/current suicidal ideation, past attempt to take one's own life, drug misuse, alcohol dependence or depression are all risk factors), and most (16 out of 21) were considered by the service as low (green) risk. Two doctors who killed themselves were rated red (the highest risk), and the other doctor died from an overdose of drugs.

Conclusion

It is important to remember that the vast majority of doctors do not kill themselves. Most doctors thrive in their working environment. However, each death is a tragedy which sends repercussions through the system and poses the risk of creating contagion. Going forward, we have to halt the decline in morale among doctors. This will mean addressing many systemic issues that are creating unhappiness: tackling the culture of naming, blaming and shaming and the constant denigration of NHS staff by the press; allowing doctors to maintain a sensible work-life balance and not ignoring the basic needs of staff who give their all to their patients. We must restore doctors' collective self-esteem by treating them as intelligent adults and not naughty schoolchildren, and by creating a culture in which their skills can flourish. We need to ensure doctors have access to early intervention and confidential support services.²⁰ Finally, we have to ensure that all NHS staff receive the same compassion that they, rightly, are expected to give to their patients.

1.5.69 Against the Stream: lowering the age of sexual consent

Philip Graham

Correspondence

Philip Graham (pjgraham1@aol.com)

date

2018-8

Abstract

Lowering the legal age of sexual consent would decriminalise a large number of ‘underage’ young people engaging in sexual intercourse. The arguments against such a change in the law are summarised and shown to lack validity.

Declaration of interest

None.

Contents

- *Against the Stream: lowering the age of sexual consent*
 - *The present legal situation*
 - *The arguments against*
 - *The arguments in favour*

The proposal that the age of consent should be lowered is not just ‘against the stream’. It is regarded by many as a preposterous idea. When, in 2013, the then President of the Faculty of Public Health, Professor John Ashton, made the proposal that the age of consent should be reduced from 16 years to 15 or even 14 years, it was immediately rejected by both government and opposition spokesmen.¹ Indeed, David Cameron, when Prime Minister referred to the proposal as ‘offensive’.

The present legal situation

It is the case that there are many cogent arguments against such a move. It will be claimed here that none of these is valid. Further, it will be proposed not only that there would be specific advantages to changing the law in this way, but that the principles on which this proposal is based have implications for other ways in which the rights of young people are inappropriately curtailed.

The existing laws in all the jurisdictions of the UK state² that the age of consent for any form of sexual activity is 16 years for both men and women. The age of consent is the same regardless of the gender or sexual orientation of a person and whether the sexual activity is between people of the same or different gender.

It is an offence for anyone to have any sexual activity with a person under the age of 16. However, Home Office guidance is clear that there is no intention to prosecute teenagers under the age of 16 where both mutually agree and where they are of a similar age.³ Further, it is an offence for a person aged 18 or over to have any sexual activity with a person under the age of 18 if the older person holds a position of trust (for example, a teacher or social worker) as such sexual activity is an abuse of the position of trust.

There is wide variation between countries in the age of sexual consent. In Europe, all countries have minimum age limits for sexual relations. Nowhere is this age set lower than 14 years.⁴ In Europe, consensual relations with 14-year-olds are legal in half of the jurisdictions, and with 15-year-olds in three-quarters.⁵ This places the UK among the quarter with the most restrictive legislation. There is no evidence that the legal minimum age of sexual consent in a country is in any way correlated with the sexual behaviour of young people.

Various principles have been adduced which should govern the legal position of minors.⁶ Although it is often implied that children should not be regarded as such, Waites⁶ (p. 218) suggests that children are indeed citizens who, like adult citizens, have a right to protection as well as a right to freedom of activity. He argues that sexual behaviour below the age of 14 should be criminal, and that there is a role for legal prohibitions for the collective good which goes beyond preventing harm in individual cases (pp. 220–241).

The arguments against

The following arguments have been used against the proposal to lower the age of sexual consent. These are followed by counter-arguments. (a) A change in the law would result in more younger children becoming inappropriately engaged in sexual activity. There is a lack of evidence this is the case and, indeed, much evidence suggesting that the existing law has no effect on the sexual behaviour of young people. Information collected between 2010 and 2012 suggests that 31% of British males and 29% of British females had full sexual intercourse before the age of 16 years. Fifty years previously, this had been the case for 15% of males and 4% of females.⁷ There had been no change in the law in relation to heterosexual intercourse in the interim. A study of the reasons for sexual abstinence in American school students revealed that the law was not cited as a reason for abstaining from sexual activity.⁸(b) The existing law gives young people, especially girls, who do not want to engage in sexual activity a powerful reason for refusing to consent. Although this reason is often cited, there is not even anecdotal evidence to suggest it is valid. It is indeed difficult to imagine a girl saying to her boyfriend that she does not wish to have sex with him because it is against the law. She might not wish to have sex with him, but she wouldn't want him to laugh at her either.(c) Focus group discussions with 11–16 year-olds reveal that they are generally opposed to a change in the law on this matter.⁹ This is indeed the case, but, as indicated above, there is a marked disparity between the behaviour of young people and their views on the existing law.(d) Young people aged 14 years are not physically mature enough to engage in full sexual activity. The median age of menarche in English and Welsh girls born between 1982 and 1986 was 12 years and 11 months.¹⁰ Thus, the great majority of girls of 14 years are indeed sufficiently physically mature to engage in full sexual activity.(e) Young people aged 14 years are not cognitively mature enough to evaluate the risks of engaging in sexual activity. There is ample evidence that 14-year-olds are as capable of analysing the risks and benefits of different interventions in complex medical situations as are 21-year-olds.¹¹(f) Young people aged 14 years are not emotionally mature enough to engage in full sexual activity. Steinberg¹² – while accepting that mid-teenagers have sufficient cognitive maturity – suggests there is evidence that this is not the case when they are emotionally aroused or exposed to peer pressure. In particular, he cites his own work¹³ pointing to age differences in sensation-seeking and impulsivity. These studies of young people aged from 10 to 11 years up to 30 years show reduction of impulsivity with increasing age under experimental conditions. The problem with his argument is that the greatest reduction in impulsivity occurs between adults aged 22–25 and those aged 26–30 years. Is it really suggested that sexual consent should be invalid up to the age of 26 years?(g) Neuroscientific evidence suggests that the adolescent brain undergoes significant changes throughout the teens and beyond. For example, Casey *et al*¹⁴ report that 'recent human imaging and animal studies provide a biological basis [...] suggesting differential development of subcortical limbic systems relative to top-down control systems during adolescence relative to childhood and adulthood'. This is taken to mean that those in their teens are not physiologically competent to make important decisions relating to risk-taking. It is surely unwise to rely on such indirect evidence when much more directly relevant studies suggest that it is the inexperience of the young rather than biological limitations that lead to their greater vulnerability in risky situations. For example, McCart *et al*,¹⁵ studying traffic accidents among young people, found that 'of the studies that attempted to quantify the relative importance of

age and experience factors, most found a more powerful effect from length of licensure’.

The arguments in favour

Having effectively countered the arguments against lowering the age of sexual consent, it only remains for me to point briefly to the obvious advantages of such a change in the law. (a) Lowering the age of sexual consent would result in the decriminalisation of just under one-third of the adolescent population. Most such law-breakers are not currently prosecuted, but it cannot be right that their freely given sexual consent is deemed illegal. (b) The numbers of young people whose sexual activity results in sexually transmitted infections is substantial.¹⁶ The number of pregnancies in 15–17-year-olds, although it is reducing, remains substantial.¹⁷ Further, the sexual experience of many young people, particularly girls, is distressing, and a substantial number of girls regret their first full sexual experience.¹⁸ Lowering the age of sexual consent would make it distinctly easier for appropriate sex education to be provided to children and young people to enable them to make wiser decisions. It would also make it easier to provide sexual health services to people of this age without the fear of conniving in illegal activity.

Note that it is not proposed here that there should be any changes in the position of those adults who abuse their positions of trust to have sex with people younger than themselves. Further, it is firmly accepted there should be a minimum age limit for sexual consent, a view that has been contested. It is important that it remains recognised that children under the age of 14 years have neither the cognitive nor the emotional maturity to make decisions about their own sexual behaviour.

It will not have escaped the notice of the attentive reader that the principles and evidence adduced here are also relevant to a number of other situations in which the current legal position of minors is highly questionable. For example, at the present time, the age of criminal responsibility in England and Wales is 10 years, while in Scotland it is currently 8 years, with 12 years as the age of criminal prosecution. The age of criminal responsibility should surely be raised to 14 years. The voting age in England and Wales is currently 18 years, while in Scotland it is 16 years. The voting age should surely be reduced to 16 years in England and Wales, with an expectation of a further reduction in due course.

1.5.70 Ethnic variation in personality disorder: evaluation of 6 years of hospital admissions

A. Hossain M. Malkov T. Lee K. Bhui

Correspondence

Tennyson Lee (tennyson.lee1@nhs.net)

date

2018-8

Abstract

Aims and method

There is limited evidence on ethnic differences in personality disorder prevalence rates. We compared rates of people with personality disorder admitted to hospital in East London from 2007 to 2013.

Results

Of all people admitted to hospital, 9.7% had a personality disorder diagnosis. The admission rate for personality disorder has increased each year. Compared with White subjects, personality disorder was significantly less prevalent among Black and other minority ethnic (BME) groups. Personality disorder was diagnosed in 20% of forensic, 11% of general adult, 8% of adolescent and 2% of old-age in-patients.

Clinical implications

The increasing number of personality disorder diagnoses year on year indicates the increasing impact of personality disorder on in-patient services. It is important to identify and appropriately manage patients with a personality disorder diagnosis due to the significant strain they place on resources. The reasons for fewer admissions of BME patients may reflect alternative service use, a truly lower prevalence rate or under-detection.

Declaration of interest

None.

 - *Local context*
 - *Objectives*
 - *Method*
 - *Results*
 - *Discussion*
 - * *Limitations*
 - * *Recommendations*

Personality disorders are characterised by enduring maladaptive patterns of behaviour, cognition and inner experience, exhibited across many domains and deviating markedly from those accepted by the individual's culture.¹ Comorbidity of personality disorder with other mental disorders is common, and the presence of personality disorder often has a negative effect on treatment outcome. Personality disorder is associated with premature mortality and suicide² and people with the disorder often use services heavily,³ leading to calls for improved identification in clinical practice.⁴

Prevalance of personality disorder

The prevalence of personality disorder increases with levels of care. In the community, estimates range from 4.4% in the UK,⁵ 6.1% in a World Health Organization (WHO) study across 13 countries,⁶ to 8.6% in Bangalore.⁷ Prevalence of personality disorder is 24% in the UK at the primary care level.⁸ At the secondary care level, psychiatric out-patient prevalence rates varied between 40 and 92% in Europe, 45–51% in the USA and 60% in Pakistan.⁹

Personality disorder is under-diagnosed in routine practice compared with when structured instruments are used.¹⁰ A USA study showed 31% of psychiatric in-patients met criteria for personality disorder, but only 12.8% of them had a chart diagnosis of personality disorder.¹¹ In the UK, there is a reported prevalence rate of 7% of admissions in general adult psychiatry wards based on routine case note diagnosis.¹²

Review of literature

We searched the PubMed, PscyInfo and EMBase databases using the search strategy ‘personality’ AND ‘disorder’ AND ‘prevalence and ethni*’. We found 10 relevant results and hand-searched references of these papers for additional relevant studies. A meta-analysis (which identified 391 relevant publications and finally included 14) showed significant differences in prevalence between different ethnic groups, raising the question of whether there is a neglect of diagnosis in some ethnic groups or whether these are genuinely differing rates. However, the study does highlight the paucity of research into the prevalence rates of personality disorder among different ethnic minorities.¹³ A study based on a national household survey suggests that the prevalence of personality disorder is at least similar in minority populations to the native population within the UK.¹⁴

Local context

London is one of the most ethnically diverse cities in the world, and East London is the most ethnically diverse part of London with 73% of the population being non-native in origin. East London contains 8 out of the top 15 constituencies in the UK with the highest diversity index scores,¹⁵ making it a useful area for investigating whether there is an ethnic variation in prevalence of illness. Within the data gathering period, East London National Health Service Foundation Trust provided services to three boroughs – Tower Hamlets, Newham and City and Hackney – comprising a population of 815 000.¹⁶ This audit and service evaluation was undertaken in partnership with the Trust as a quality improvement initiative.

Objectives

The objectives of this audit were: 1.to describe the ethnic variation of psychiatric in-patients with a personality disorder diagnosis in East London;2.to contrast services such as old age, adolescent, forensic and general adult services.

Method

Anonymised data from routine service contact were collected from the Trust’s electronic patient record system on all admissions between April 2007 and April 2013. Ethnicity categories from the 2001 UK census were used. These data were then compared to census data of local demographics from the census data of 2011. Individual identifiers were not examined because routine clinical data were used in aggregate. As this was a service audit to inform our quality improvement initiatives, ethical approvals were deemed to not be necessary.

Results

Out of a total of 19 102 in-patient admissions in 6 years across three boroughs in all services, 1853 of them had or were eventually given a diagnosis of a personality disorder, which gives us a mean prevalence estimate of 9.7%. Of these in-patients, 56% were female and 44% male. This mean prevalence varied from 3% in Indian and Pakistani populations, to 17% in the native White British population (Table 1). There is a statistically significant lower prevalence of personality disorder in all ethnicities compared with the White British population, except in those of mixed race heritage where the sample size is too small. There was little variation in personality disorder diagnosis rates between Black and other minority ethnic (BME) groups where there was a sufficiently large sample size. Table 1 Mean period prevalence of personality disorder diagnoses in in-patients in the years 2007–2013

Ethnicity	Prevalence of personality disorder	Odds ratio (95% CI)
White British	17%	1.0
Irish	7%	0.3635 (0.25–0.52)
Black African	4%	0.19 (0.105–0.24)
Black Caribbean	4%	0.22 (0.17–0.28)
Chinese	4%	0.17 (0.06–0.56)
Indian	3%	0.17 (0.11–0.25)
Bangladeshi	4%	0.22 (0.17–0.28)
Pakistani	3%	0.28 (0.19–0.419)
White/Asian mix	20%	1.192 (0.68–2.11)
White/Black African mix	1%	0.0638 (0.009–0.46)
White/Black Caribbean mix	16%	0.8904 (0.62–1.28)
Other mix	14%	0.799 (0.54–1.18)
Other Asian	11%	0.6 (0.46–0.9)
Other Black	7%	0.38 (0.29–0.49)
Other White	8%	0.408 (0.34–0.88)
Other ethnicity	7%	0.36 (0.28–0.47)

Table 2 shows the breakdown of the prevalence of personality disorder diagnosis in the different directorates of the Trust. The prevalence was 20% in forensic, 11% in general adult, 8% in adolescent services and 2% in old-age in-patients. Table 3 compares admission rates to the local population levels of each ethnicity. Table 2 Prevalence of personality disorder diagnosis in adult, child and adolescent, old-age and forensic services

Directorate	Prevalence of patients
Adults	11%
Child and adolescent	8%
Forensic	20%
Old-age service	2%

Table 3 Comparison of admission rates to local population levels

The number of people admitted to hospital with a diagnosis of personality disorder has increased year on year, nearly doubling at the end of the 6 year period (Fig. 1). Fig. 1 Number of yearly admissions of people with personality disorder.

Discussion

Our analysis of in-patients in East London demonstrated a 9.7% prevalence rate of personality disorder, which is in line with previous studies of in-patients in the UK.¹²

Although our results indicate little variation in personality disorder rates between different BME groups, they consistently show lower rates compared to the White British population. Lower rates of referrals for BME groups to the local personality disorder service have also been found.¹⁷ Our findings raise key questions in light of international and national data pointing to the contrary (e.g. the WHO study across 13 countries that found that personality disorder is no less prevalent outside ‘westernised’ countries⁶ and the UK survey¹⁴). However, the lower incidence of personality disorder presentations in psychiatric emergencies in ethnic minorities has been noted before.¹⁸

Possible reasons for our findings may include that BME community structures contain the mild to moderate presentations of the disorder, meaning that only those people with extreme cases present to mental health services. BME communities also have difficulties in accessing healthcare, more complex pathways to specialist treatment¹⁹ and lower rates of accessing healthcare than the majority of the population.²⁰

There is some evidence that there are ethnic variations in the presentation of the disorder,^{21,22} that specific symptoms can be shaped by culture²³ and that individuals of differing ethnicity may present with different patterns of personality disorder pathology.^{24,25} In the key population group in East London, there is insufficient consistent evaluation into

prevalence, recognition and service access for people with personality disorder from Asian populations²⁶ and studies showing low rates of personality disorder in Asian-origin samples may be a result of a lack of understanding of what constitutes personality and personality disorder in Asian culture.²⁷ Differences in the presentation of symptoms of personality disorder in different cultures would not adequately be screened for by the tools currently in use. The preceding factors raise the possibility of misdiagnosis and suboptimal treatment.²⁸ In addition, ‘reverse racism’ may be occurring, with psychiatrists reluctant to make a diagnosis of personality disorder because it may be perceived as racist.

The annually increasing number of personality disorder diagnoses may reflect an increased willingness to diagnose this condition due to the increase in evidence-based treatment and the publication of National Institute for Health and Care Excellence guidelines on personality disorders in 2009. However, it is interesting to note that the proportion of patients admitted under sections of the Mental Health Act (2007) (MHA) has been steadily increasing since at least 2009 (<http://www.cqc.org.uk/publications/major-report/monitoring-mental-health-act-report#old-reports>), and there could possibly be a correlate, especially after the changes introduced to the act in 2007.²⁹ Our analysis did not pick out whether the people diagnosed with personality disorder were informal or under a section of the MHA.

The prevalence of 8% of adolescent in-patients with a diagnosis of a personality disorder is remarkable, as ICD-10 (1992) discourages the diagnosis in under 18s.³⁰ This suggests that clinicians may find the diagnosis of heuristic value. There has been considerable evidence that the diagnostic criteria for borderline personality disorder (and other personality disorders) are as valid, reliable and stable before age 18 as after age 18.³¹

The prevalence of personality disorder among older people in the community has been estimated to be about 10%.³² Among older in-patients, personality disorder has been seen in 6% of those with organic mental disorders and 24% of those with major depressive disorder.³³ Our finding of a 2% prevalence suggests that personality disorder may be under-diagnosed significantly in routine practice in old-age patients.

Limitations

Data were collected from one Trust in the UK. However, it is the most ethnically diverse one (Census 2011)¹⁶, and there is no reason to expect differences in routine diagnostic practice in other Mental Health Trusts in the UK. We do not anticipate problems relating to quality and validity of the personality disorder data compared with other diagnostic groups because all diagnoses are made on the basis of routine clinical care provided by the Trust.

Recommendations

The significant and rising proportion of in-patients diagnosed with personality disorder, combined with cost and pressures on in-patient beds, indicates that variations in recognition, access and management of these patients needs to be understood to ensure accurate identification and an improvement in present services.

Research targeting reasons for the lower diagnostic rates of personality disorder in BME groups could include whether there are cultural norms shared between BME communities that limit seeking help from mental health services for symptoms of personality disorder, whether there are variations in pathways to care, or whether there are variations in the attitudes of clinicians in diagnosing personality disorder in different ethnic groups.

The high proportion of adolescent in-patients diagnosed with personality disorder highlights the importance of a good transition from Child and Adolescent Mental Health Services to adult services, especially given difficulties these patients have with attachment. The ongoing presence of personality disorder in old-age services indicates the need for expertise in detecting and managing this diagnosis in these services, as these patients may represent the most difficult of personality disorder presentations in terms of not having ‘burnt out’ as is often expected.

There is a role for well-designed databases that lend themselves to ongoing analyses of routinely collected clinical data reflecting real service activity. All our results and inferences were obtained from such data, which provides us a low-cost opportunity for comparison over time and in different regions.³⁴ These data inform our quality improvement actions to improve clinical skills in assessment and management of personality disorder, and to better understand the needs of adolescents and elderly people with personality disorder.

We thank the staff at the Information Department of the East London National Health Service Foundation Trust for their excellent help in routine data retrieval. A poster presentation of preliminary results was presented at the 3rd World Congress of Cultural Psychiatry in London on 9–11 Mar 2012.

1.5.71 Revisiting neuropsychiatry as a psychiatric discipline

Jack C. Lennon

date

2018-8

Contents

- *Revisiting neuropsychiatry as a psychiatric discipline*

There has been a long-standing debate around the merging of disciplines, owing not to a lack of necessity in multidisciplinary approaches, but the increase in specialisation and fear of each field losing its perceived uniqueness. Fitzgerald¹ made this clear in his remarks regarding how neuropsychiatry can possess that which is both neurology and psychiatry. In a strong refutation, Datta² stated with vigour that while psychiatry could be improved with greater knowledge of behavioural neurology and neurosciences, it is unique in its approach. This rebuttal seems to have touched on a view of the psyche that may be one specific to psychiatry and psychology, but it cannot escape the organ from which these cognitions spontaneously arise.

It is clear that behavioural neuroscience is the foundation of psychiatry, an unassailable statement with which Datta² agreed. Fitzgerald's editorial,¹ however, does not necessarily minimise or underappreciate the importance of psychiatry in managing presentations such as suicidality from psychosocial perspectives, which a neurologist, for example, would not have the training to assess and treat. Instead, this editorial seems to serve an explicit purpose – to identify how specialisation in these specific circumstances may actually harm the field of psychiatry. It can be seen in the present day that psychiatry is stigmatised as much as the disorders it treats – it has been viewed as an intentional deviation from neurology, which is well known to treat organic disorders of the brain. A lack of merger, then, serves to ostracise psychiatry insofar that it becomes less about the brain. To state that discussions about psychotherapy and other psychological interventions are not rooted in neuroscience would be demonstrably fallacious. Even cognitive-behavioural therapy, one of the most studied psychotherapeutic interventions, was developed by a neurologist and recognises that the brain undergoes significant changes due to cognitions, ultimately leading to maladaptive behaviours beyond conscious awareness or personal agency.³ One cannot speak of psychiatric disorders without recognising and appreciating the organ responsible for behaviour and cognition.

The formulation of diagnoses and treatments for psychiatric conditions certainly differs from that of ‘neurological’ conditions such as mild traumatic brain injury, stroke and epilepsy. However, significant evidence suggests that psychiatric research is on the brink of discovering quantitative measures of its disorders, including but not limited to neuroimaging techniques,^{4,5} neuropsychological evaluations,⁶⁻⁸ and psychological tests such as those related to implicit associations.^{9,10} If one is to believe that psychiatry will remain entirely distinct from neurology and that the field need not merge with the professionals who also treat the central nervous system manifestations of brain dysfunction, regardless of aetiology, then psychiatry is destined to lose its footing when technology catches up to the incessantly changing brain that falls prey to inter- and intrapersonal events.

The Mental Capacity Act (MCA) has now been in operation for 10 years, and MCA case law has proliferated over this time. Books on this subject still remain vital to continue to embed this statute in practice. This book is a reprint of the original publication in 2013. It is aimed at psychiatrists and other mental health professionals and aims to provide ‘user-friendly’ guidance for medico-legal dilemmas that require an understanding of the MCA (and where it juxtaposes with the MHA statute). It is a readable book of only six chapters and 128 pages, which should appeal to busy professionals.

All chapters contain salient advice. Probably the most apposite chapter is that on best interests, especially with important case law having emerged in this area in recent years since the book was published (and given a prescient statement regarding best interests assessments and the need to fully involve the person and people who know them well that psychiatrists ‘have not been accustomed to this type of thinking’, which this chapter readily addresses). The section on the role of the Court of Protection is enlightening. Useful advice around the practical challenges of applying the MCA in the clinical setting is elucidated in the final chapter analysing clinical ambiguities in the assessment of capacity.

The book could have been improved for the reader by having easy to read learning points at the end of each chapter, and by having an annexe with the relevant MCA sections cited in full. Also, because case law does evolve, having a section recommending various legal resources would be helpful to enable professionals to readily keep up to date, e.g. online legal search engines and access to free monthly legal newsletters. A table comparing enduring power of attorney and both types of lasting power of attorney would also be useful.

It is unclear as to why the book has been reprinted without being updated with the advances in MCA case law since 2013. Some of these advances have been seminal in nature, especially in the areas of consent to treatment, best interests, end-of-life care and Do Not Attempt Cardiopulmonary Resuscitation orders, and, importantly Deprivation of Liberty Safeguards (DoLS), namely the ‘acid test’ that emerged from the Supreme Court after a ‘DoLS-athon’ in the lower courts. However, it still covers many areas of the MCA well enough for clinical practice, and is indeed ‘user-friendly’. It is a shame it wasn’t updated, as it would undoubtedly then be an extremely useful book to have for clinical practice.

1.5.72 Accurate recording of personality disorder in clinical practice

Peter Tyrer

Correspondence

Peter Tyrer (p.tyrer@imperial.ac.uk)

date

2018-8

Abstract

Disturbances of personality are recorded very poorly in official statistics, but there are signs that this is changing. For many years, personality disorder has been either regarded as a secondary diagnosis that can be forgotten in the presence of another mental disorder, or avoided as the diagnosis gives the impression of untreatability or stigma. What is now abundantly clear is that under-diagnosis of personality disorder represents a disservice to patients and practitioners. It prevents a proper understanding of the longitudinal course of psychiatric disorder and an appreciation of some of the positive aspects of abnormal personality that can be used in treatment. We must no longer bury personality disorder, ostrich-like, in the diagnostic sand. It is there for the asking and needs to be embraced honestly and without fear if we are to improve the management of psychiatric patients.

Contents

- *Accurate recording of personality disorder in clinical practice*

The paper by Hossain *et al* in this issue is noteworthy for two reasons: it records ethnic variation in a sensitive subject and provides a rare longitudinal record of personality disorder diagnosis. This type of research, based in clinical practice, should help to destigmatise the diagnosis of personality disorder, which for many years has been under-recorded in formal statistics. There is something bizarre in the contradiction between the research data, showing prevalence figures of up to 40% in psychiatric in-patients^{2,3} (and much higher for those in tertiary services)⁴ and the official national diagnostic figures, which rarely exceed 8%.⁵ This difference can only be explained by either (a) failure of detection; (b) diagnostic avoidance for a number of reasons; or (c) observance of a separate axis for personality disorder, one of the advantages of the DSM system that has now been lost.⁶ I would like to think that the fourth option, a complete rejection of the diagnosis of personality disorder, is not currently embraced.

It is likely that all three may be relevant in under-diagnosis and readers might ask themselves how they normally avoid this diagnosis in practice. One of the reasons may be the perceived lack of utility of the diagnosis. Does it help clinical practice? Many feel it does not as it is felt to confer an unfair label of untreatability; but this is mistaken. Three-quarters of those with personality disorder admitted to UK psychiatric hospitals are given the diagnosis of emotionally unstable (borderline) personality disorder,⁵ and this has the best evidence base for treatment.⁷ Lack of treatment options may be a reason for the low diagnosis rates of other personality disorders – anankastic personality disorder only accounts for 0.18% of all diagnoses in the group⁵ – but this does not mean diagnoses of personality disorders other than borderline are of no therapeutic value.⁸

Personality dysfunction may also be an advantage in aiding the effectiveness of certain forms of treatment^{9,10} and such findings, if confirmed in other settings, would help greatly in destigmatising the disorder. Hossain *et al* also report a high rate of diagnosis in adolescence. The new ICD-11 diagnostic classification of personality disorder, to be introduced later in 2018, includes the diagnostic option of ‘personality disorder in development’,¹¹ and this will allow clinicians to make this diagnosis in younger people. This does not mean that a diagnosis made at this time becomes an indelible stain on a person’s mental health; it merely states that, at that particular time, the individual concerned has

significant personality dysfunction and this should be acknowledged instead of reducing every form of pathology to symptoms or behaviour.

The low rate of diagnosis in Black and minority ethnic populations¹ can probably be explained by what could be called 'compensatory stigma'. Of the three prevalence studies of personality disorder in ethnic minorities, two have shown reduced prevalence compared with White comparators^{1,2} but the other, assessed as part of a national survey, showed an increase.¹³ My view is that the national survey is nearer to the truth. There is a concern that a psychiatric diagnosis of personality disorder in certain ethnic minority groups might be construed as racist and so is avoided. I have certainly behaved like this in my own diagnostic practice in the past.

The increased prevalence of personality disorder over time shown by Hossain *et al*¹ should not be regarded as necessarily a true reflection of increase; rather it shows that clinicians may be less wary about making the diagnosis that they previously did. This may well be good for practice, as assessment of personality as well as mental health status makes for better understanding and broader predictive value. The ICD-11 classification may increase prevalence rates of personality disorder³ as it allows for the diagnosis to be made for the first time both earlier and later in life.¹¹

Further studies along the same lines as Hossain *et al*¹ should also examine the proportion of people admitted with personality disorder under the Mental Health Act. Those with personality disorder are sectioned less often after formal assessment than those with other diagnoses, but at 41% the proportion is still substantial¹⁴ and may be increasing. This certainly appears to be the case in those with personality dysfunction and intellectual disability¹⁵ and is a matter of some concern, as in this population the diagnosis of personality disorder is more contentious. It should also help to have a simpler diagnostic system that clarifies the difference between severe and milder forms of personality disorder; the severe level is actually rare.

Peter Tyrer is Emeritus Professor of Psychiatry at the Centre for Psychiatry, Imperial College, London. He was the Chair of the World Health Organization ICD-11 Revision Group for Personality Disorders between 2010 and 2017.

1.5.73 Size and clustering of ethnic groups and rates of psychiatric admission in England

Gayathri Venkatesan Scott Weich Orla McBride Liz Twigg Helen Parsons Jan Scott Kamaldeep Bhui Patrick Keown

Correspondence

Gayathri Venkatesan

(Gayathri.venkatesan@ntw.nhs.uk)

date

2018-8

Abstract

Aims and method

To compare rates of admission for different types of severe mental illness between ethnic groups, and to test the hypothesis that larger and more clustered ethnic groups will have lower admission rates. This was a descriptive study of routinely collected data from the National Health Service in England.

Results

There was an eightfold difference in admission rates between ethnic groups for schizophreniform and mania admissions, and a fivefold variation in depression admissions. On average, Black and minority ethnic (BME) groups had higher rates of admission for schizophreniform and mania admissions but not for depression. This increased rate was greatest in the teenage years and early adulthood. Larger ethnic group size was associated with lower admission rates. However, greater clustering was associated with higher admission rates.

Clinical implications

Our findings support the hypothesis that larger ethnic groups have lower rates of admission. This was a between-group comparison rather than within each group. Our findings do not support the hypothesis that more clustered groups have lower rates of admission. In fact, they suggest the opposite: groups with low clustering had lower admission rates. The BME population in the UK is increasing in size and becoming less clustered. Our results suggest that both of these factors should ameliorate the overrepresentation of BME groups among psychiatric in-patients. However, this overrepresentation continues, and our results suggest a possible explanation, namely, changes in the delivery of mental health services, particularly the marked reduction in admissions for depression.

It has been known for some time that Black and minority ethnic (BME) groups are overrepresented among psychiatric in-patients in the National Health Service (NHS).¹ The Count Me In census confirmed that this overrepresentation persists and may be becoming more pronounced.² The census also consistently demonstrated significant variation between BME groups, with most having higher rates of admission but some having lower rates compared with the national average. These differences in admission rates are likely to be explained by three main factors: differences in the incidence and rates of mental disorder; service-related factors, such as pathways into in-patient care; and changes in the size and distribution of the ethnic minority groups in the UK.^{1,3-5}

Background

One of the earliest demonstrations of the ethnic density hypothesis was the study of psychiatric admission rates in Chicago by Faris and Dunham.⁶ Several subsequent studies have supported this idea of a ‘protective’ ethnic density effect, whereby individuals living in areas with a greater proportion of people of the same ethnicity have better health.⁷⁻¹⁰ However, not all studies have consistently found results that support the ethnic density hypothesis.¹¹ A study at a wider regional scale in England failed to show any effect within individual ethnic groups, although there was some evidence to support differences between ethnic groups.¹²

In response, Halpern argued that within-group ethnic density operates at a local level, for example, by reducing levels of ethnic discrimination and increasing levels of social support, and may not be detected when the scale of investigation is at a regional or national level.¹³ Halpern made two predictions about between-group effects that might be evident at a larger scale: (a) smaller ethnic groups will tend to have higher psychiatric admission rates than larger groups, and (b) groups that have a stronger tendency to cluster together will tend to have lower admission rates. We aimed to empirically test these two predictions at a national level in England by linking NHS mental health admission rate data from 2005/06 to UK census ethnic group population estimates, and examining national level mental health admission rates for each BME group according to the population size of each group and the degree of clustering of each group across England.

Method

Rates of admission were calculated for the 16 ethnic groups as used in the UK census, while controlling for age and symptom type.

Population

The population size of each ethnic group was obtained from the ‘Understanding Population Trends and Processes’ section of the Ethnic Group Population Projection (ETHPOP) database. This is a web resource maintained by the University of Leeds, which provides projections of each ethnic group at various levels, including the national level.¹⁴

The index of dissimilarity was used as a measure of clustering for each ethnic group.¹⁵ This ranges from 0 (indicating full integration) to 100 (indicating full segregation). An index of less than 40 indicates low levels of segregation, while one of 40 or more indicates moderate to high levels of segregation.¹⁶ Data were obtained from the Centre on Dynamics of Ethnicity website.¹⁷

Number of admissions and symptom type

Routine clinical data were used. The numbers of in-patient episodes in the NHS (finished consultant episodes) in 2005/06 were obtained for three broad diagnostic groups: schizophreniform (schizophrenia and related disorders), mania (manic episodes) and depression (unipolar and bipolar depressive episodes).

Age at admission

Five age bands were created: 10–19, 20–29, 30–39, 40–49 and 50–59 years. The age range was restricted to 10–59 years for two reasons. First, there are far fewer admissions for these diagnostic groups prior to the teenage years. Second, beyond 60 years of age, the population size of several ethnic groups is so small, even at the national level, that there are too few admissions for the calculation of meaningful rates to be possible.

Rates

Rates of admission were calculated per 100 000 population for each ethnic group. Age standardisation was used to compare the 16 groups by assuming each group had the same population as the European standard.

Relative rates

The average rate of admission for BME groups was compared with the White British group to calculate relative rates for each of the 10-year age bands.

Outlier

One group (other Black) had rates that were consistently outside the spread of the other groups. Subsequent years of the Count Me In census showed that this was the one group that decreased in size as self-recording of ethnicity improved instead of staff recording of ethnicity. An adjustment was made by distributing the excess admissions among four other groups (Black Caribbean, Black African, mixed White and Black Caribbean, and mixed White and Black African).

Results

Rates of admissions

The average (s.d., range) age standardised rates of admission per 100 000 were 139.3 (89.9, 46.7–335.0) for schizophreniform disorders, 30.0 (16.3, 6.6–53.5) for mania and 66.9 (23.9, 21.9–106.6) for depression. There was an eightfold difference in rates of schizophreniform and mania admissions, and a fivefold difference in the rate of depression admissions, between ethnic groups. The rate of admission in the White British group was within the range for all three types of admission, albeit at the lower end of the range for schizophreniform (59.3) and mania admissions (14.3), and the middle of the range for depression (63.7).

Relative rate of admission

In each of the 10 year age bands, the average relative rate of admission for BME groups was higher than that of the White British group for schizophreniform and mania admissions, but not for depression. These differences were most pronounced in younger age bands and tended to decrease with age. The relative rate of admission for mania dropped the most, from 3.5 (1.6–5.4) to 1.7 (1.2–2.3). The relative rate of admission for schizophreniform disorders dropped from 2.9 (2.0–4.0) to 2.3 (1.6–3.1). In depression, the relative rate was 1.5 (0.9–2.2) in those aged 10–19 years and 1.1 (0.8–1.3) in those aged 50–59 years (*Fig. 1*). *Fig. 1* Average relative rates (with confidence intervals) of admissions for BME groups compared with the White British group. Data are shown separately for schizophreniform (red), mania (blue) and depression (black) admissions. Data are for England 2005/6.

Association of rate of admission with group size and clustering

The mean (s.d.) index of dissimilarity score for the 16 ethnic groups (including White British) was 46% (13) with a range of 27–67%. The average population size for those aged 10–59 years was 2116 k with a range of 65 k to 28 170 k. There was a moderate positive rank correlation between the index of dissimilarity score and rates of admission for schizophreniform disorders, and a weak correlation with rates of admission for mania, and no correlation with rates of admission for depression. By contrast, there was a weak or moderate negative rank correlation between the size of each of the 16 ethnic groups and the corresponding age-standardised rate of each category of admission (*Table 1*). *Table 1* Spearman's correlation between age-standardised rates of admission and ethnic group population size and the index of dissimilarity score for each group

Category	ρ	P	N
Schizophreniform	+0.50	0.04	16
Mania	+0.20	0.46	16
Depression	+0.04	0.88	16

Population aged 10–59

Category	ρ	P	N
Schizophreniform	0.39	0.14	16
Mania	0.47	0.06	16
Depression	0.21	0.44	16

Ethnic groups with populations aged between 10 and 59 years that were larger than half a million had relatively low rates of admission. Smaller ethnic groups with low levels of clustering (<40% index of dissimilarity) also tended to have lower rates of admission. Smaller ethnic groups with high levels of clustering (>40% index of dissimilarity) had higher rates of admission.

This pattern was most evident in schizophreniform admissions, where rates were on average three times higher in small clustered groups than the rates in groups with a larger population size. The rates of admission for mania were twice as high in smaller ethnic groups with high levels of clustering when compared with rates of admission for mania in ethnic groups with a larger population. The increase was least evident in depression admissions, where rates were about 40% higher in small clustered groups than the rates in groups with a larger population size (*Table 2*). *Table 2* The rate of admission in 16 ethnic groups including White British for schizophreniform, mania and depression admissions, according to large or small group population size and high or low group clustering.

Category	Population > 500 000	Population < 500 000
Schizophreniform	71.673	10206.4
Mania	17.919	341.3
Depression	56.950	880.0

1

The data are for 16 ethnic groups in England.

Discussion

In line with previous studies, our results demonstrate an increased rate of admission in the majority of BME groups. There was significant variation in admission rates between ethnic groups, and there appeared to be an interaction with age. According to our results, the greatest increase in admission rates was in teenagers and young adults. By contrast, the AESOP study indicated that the incidence of psychosis remains raised in ethnic minority groups throughout the age range of our study.¹⁸ This may indicate a reduced risk of (re)admission with increasing age in BME groups relative to the White British population.

Our findings provide support for the hypothesis that larger ethnic groups have lower rates of admission. This is a between-group effect rather than a within-group effect. In this study, located in England, which has a population aged 10–59 years of 40 million, ethnic groups with populations over half a million had lower rates of admission. Our findings do not support the hypothesis the more clustered groups have lower rates of admission. In fact, they suggest the opposite: groups with low clustering had lower admission rates. Again, it is important to emphasise that this study only looked at between-group effects and did not investigate within-group effects.

The BME population in the UK is increasing in size and becoming less clustered.¹⁶ Our results suggest that both of these factors should ameliorate the overrepresentation of BME groups among psychiatric in-patients. However, the Count Me In census indicated that this overrepresentation continues. The answer may lie in changes in the delivery to mental health services. We have previously shown that although rates of admission have fallen across England, one of the largest reductions has been in admissions for depression, whereas admissions for schizophrenia and mania have shown only a modest, if any, reduction.¹⁹

In this work, we have shown that the increased rate of admission for BME groups was confined to schizophreniform disorders and mania, but was not found in depression. Therefore, all other things being equal, reducing the rate of admissions for depression alone will have the unintended consequence of increasing the overrepresentation of BME groups in the psychiatric in-patient population. The same applies to interventions that are more effective in reducing admissions in adults over 35 years of age than in younger adults, such as crisis resolution home-based treatment (<http://www.ethpop.org>).

Limitations

Gender-specific data were not available; hence, standardisation by gender was not possible. The diagnostic information was from routine clinical practice. For the majority of patients, ethnicity was self-determined, but for a minority of patients the ethnicity category would have been picked by staff.

It is impossible to avoid the ecological fallacy when analysing population level data. This ecological study was undertaken at a national level and, therefore, the results may be affected by the ecological fallacy (i.e. associative results observed at this national level are not necessarily replicated at the individual or smaller geographical levels.²⁰ However, the finding of an association between ethnic groups and higher rates of detention is fully consistent with a number of studies that have found higher rates of psychosis and admission among individuals from BME groups.

Local area of residence is likely to reflect aspects of group membership dynamics, such as local ethnic density, dissimilarity and sense of membership. These are likely to be more fluid than individual-level variables. We argue that ethnicity may operate at various levels, including those of the individual, local area, region, and nation, and perhaps even beyond national boundaries; however, our national-level data did not allow us to investigate these nuances.

This study included information on the number of admissions in England for each ethnic group. It did not have access to any individual-level data or local area data. A further study is required with a more detailed data-set, including detention outcomes recorded at individual, local area, regional and national levels, and corresponding explanatory variables as in our previous study.²¹ Dual diagnoses, specific substance use and multiple admissions should all be considered in future studies.

Clinical implications

If these associations are replicated, then this study has several implications. The first is that as ethnic groups increase in size and become more evenly spread, relative rates of admission will fall.

Second, any change in the pattern of admission, according to broad diagnostic group, symptom type or age, is likely to affect the ethnic make-up of the psychiatric in-patient population. For example, home-based treatment as an alternative to admission has been shown to be more effective for depression and for adults over the age of 35. An indirect consequence of this could be an exacerbation of the overrepresentation of BME groups among the remaining in-patient population.

Future research in this area will model the effects that population change and changes in psychiatric practice since 2005/6 have had on the psychiatric in-patient population over the subsequent decade.

- *Donald Eccleston, FRCPsych, PhD, DSc*

Formerly Professor of Psychiatry, Newcastle upon Tyne Medical School, UK

2018/S2056469418000608_inline1.jpg

Donald (Don) Eccleston, who died recently at the age of 86 years, was one of the first to elaborate a hypothesis of depression which argued for the role of monoamines, particularly 5-hydroxytryptamine (5-HT), in the regulation of mood. He went on to translate his experimental observations into treatment for patients with refractory depressive disorders, devising the ‘Newcastle cocktail’ (phenelzine, L-tryptophan and lithium). This was a pharmacological strategy offering a window of opportunity through which cognitive-behavioural therapy (CBT) and intensive nursing care could be directed to reduce the secondary handicaps of chronic depression.

In 1962, he took up a post at the Medical Research Council (MRC) Brain Metabolism Unit at the University of Edinburgh, joining a highly innovative group of psycho-pharmacologists including George Ashcroft. Between them, over the next decade, they elaborated the role of amines, in particular 5-HT, in the regulation of mood. In the absence of today’s sophisticated imaging and analytical techniques, these must have been difficult experiments to conduct; his

first published paper describes measuring changes in 5-HT metabolites in volunteers who were being investigated for neurological disorders by air encephalography, a procedure in which most of the cerebrospinal fluid was drained from around the brain by means of a lumbar puncture and replaced with air.

In 1966, he spent an enjoyable year at the National Institutes of Health in Bethesda, Maryland, USA, where he worked with Julius Axelrod – one of the three winners who shared the 1970 Nobel Prize in Physiology or Medicine for their discovery of the actions of neurotransmitters in regulating the metabolism of the nervous system. He then returned to Edinburgh to be appointed Deputy Director of the MRC unit, where he continued to elaborate the monoamine hypothesis of depression by demonstrating that drugs which influence mood in humans may alter the turnover of 5-HT, and levels of 5-HT, in the brains of animals.

On appointment to the Chair of Psychiatry in Newcastle upon Tyne in 1977, he set up his own research unit at 1–4 Claremont Terrace and established the Regional Affective Disorders Unit, the longest-standing in-patient unit for the treatment of depression in the UK. The Newcastle Chronic Depression Study, published in 1987, described new therapeutic approaches to treatment-resistant chronic depression, including the use of CBT, which was just emerging from US research as having antidepressant potential. The Chronic Depression Study demonstrated a now well-accepted principle in the treatment of chronic depression, namely that intensive drug treatment may be a necessary preliminary that enables effective rehabilitation of the secondary handicaps. Donald promoted development of psychotherapeutic treatments, particularly CBT, and innovative nursing practices for his patients, and became increasingly interested in predictors of refractory depression and its prophylaxis.

While he was Head of the Academic Department of Psychiatry in Newcastle, lecturer and fellowship posts in his department were always in demand; it was a happy place to work, with many appointees going on to professorial appointments in psychiatry, psychology, nursing and neuroscience, both within and beyond Newcastle. He also trained a generation of research-supportive National Health Service (NHS) clinicians who, through him, had been exposed to evidence-based medicine just as the term began to be coined. Early on, he realised the limitations of an academic ivory tower. As the management of the NHS started to change, he recognised the mutual benefits of close partnerships between academia and care providers.

Born in Preston, Lancashire, Don was encouraged by his local general practitioner to consider a career in medicine, even if only to get enough money to support his preferred option of working on the land! He attended Preston Boys' Grammar School. After leaving school, Don studied medicine in Aberdeen, balancing bookwork with what became lifelong interests: fishing, tennis and squash. In 1958, he married Maureen (Mo) Ellison and they settled in Aberdeen where he had commenced psychiatric training.

He was an early advocate of work–life balance, and this at a time when medical prowess was generally measured by how much time one spent at work. In addition to his family life, home and animals, Don made sure that he found plenty of time for his friends, his love of food and wine, fishing, squash, gardening and his art collection. His welcoming family home, West Luddick House, with its walled garden and greenhouses, was populated not only by Don and his family, but by generations of cats, dogs and hens. The monthly entry in his diary for 'the Melrose Clinic' was a euphemism for a day's fishing in the Scottish Borders and wasn't the most closely guarded secret from those around him.

After retirement in 1995, at the age of 64, Donald continued to see patients and remained involved in University life, but had more time to busy himself with his cottage deep in the Borders where he spent happy days foresting and looking after the land. He benefited from modern surgical advances, with a total of five joint replacements that kept him mobile. He died suddenly at home on 18 March 2018.

Don is survived by his wife Mo, three children and five grandchildren.

1.5.75 The outcomes of home treatment for schizophrenia

Hannah Chu Han Huang Mark Taylor Alasdair Carmichael

Correspondence

M. Taylor (marktaylor2@nhs.net)

date

2018-12

Abstract

Aims and method

We examined whether intensive home treatment (IHTT) was beneficial for acute schizophrenia, using the Clinical Global Impression (CGI) scale as a measure of severity and change, between 2011–2015. Demographic and clinical details were collected.

Results

309 cases were referred to IHTT, comprising 245 separate individuals. This represented all severe acute psychotic episodes in Edinburgh during the study period. Three quarters of individuals had an improvement in CGI following IHTT and were safely managed at home. Thirty-nine per cent of all people received three or more regular medications. Comorbid drug and alcohol misuse was also frequently seen.

Clinical implications

IHTT can be beneficial to those suffering an acute episode of psychosis and has been shown to improve overall clinical outcome based on the CGI. Medication polypharmacy, as well as drug and alcohol use, are commonly seen in this population.

Declaration of interest

M.T. worked in IHTT at the time of the study, and has received fees and/or hospitality from Janssen, Lundbeck and Otsuka in the past 3 years.

Background

Crisis resolution and home treatment (CRHT) teams have been recommended in mental health for many years,¹ with intensive 24 h home treatment being seen as an alternative to hospital admission. A randomised control trial reported by Johnson *et al*¹ showed a reduction in the number of hospital admissions as well as a decrease in the cost to the service² with CRHT. There have been positive experiences for patients or consumers of CRHT,³ although reports have also highlighted some dissatisfaction, namely that too many staff members are involved and the contacts are short-lived.⁴

The Edinburgh CRHT is called the Intensive Home Treatment Team (IHTT)³ and has two main points of entry into treatment – referral from the community (either from primary or secondary care) and from in-patient units to facilitate early discharge from hospital (but no self-referral). Edinburgh has well developed community mental health teams but no specific first episode or early intervention programme for adult psychosis; therefore, as far as is known, all acutely relapsing patients with schizophrenia and psychosis are referred to the IHTT.

Coping with schizophrenia and related psychoses remains a challenge, and globally⁵ schizophrenia contributes 7.4% of all lost years of life to all disabilities. Relapse of schizophrenia, sadly, is common, with only about 20% of patients having only one episode of psychosis.^{6,7} Predictors of relapse include medication non-adherence and comorbid substance misuse,^{6,7} and relapse is considered a time of increased risk of suicide in schizophrenia.⁸

Aims

Although there have been reports of patient satisfaction with CRHTs, very few studies have examined how a CRHT affects patients' clinical outcomes. In this observational study, we examine whether intensive home treatment was of benefit to people experiencing a relapse of schizophrenia in terms of routine clinical outcome measures, and identify the demographic and clinical characteristics of those who have responded (or not) to this intervention.

Method

Data were collected retrospectively from medical records of patients assessed and cared for by the IHTT between 2011 and 2015. Those with an ICD-10 code diagnosis of schizophrenia (F20) and related disorders (F22 – delusional disorder, F23 – acute transient psychosis, F25 – schizoaffective disorder, F28 – other psychotic disorder not due to substance or known physiological condition, and F29 – unspecified psychosis not due to a substance or known physiological condition) were included. The validity of the diagnosis was established by consultant psychiatrist review. Using unique identifying codes, the electronic records of these patients were retrieved and reviewed using *a priori* criteria. Ethical approval for the study was provided by the University of Edinburgh, UK.

IHTT records the severity of the presenting mental disorder using the Clinical Global Impression Scale⁹ (CGI) at the time of referral to IHTT. The CGI objectively assesses the global severity of illness and change in clinical condition over time.⁹ CGI-S is rated on the following seven-point scale: 1, normal/not at all ill; 2, borderline mentally ill; 3, mildly ill; 4, moderately ill; 5, markedly ill; 6, severely ill; 7, among the most extremely ill patients. CGI-I is similarly rated on a seven-point scale: 'compared with the patient's condition at admission, this patient's condition is' 1, very much

improved: 2, much improved; 3, minimally improved; 4, no change; 5, minimally worse; 6, much worse; 7, very much worse. IHTT clinicians noted the improvement or lack thereof in the presenting condition via the CGI-Improvement (CGI-I) score at the point of discharge from IHTT. This was routinely rated for every patient during his or her care with the team by an adequately trained clinician, although the pattern of staff shift working meant that the CGI and CGI-I for an individual patient were not always rated by the same clinician.

Other data collected for each patient included demographic details and relevant clinical details (see Supplementary Appendix 1 available at <https://doi.org/10.1192/bjb.2018.56> for full list), as well as data about each patient's regular medication(s) (see Supplementary Appendix 2 for a list of categories).

Statistical analysis

Unpaired *t*-tests were used (with the assumption of normality in CGI distribution being satisfied) to test whether there was a statistically significant change in CGI for patients who were discharged to the community, compared with those who required hospital admission, as well as to determine whether there was a statistically significant reduction in CGI for all referrals treated by IHTT.

Pearson's ²-test was used to test the hypothesis that people who were not prescribed medication or were non-adherent with their medication were more likely to be admitted to hospital than patients who were taking prescribed medication.

Mixed model regression analysis was used to control for any confounders that could be significantly associated with CGI difference. Variables included as potential confounders were age, gender, treatment duration, number of psychotropic medications prescribed, and drug and alcohol status. Pearson's correlation was also conducted to see whether there was a correlation between CGI and age or gender.

Results

Demographics of patient population

Over the 5-year period, there were 309 referrals to IHTT that met the inclusion criteria, comprising 245 separate individuals with the majority (82%) being new to IHTT and mental health services. Thirty-six individuals were referred more than once, with 16 people being referred to IHTT at least three times. One person was referred on five separate occasions, and another individual was referred seven different times. The patients referred had a mean age of 41 years, and 162 (52%) were men (*Table 1*). *Table 1* Demographics of individual referrals *N* = 309 Age, mean (range), S.D. 40.4 (18–66), 12.0 Male gender, *n* (%) 158 (51) Number of psychotropic medications prescribed, mean (range), S.D. 1.6 (0–4), 1.0 Treatment duration in days, mean (range), S.D. 22.3 (1–167), 23.2 Drug use: *n* (%) 23 (7.4) Alcohol use: *n* (%) 46 (14.9) Both drug and alcohol use: *n* (%) 26 (8.4)

Referrals and outcomes

The majority of the 309 referrals to IHTT over the 5-year period (56%, *n* = 173) were from the community. The remaining 44% of referrals were from in-patient units, in order to facilitate early discharge from hospital.

In terms of outcomes at discharge from IHTT, a total of 221 referrals (76%) were discharged to the community, and 70 referrals (24%) required transfer into hospital owing to their risk status or severity of illness. Twenty-seven per cent of repeat referrals were discharged to hospital, compared with 23% of 'one-off' referrals (*P*-value = 0.6).

There were five deaths (2%) within the 5-year period, including one suicide, from the total group of 255 people. None of those who died were under the care of IHTT at the time of death. Two of the deceased had a history of extensive alcohol and drug misuse. All five of those who died had a history of repeated hospital admissions. The suicide occurred in December 2013, after an urgent referral to hospital, but the person was not deemed unwell enough for admission at that time.

Fifty-two per cent (14 referrals) of the 27 referrals who were on no regular medications, or who were non-adherent with their medications, went on to require hospital admission, in comparison with 20% of patients who were taking at least one medication, and 24% of all referrals.

Eighteen referral outcomes were missing from records throughout the 5-year period.

CGI

The mean value of CGI of all patients at admission to IHTT was 4.1. The mean value of CGI of all patients at discharge was 3.05, an improvement of 1.05 (Table 2), which was a significant change ($P < 0.05$). Patients who were later admitted to hospital from IHTT had a higher mean value of CGI at 4.2 on admission to IHTT compared with the mean value of CGI of all patients. The mean value of CGI on discharge to hospital in this population was 4.6, i.e. they were more unwell, according to CGI. Table 2 Severity of illness and any subsequent improvement or not with IHTT, as measured by CGI

Year	2011	2012	2013	2014	2015	Total
Average CGI at referral – all patients	3.84	24.34	04.14	1.1		
Average CGI on discharge – all patients	3.33	02.93	32.83	1		
Average CGI at referral, those later discharged to the community	3.84	24.23	94.14	0		
Average CGI on discharge to the community	3.02	92.52	72.22	6		
Average CGI at referral, later transferred to hospital	3.84	34.64	34.14	2		
Average CGI on transfer to hospital	3.53	254.25	05.04	6		

Patients whose clinical outcome was discharge back to their usual carers had a mean value of CGI of 4.04 on admission to IHTT and a mean value of CGI on discharge from IHTT of 2.57. This was a decrease of mean CGI (i.e. improvement in health) of 1.47.

The difference in average CGI between the mean discharge CGI of all referrals and the mean discharge value of patients admitted to hospital was non-significant (1.55, $P < 0.15$). The difference in average CGI, on discharge, between referrals admitted to hospital and referrals discharged to the community was 2.03, a statistically significant change ($P < 0.05$).

The average CGI of all repeat referrals at the beginning of treatment with IHTT was 3.94, 0.11 lower than the average CGI of all referrals. The CGI on discharge for repeat referrals was 3.22, an average decrease in CGI of 0.72. These differences were not significant.

Age, gender, number of medications prescribed and drug/alcohol status were found not to be significant confounders in the regression analysis (see Supplementary Appendix 3). Only treatment duration was found to be a significant confounder, with patients having a longer treatment duration demonstrating a greater difference in CGI.

Medication

Table 3 illustrates the different medications and number of patients taking them: 2.8% of patients were on no medications, 31% were prescribed one medication, 27% were prescribed two medications, 18% were prescribed three medications and 21% were prescribed four or more medications. The mean number of any medications, including non-psychotropic medications, taken by an average patient across the 5 years was 2.1. A total of 27 referrals (9%) refused medication, did not require medication or were judged as non-adherent. Table 3 Medications prescribed

Year	2011	2012	2013	2014	2015	Total
FGA	243	232	352	614	9	1518
SGA	151	84	55	85	71	93
Benzodiazepines or other hypnotic	81	02	63	92	71	110
Antidepressants	64	131	22	15	6	221
Mood stabilisers/anticonvulsants	42	56	21	9		125
Other medications	68	102	03	07	4	184
No medication	2	12	38			52
No information	7	21	37	20		85
Mean number of medications	2.01	1.61	1.92	2.22	0.2	1.1 ¹

Pearson's χ^2 -test showed that patients who were taking no medications, or were non-concordant with their medication, were more likely to be admitted to hospital from IHTT compared with patients who were taking at least one medication ($\chi^2 = 43.3$)

¹ FGA, first-generation antipsychotic; SGA, second generation antipsychotic.

Drug and alcohol use

In total, 122 (39.5%) referrals were misusing either alcohol or drugs (*Table 4*) as rated by the IHTT clinician. The drug use was varied and often involved poly-substance misuse. Cannabis had the highest frequency of use, followed by amphetamines. *Table 4* Comorbid drug and alcohol misuse

Year	2011 (n = 42)	2012 (n = 33)	2013 (n = 60)	2014 (n = 80)	2015 (n = 94)	Total (n = 309)
Drugs	7 (17%)	8 (24%)	19 (32%)	27 (34%)	22 (23%)	83 (27%)
Excess alcohol	18 (19%)	9 (27%)	19 (32%)	24 (30%)	13 (14%)	73 (24%) ²

Discussion

Crisis resolution and home treatment teams, such as IHTT, are designed to manage acute mental health problems in the individual's home environment, minimising the risk of hospital admission while promoting autonomy and self-efficacy. It is incumbent on health services to demonstrate the effectiveness of their interventions, and IHTT from inception chose the CGI as an observer-rated measure of illness severity and subsequent improvement (or deterioration).

Our results show that 76% of people were discharged back to their usual care after IHTT involvement following an acute episode of psychotic illness, supporting the conclusion that IHTT can help people manage an acute psychotic episode, and avoid hospital admission. This belies a negative therapeutic outlook for schizophrenia, with the majority of people with schizophrenia in crisis or relapse avoiding the need for hospital care.

The total CGI score diminished by 1.05 for the whole sample, and a one-point shift in CGI is usually regarded as a clinically significant change.⁹ Since CGI has been shown¹⁰ to be an effective method of mapping illness severity, with reliability equivalent to that of more complex scales such as Positive and Negative Symptom Scale (PANSS), we can conclude from our results that the Edinburgh IHTT service, on average, can help reduce the severity of schizophrenia and related disorders. The CGI score of those people discharged home from IHTT improved by 2.03 compared with those being transferred to hospital from IHTT, implying an association between hospital admission and a worsening CGI score, and adding to the face validity of this measure. A study from Taiwan¹¹ also showed that patients with schizophrenia treated with community home care case management had a significant reduction in the frequency of hospital admission, and a systematic review¹² from 2017 showed that home-based intervention improves patients' quality of life and autonomy.

Twenty-four per cent of patients were admitted to hospital from IHTT, and the average CGI score at entry to IHTT of those who were eventually admitted to hospital was 0.16 higher than those who were eventually discharged home. This implies that those with a more severe psychotic relapse were more likely to require hospital admission, although non-illness-related factors such as accommodation were not taken into account in this study.

Of note, the gender ratio of the patient population in our study was almost 1:1, whereas usually one would expect a ratio of 1.4:1 in a population of patients with a diagnosis of schizophrenia.⁵ This may have been due to our inclusion criteria being not just schizophrenia but also its related disorders. Additionally, amongst the five deaths in our patient population over the 5-year period there was only one suicide, which is theoretically lower than expected for this city-wide population.⁸ Beyond this, however, we have no reason to regard our study population as unrepresentative, given the lack of local alternative acute care pathways.

2

Number and percentages of referrals with a history of use of illegal drugs or legal highs declared within records, and number of referrals with significant alcohol-related history, e.g. consistently over weekly recommended allowance, often by a considerable margin.

The mean number of medications a patient was taking was 2.1, with 21% of patients prescribed four or more medications. This replicates work elsewhere in the UK,¹³ indicating that polypharmacy in this complex disorder is often the ‘real world’ norm, despite a paucity of supportive evidence on added efficacy.¹⁴⁻¹⁵ Polypharmacy is also generally associated with an increased burden of adverse side-effects.¹⁶ Our results show that people who were taking no medication, or were non-adherent with their medications, were more likely to be admitted to hospital than those taking medication. Interestingly, patients taking four or more medications demonstrated the most improvement, as measured by CGI-I.

Our results showed that 9% of the patient population in this study were taking no medication or were non-adherent with medication according to recorded clinician ratings, although medication non-adherence rates in wider community samples are closer to 50%.¹⁷ This discrepancy may have been due to many factors, including simple forgetfulness, a reluctance of the patient to acknowledge non-adherence, and a failure to enquire about it in a consistent manner.

Drug and alcohol misuse are common in people with schizophrenia,¹⁸ and our results show a higher proportion of people with schizophrenia misusing drugs than alcohol (*Table 4*), suggesting a correlation between drug use, rather than alcohol misuse, and schizophrenia. Menezes *et al*¹⁹ analysed drug and alcohol problems among 171 individuals with severe mental illness in South London, finding that 36% had a 1-year prevalence rate for any substance problem, compared with alcohol at 32% and drugs at 16%, contrary to our findings. This comorbidity has been shown previously to contribute to the premature mortality of those with schizophrenia.²⁰

Limitations

There were various limitations to this study. First, the patient population was from one IHTT only; therefore, the results may not be applicable to all IHTTs or CRHTs. Furthermore, this was an observational study, so comparative conclusions should not be made. Although CGI has been shown to be a good measure of observer rated clinical outcomes,¹⁰ it remains open to potential bias. Finally, data collection errors may possibly have occurred without our knowledge.

Summary

Intensive multi-disciplinary home treatment (here via IHTT) can be an effective intervention for most people suffering an acute episode of psychotic illness, with the majority being successfully managed at home and not requiring hospital admission. The minority that do go on to need hospital admission tend to have higher initial severity of illness, as measured by CGI, as well as being on no medication or being non-adherent with medication according to their treating clinicians.

Polypharmacy appears to be standard medical practice for people with schizophrenia, despite a lack of supportive evidence of added efficacy. Drug and alcohol misuse are common in people with psychotic illness, with higher rates than in the general population, arguably contributing to the significant morbidity and mortality seen with this condition.¹⁹

We thank Dr Kader, Julie, Trish and all other IHTT staff, as well as Nicoletta Adamo.

Lachlan Campbell has a point. My own view is that children under the age of 14 are unlikely to have sufficient emotional maturity or knowledge to make an informed decision as to whether to engage in sexual intercourse.

John Eagles's first novel is a rollicking tale of a young psychiatrist in the early 1980s, on the threshold of his career. Unfortunately, this promising career is nearly terminated as a consequence of various antics – alleged and otherwise – and the book culminates in a visit to the General Medical Council after the protagonist, Dr Douglas Barker, is accused of sexual misconduct with a patient.

This book was easy to read and something of a page-turner, but ultimately the characters were rather difficult to like. Douglas, who is clearly meant to be a nice chap, has a hint of arrogance that detracts from any potential sympathy for his plight. His approach to women centres on their appearance and he has no compunction in forming quick and easy relationships. There are allusions to his lost girlfriend, Spider, possibly in an attempt to account for his behaviour, but this is never really developed in a credible way. Most of the women in the book are minimally developed as characters, either presented as sexually attractive, needy, unpleasant or a combination of these. Pauline, a nurse who supports Douglas at his hearing, may be an exception. However, at the end of the book, Douglas rather disappointingly refers to her as sexy and it also becomes evident that she lied for him; suggesting that she may not be an exception after all.

Douglas's best friend, Chris, is another male psychiatric trainee from the west of Scotland, with a rather stereotypical accent and drinking habit. Both his educational supervisors are men and both of them are rather unlikely characters, particularly Dr Burlington, who speaks in a strange psychopathological manner, involving bizarre words that often start with consecutive letters of the alphabet. Dr Burlington is actually unbelievably nasty, but there is no hint as to why this is, which might have created some more tension. There are two female trainees in the story: Douglas has a fling with one before casting her off to Chris, the other achieves a liaison with the much older, married psychotherapy consultant. It would have been good to have incorporated an intriguing female character with a storyline beyond providing interest to the male characters of the book.

There is potential historical interest to current trainees, who may like to read about training practices and services nearly 40 years ago. Some things don't change and the patients' presentations and many treatments remain similar; but it is a very different job now.

However, my main difficulty with this book was the denouement (spoiler alert). Douglas was technically innocent because he had slept with the patient in question before she was a patient, and he had forgotten due to his previously unmentioned facial agnosia. But any opportunity for exploration of such an unusual ethical dilemma was then subsumed in a drunken train journey, in my view a great loss.

We are called, as citizens and as professionals, to sit down and examine the facts. We must somehow assimilate the bewildering array of information, as it hurtles towards us, through our screens and across our airwaves, to get to the truth of the matter.

In our clinical lives, this becomes a responsibility and the challenge here is considerable. The public perception of mental illness, its fixation with ‘madness,’ is fertile ground for the development of half-truths, fallacies, myths and speculations. Publicly and privately propagated, we amass a compendium of ‘alternative facts,’ harmful to our patients as well as to our professions.

Psychologists Arkowitz and Lilienfeld are having none of it. They have subjected our day-to-day assumptions to a rigorous interrogation, pitching them against the most current evidence, to separate fact from fiction. Their book is presented neatly into sections by diagnostic category, each comprising a collection of bite-size chapters, asking questions such as: *What is a psychopath? How violent are people with mental illness? Can herbs ease anxiety and depression? Is divorce bad for children?* The questions they select feel current, the sort frequently encountered in the public domain, making the book highly suitable for a general readership. It is also probably quite helpful for mental health professionals, who may read the pages with the occasional blush, when they find a long-held position ruthlessly upended.

At times the book feels a little political, particularly in its service to psychological therapies; there is a sense that the authors feel a duty to redress the pharmaceutical dominance in mental health treatments. Though perhaps a worthy pursuit, this sits a little uneasily as a potential source of bias in a book that sets itself up on a truth-seeking mission.

Nevertheless, the book is a steadying force in a world where we now take a rather relaxed attitude to accuracy. Where the truth is often obscured by a more marketable headline, it is important as professionals that we anchor ourselves as far as we can in the facts. Arkowitz and Lilienfeld are to be thanked for doing a lot of the hard work for us.

1.5.77 Patients with depression who self-refer for transcranial magnetic stimulation treatment: exploratory qualitative study

Martin Clarke Sudheer Lankappa Mark Burnett Najat Khalifa Charlotte Beer

Correspondence

Dr Martin Clarke

(martin.clarke@nottshc.nhs.uk)

date

2018-12

Abstract

Aims and method

As part of a larger clinical trial concerning the use of transcranial magnetic stimulation (TMS) for treatment-resistant depression, the current study aimed to examine referral emails to describe the clinical characteristics of people who self-refer and explore the reasons for self-referral for TMS treatment. We used content analysis to explore these characteristics and thematic analysis to explore the reasons for self-referral.

Results

Of the 98 referrals, 57 (58%) were for women. Depressive disorder was the most commonly cited diagnosis, followed by bipolar affective disorder. Six themes emerged from the thematic analysis: treatment resistance, side-effects of other treatments, desperation for relief, proactively seeking information, long-term illness and illness getting worse.

Clinical implications

TMS has recently been recommended in the UK for routine use in clinical practice. Therefore, the number of people who self-refer for TMS treatment is likely to increase as its availability increases.

Declaration of interest

None.

Depression

Approximately one-half of patients with depression do not achieve an adequate response to antidepressants.¹ A review found that approximately one-third of patients with depression showed no response while some achieved only a partial response to treatment, as operationalised by a reduction in depressive symptoms.²

Brain stimulation technique

Electroconvulsive therapy (ECT) is a well-established neuromodulation technique used to treat depression,^{3,4} but it is associated with side-effects such as memory deficits⁵ and risks associated with general anaesthesia. This has provided the impetus to develop other brain stimulation techniques, such as transcranial magnetic stimulation (TMS). TMS is a non-invasive brain stimulation technique that induces changes in cortical excitability using high-intensity magnetic pulses delivered through the scalp.^{6,7} It has been used to treat various neuropsychiatric conditions including depression. In the UK, repetitive TMS (rTMS) for depression has been recently recommended for use in routine clinical practice.⁸ In comparison with ECT, TMS treatment confers certain advantages, in terms of tolerability and ease of administration.⁹

The TMS trial

The current study was conducted as part of a clinical trial (TDep TMS trial, Clinicaltrials.gov: NCT02016456), which sought to examine the effectiveness of repetitive high-frequency TMS versus intermittent theta burst TMS in reducing the symptoms of treatment-resistant depression. The trial was conducted under the auspices of the Nottingham Neuro-modulation Unit. The lead trial investigator (S.L.) received emails from patients enquiring about the trial or requesting TMS treatment. Such enquiries were considered important given the generally poor rates of treatment-seeking and self-referral by people with depression.¹⁰

The current study

The self-referral emails offered a novel opportunity to explore why people with depression self-referred for TMS. The current study aimed to explore the referral emails and describe the clinical characteristics of people who self-refer and the reasons for self-referral for TMS treatment.

Method

Design

This qualitative study used self-referral email correspondence to explore the characteristics of patients self-referring and the reasons for self-referral for TMS treatment. Emails had been sent by the self-referrer, their relative or their doctor, and requested TMS treatment for medical conditions (most often depression).

Approvals

This study is part of a clinical trial which has both research ethics and Research and Development approval. Approval to review the content of the referral emails was granted by the Research and Innovation Department of the Nottinghamshire Healthcare National Health Service (NHS) Foundation Trust.

Participants

The participants were people with a health condition, most commonly depression, seeking treatment or further information on TMS. The emails were often sent by the potential participant themselves; however, a few were sent by doctors or family members. These were also regarded as self-referrals because it was clear that they were written on the instruction of, or in collaboration with, the patient. All 98 self-referral emails received between the start of the trial in May 2014 and October 2015 were analysed.

Analysis

Referral emails were redacted to obscure all identifiable patient information. They were analysed using content and thematic analysis. Details about participant characteristics were briefly stated in the emails or in some instances inferred from details such as name, and so content analysis was used to extract and analyse these data. Thematic analysis was used to explore reasons for self-referral, as this approach enables the researcher to explore themes both inductively from the data and deductively based on theory and research.¹¹ Analysis followed Braun and Clarke's six phases of thematic analysis.¹¹ Emails were read and re-read (by M.B.) and, after familiarisation with the data, codes were generated by coding interesting and shared features in a systematic way across all the emails. Codes were sorted into potential themes and the coded extracts were collated into these themes. Analysis proceeded iteratively and was refined in collaboration with another qualitative researcher (C.B.). Themes were defined and coded, following accepted guidelines.¹² Interrater reliability of coding was also assessed; 89% interrater reliability was achieved (scores >70% are considered acceptable).¹²

Results

Participant characteristics

Of the 98 referral emails analysed, in 90 (91.8%), it was clear whether the potential participant or someone else had written the email. Of these, the majority (78.9%, $n = 71$) were written by an individual who was applying to take part in the TMS treatment, with the others written by doctors (11.1%, $n = 10$) or family members on behalf of the individual (10.0%, $n = 9$). Gender was explicitly stated, or could be inferred from the name, for 83 referrals (84.7%). Of these, there were 48 women (57.8%) and 35 (42.2%) men. Age was provided for 31 referrals (31.6%). The mean age was 44 years (range early 20s to mid-70s). The length of illness was given for 33 referrals (33.7%). Where stated, the mean length of illness was 17 years (range 4 months to more than 40 years). The primary diagnosis was specified for 63 referrals (64.3%). Depression was the most commonly cited diagnosis (88.9%, $n = 56$), followed by bipolar affective disorder (6.3%, $n = 4$) and schizophrenia (4.8%, $n = 3$). Twenty referrals (20.4%) mentioned comorbidities, the most common being anxiety (50.0%, $n = 10$).

Reasons for self-referral

Thematic analysis of the data revealed six themes that explained the reasons for self-referral for TMS treatment. The self-referral emails varied widely in the depth of detail provided, and themes were expressed in very diverse ways. Given that there were 98 emails, the prevalence of themes was reported (*Table 1*). This is important since a powerful and memorably described theme might assume disproportionate importance. *Table 1* List of themes

Theme	Number of participants identifying with theme	Percentage
1. Current treatment not working	39	39.8%
2. Proactively seeking information about treatment for depression	29	29.6%
3. Suffering from chronic or long-term depression	25	25.5%
4. Desperate for relief from depression	13	13.3%
5. Motivated to seek alternative treatment owing to side-effects of current or previous treatment	12	12.2%
6. Getting worse in spite of current treatment regime	6	6.1%

Current treatment not working

This theme was coded in 40% of the emails. The most commonly cited reason for self-referral for the TMS trial was lack of, or only limited response to, treatment despite undergoing various treatment modalities. For example, one email described constant relapsing even after many different treatments. “I have tried various medications, CBT and Mindfulness but I relapse again and again (W7, Female).”

Another email described how treatment, including ECT, had never worked, even partially or for a short period of time. “I have tried at least 20 different types of anti-depressant tablets ... none of which have worked. I have also had [sic] 2 courses of ECT and several years of CBT (both group and individual) all with no effect (M15, Male).”

This theme reflects the definition of treatment resistance used in the wider study, namely the ‘failure to improve or only partially improve after trying two or more antidepressants or two or more psychotherapies/ECT’. Indeed one writer explicitly stated that her mother’s depression was treatment resistant. “... has suffered with what is proving to be treatment resistant depression for over 12 months (W61, Female).”

Suffering from chronic or long-term depression

Another important motivator for self-referral was experiencing chronic or long-term depression, with this theme coded in a quarter of the emails. For example, one writer stated that he had suffered with depression for more than 20 years. “I have been suffering with depression for over 20 years (M30, Male).”

‘Desperate’ for relief from depression

For some participants, their self-referral was prompted by their desperation for relief from depression (13%). One writer powerfully described how he was not even really ‘living’ and was desperate for this to happen. “I am desperate of finding a way to start living and enjoining [sic] life again (M3, Male).”

Another writer described their increasing state of despair. “As I feel that age and time are against me, and I feel that I am slipping further and further down the well of total despair (M15, Male).”

These calls for help are all the more powerful given that they were sent to a clinician with whom the patient had no therapeutic relationship. Such desperation is clear in the following plea. “Sir, I have no idea where to turn next, please offer me some help and hope before my marriage is stretched beyond it’s [sic] tolerance – before it is too late (M7, Male).”

For some, this desperation was caused by depression affecting their ability to function normally. This impaired functionality often affected the participant’s ability to work. It also manifested in other ways such as problems with social functioning and lack of motivation. One email described how the writer had previously had a good career, but depression had significantly affected this and resulted in him losing his job. “Although I had a good professional career, 2 postgraduate degrees, my personal, social and working life is seriously limited by depression (I lost my job as well) (M3, Male).”

Another email described how his social life had been affected so badly that he had cut himself off from those around him. “Have not been able to work since and have now become a recluse cutting myself off from family and friends (M20, Male).”

Another writer talked about how upsetting they found their lack of functionality. “I am finding it very tedious and upsetting that I am unable to do the things I would [want] to do and need to do at times (W46, Female).”

Motivated to seek alternative treatment by side-effects of current or previous treatment

Self-referral was sometimes prompted by a desire to seek an alternative treatment to avoid side-effects. TMS is a treatment with few side-effects; these include headache, nausea, tiredness, syncope and, very rarely, epileptic seizures. As such it was attractive to people who had previously experienced negative side-effects with other treatments. Participants were clearly aware of this and referred in their emails to the intolerable side-effects they had previously experienced. “I was on medication for several years but after coming off I have found it impossible to get back to a medication without intolerable side effects (W1, Female).”

Some participants had received ECT treatment and also had problems with the severe side-effects associated with it. TMS is recognised as having fewer severe side-effects, which is probably why the opportunity to receive TMS was being explored. For example, one email described a patient who had previously tried ECT but could not tolerate it so was looking for a similar treatment but with less severe side-effects. “I attempted ECT with her which she could not tolerate (W11, Female).”

Getting worse in spite of current treatment regime

A small number of people requesting TMS mentioned that their symptoms were worsening despite treatment and that this is what prompted their request to participate in the trial (6%). While this theme appeared in only six emails, it powerfully describes the effect of progressive deterioration on people’s lives, as in the account below of a patient’s relative. “She is now living a twilight existence and progressively deteriorating (W61, Female).”

Proactively seeking information about treatment for depression

An interesting inductive theme that emerged from the data was that for some individuals, the self-referral was motivated by a desire to try newer, unconventional, treatments for their illness (29.6%). Proactive searching of the internet or health-related articles in papers and magazines for novel treatments was how these individuals had found out about the TMS trial.

Many of the patients had significant knowledge about TMS, having previously researched TMS treatment. This theme illustrates how patients with depression wish to be actively involved in exploring treatment choices which are not offered by their general practitioner or psychiatrist. For example, one patient described how they had been researching TMS compared to other treatments they had been offered and had found that it could be better. "I have read and looked at articles regarding TMS and they look promising to cure depression with much better success rate than medications alone or medication and counselling (W7, Female)."

Another patient had been offered ECT but, having researched TMS, decided that TMS was superior to ECT. "I have researched ECT and found that TMS seems to [be] much superior but still evolving as a treatment for depression (M20, Male)."

Discussion

Depression is one of the most commonly cited causes of morbidity worldwide,¹³ with a lifetime prevalence of approximately 8–12%.^{14,15} Depression can result in suicide,¹⁶ which accounts for 1.4% of all deaths worldwide.¹⁷ To our knowledge, this is the first study to describe the characteristics of people with depression self-referring and the reasons for self-referral for TMS treatment, albeit in the context of a trial.

Content analysis of the emails revealed that self-referrers were a heterogeneous group. There was a broad age range, indicating that TMS has a broad appeal across all age groups. Participants had generally experienced their illness for several years. However, the average illness length may be confounded if those who included their length of illness were those who had experienced it for longer. For example, participants may have included their long length of illness to emphasise its severity, perhaps in the belief that it would increase their chance of being accepted onto the trial.

More women than men self-referred for TMS treatment. This is in line with research that has shown that women are more likely than men to seek help for mental disorders,^{18,19} and that depression is more prevalent in women than men.²⁰

Thematic analysis of the emails revealed a number of factors prompting self-referral. The themes offer some important insights into what motivates people with depression to enquire about TMS treatment. The most common theme that emerged was 'current treatment not working'. Other related themes included 'motivated to seek alternative treatment owing to side-effects of current or previous treatment', 'suffering from chronic or long-term depression' and 'getting worse in spite of current treatment regime'. The side-effects of treatments with antidepressants have been well documented^{21,22} and so this was not an unexpected theme. The chronicity and possible long-term nature of depression are also well documented²³ and perhaps unsurprisingly this was mentioned in one-quarter of self-referrals. Self-referrers also reported that their symptoms were 'getting worse in spite of a current treatment regime'. Although this theme was the least common, revealed in only six emails, it was powerfully described and resonates with the literature on why people seek help,²⁴ and so should not be ignored.

A related and powerful theme was 'desperate for relief from depression'. Participants movingly described their desperation for relief from depression. The lack of treatment options, and not just symptom severity, may contribute to feelings of desperation.²⁵ Evidence of such themes need not exclude participants from trials; as Swift²⁶ commented, desperation affects voluntariness rather than capacity to enter into a trial, and this is related to whether acceptable alternative treatments are available. Moreover, Dunn and colleagues argued that including desperate patients in clinical trials is ethical.²⁵

The themes described above go some way towards explaining why, despite their depression, participants were actively seeking information about treatment. The unexpected and inductive theme 'proactively seeking information about treatment for depression' revealed how participants had found information about the TMS trial while researching alternative

treatments.

To date, no published studies have examined why patients with depression self-refer for TMS. However, gaining access to additional services, such as otherwise unavailable interventions, has been identified as a key facilitator for recruiting people with depression into clinical trials.²⁷ Although TMS was not discussed, the authors noted a preference for interventions that did not involve medication.²⁷ This has important implications for recruitment and resonates with Locock and Smith's study, which found personal benefit to be a primary motivation for volunteering in a research study, more so than altruistic considerations.²⁸ Their study explored the reasons people volunteered to participate in clinical trials across different (mainly physical) conditions, and found that such personal benefits included access to new treatment, access to better information and receiving care from expert specialised teams.²⁸

Limitations

The main limitation of this study was the availability of data. Analyses were constrained by the information available in the initial referral email. Emails tend to be short and contain only information the writer wishes to share. Accordingly, there was no opportunity to clarify information with the participants, and relevant information may have been omitted in the referral email. For example, there were missing data for some of the participant characteristics. Furthermore, the prospective provision of TMS was linked to a clinical trial where participants received an intervention 4 days a week for 4 weeks. Potential self-referrers may have been restricted by this costly and time-consuming commitment, especially for those who lived further afield. However, while these constraints may have had an influence on who ultimately participated in the trial, the email writers were enquiring about, rather than enrolling in, the study. Therefore, the participant demographics may still be credible. Future research should include interviews with participants to explore their reasons for referral to TMS, to see whether similar reasons are identified which support our findings. There was also no opportunity for participants to provide feedback on the findings. It would also be informative to explore whether participants' reasons for referral were related to their response to TMS. However, given that TMS is a relatively new technique and is not yet widely used in the NHS, we are not aware of any previous research on the characteristics of those who request the treatment or their reasons for referral to it, particularly in the UK.

Summary

In conclusion, the 98 people who self-referred for TMS were a heterogeneous group, although the majority were female (57.8%). Thematic analysis of the self-referral emails revealed that participants were motivated by a desire for an effective alternative treatment for their treatment-resistant depression. These findings have implications for how participants for future TMS trials could be targeted; they also suggest an increased demand for TMS as it becomes more widely known. Given the updated guidance recommending rTMS for depression in routine clinical practice in the UK⁸, it is likely that more treatment centres will be developed to facilitate this.²⁹ Prior to this, rTMS was only administered in research settings as National Institute for Health and Care Excellence guidelines stated that although TMS was judged to be safe, there was uncertainty about the clinical efficacy.^{6:30}

1.5.78 Getting a balance between generalisation and specialisation in mental health services: a defence of general services

Abstract

Mental health services in the UK National Health Service have evolved to include primary-care generalist, secondary-care generalist and secondary-care specialist services. We argue that there continues to be an important role for the secondary-care generalists as they minimise interfaces, can live with diagnostic uncertainty and support continuity of care. The lack of commissioning and clinical boundaries in secondary-care generalist services can undermine their feasibility, leading to difficulties recruiting and retaining staff. There is a risk of a polo-mint service, where the specialist services on the edge are well resourced, but the secondary-care generalist services taking the greatest burden struggle to recruit and retain clinicians. We need to establish equity in resources and expectations between generalist and specialist mental health services.

– *Some suggestions*

We all like to feel special. The word ‘generalist’ seems to imply the opposite – ‘Jack of all trades, master of none’. Being a specialist suggests one is at the top of the knowledge tree, whereas the generalist might feel that the term implies that there is someone out there with greater expertise.

And yet ... the crowning glory of the British National Health Service (NHS) is the general practitioner (GP). All western countries have specialists, but the central role of the GP in British medicine is a distinctive characteristic of the NHS. There is a high degree of trust between the GP and patient,¹ created by continuity of care, good therapeutic relationships and a holistic view of the whole patient. The role of the GP creates a degree of efficiency, as those referred to the specialists are screened by doctors who know the patient and ration precious health resources according to need. This may be an idealised picture, but there is still a strong coherent relationship between the GP and patient in the UK. Leinster² argued that medical schools need to concentrate on producing doctors who are good generalists who can orchestrate good care by specialists.

Within UK secondary-care mental health services, there are disparities between general services and specialist services. The latter include specialist services defined by diagnosis or treatment: rehabilitation, early intervention in psychosis, eating disorder, forensic and personality disorder teams. Within secondary-care mental health general services, there can be specialised services according to the environment (in-patient wards), crisis teams and community mental health teams.

As a result, it can be argued that a three-tier service structure has developed, in terms of medical treatment of mental illness in the NHS (*Table 1*). Some areas straddle the secondary-care generalist and specialist categories, such as forensic teams who are accessed through secondary-care generalists but also through the criminal justice system. We will refer to ‘secondary-care generalist psychiatrists’ as generalists for brevity in this article. *Table 1* The three-tier service structure for medical treatment of mental illness in the National Health Service

Medical expertise	Characteristics	Example environments	Patients treated
Primary-care generalists	GPs with broad medical knowledge, open access to the public	General practice	Mild to moderate depression and anxiety
Secondary-care generalist psychiatrists	Psychiatrists working across an age group, usual access by referral from a GP	Psychiatric wards, community mental health teams, crisis teams, liaison teams	Severe mental illness
Secondary-care specialist psychiatrists	Psychiatrists working in narrow diagnostic fields, usual access through secondary-care generalist psychiatrists	Early intervention teams, personality disorder teams, eating disorder teams, rehabilitation/recovery teams	As defined by the team diagnoses ¹

Strengths and weaknesses of generalists and specialists in secondary-care psychiatry

Specialists concentrate on a specific diagnosis or treatment of mental illness. In doing so, they develop greater expertise in interventions, which may improve clinical outcomes. There is clear coherent communication to the team and regarding what they are trying to achieve. Often, workload is more precisely commissioned and framed by inclusion criteria and case-load limits. Evidence suggests experts may be better at detecting clinical errors in their field.³

Generalist psychiatrists take responsibility for patients across a broad group of diagnoses and often across different environments. Their strength is in their versatility, working across situations, with diagnostic uncertainty and with patients who have more than one diagnosis. As such, they may provide more holistic care, and interfaces between services are less likely to hinder care or waste time. Continuity of care and therapeutic relationships may be easier to establish.

The weaknesses of specialisation include interfaces between teams, which are often inefficient. Working with one group of patients can get boring for staff and they can miss the variety that comes with being a generalist. There is evidence that specialists 'pull' cases toward their specialism and are less flexible in their thinking. Their specialism can lead to a bias in their clinical reasoning.⁴

The weaknesses of generalists mirror the strengths of the specialist in that, because they are doing a variety of interventions less often, they can have less expertise, and this can compromise outcomes. Paediatric heart surgery is an example of specialist teams having better outcomes than general heart surgeons in the cardiac care of children. Generalists may neglect certain diagnoses that are difficult to treat and provide a service skewed toward their own interests.

A defence of generalist services

The issue of diagnostic uncertainty and avoiding difficult patients

A difficulty in mental health is that diagnostic boundaries are not so sharp that competent colleagues may disagree. For example, there can be differences in defining psychosis from non-psychosis, leading to disagreements as to individual suitability for the early intervention teams. The distinction between bipolar type II disorder and emotionally unstable personality disorder is grey, so that many patients meet diagnostic criteria for both. Dual diagnoses are common, for example, between depression and personality disorder, and psychosis and substance misuse. It is human nature that if a particular patient is challenging to treat, we see aspects of their presentation that exclude them from our responsibility and make them suitable for another team.

The pain of interfaces

The resulting disagreements between multiple teams are distressing for patients, inefficient and cause resentment between staff, in that referrers have to convince the specialist team that a patient is appropriate. The fewer interfaces the better, and if different staff members know each other and have a relationship, these problems are easier. For a successful service, therapeutic relationships between staff are as important as the therapeutic relationships between patients and clinicians.

The inequitable distortion of resource allocation

Specialist services often have more tightly defined boundaries than general services and are often commissioned with a defined capacity. For example, specialist teams may have a cap on individual clinician case-loads (e.g. 12–15 in early intervention services) whereas generic community mental health teams (CMHTs) often do not, and case-loads can increase to over 40, with no managerial definition of a reasonable case-load despite the same team taking and assessing most referrals from primary care. The lack of a 'lid' on capacity in generalist CMHTs can lead to staff burnout, difficulties in retention and unsafe services.

The risk of the polo-mint service

Commissioners can prioritise specialist teams over generic teams and skew the service. When the more specialist teams have a protected case-load size and patient number, they can effectively become a local tertiary service. Staff can observe that clinicians have the time and resource in the specialist teams to deliver better quality care that they do not have in generic teams on the wards and in the CMHTs, and apply for specialist posts. This can result in a polo-mint service: posts are filled in specialist teams, which do not take on the immediate burden of new assessments, admissions and the ongoing care of the majority of the patients. Generic teams can be staffed with less-experienced staff and temporary staff. This is inequitable and breeds resentment. There is good evidence that staff burnout increases levels of sickness absence and staff turnover.⁵

The needs for specialist teams change over time

In the 1980s the day hospital specialist was popular as the asylums were closing. There are very few day hospitals now. The HIV psychiatrist emerged in the 1990s, but thankfully was soon not needed because of the rise of better treatments for HIV. Specialists in assertive outreach were appointed in the 1990s and 2000s but are now disappearing. In the past decade, addiction specialist posts have been eroded, but liaison psychiatry is experiencing a renaissance with medically unexplained symptoms a rediscovered clinical challenge and patients with dementia in general hospitals also a priority to manage.

So what? The world changes, patients' needs change and specialisms come and go. That may be a good thing, but it emphasises the need for psychiatrists and mental health clinicians to protect their core generic skills and adapt them to fluid challenges. Being a specialist and protecting your speciality may stifle innovation and generalists have the overview to spot new needs requiring innovation.

How do we get the balance right?

We offer some scenarios to consider.

Abolish secondary-care generalist teams and have specialist-only teams

This would be an answer, and has parallels in acute medicine where the role of the general physician has diminished and cardiologists, renal physicians, gastroenterologists and other subspecialists have emerged. This may have led to better treatments and outcomes. However, the care of elderly patients with multiple morbidities has fragmented, and the experience of going to hospital has become socially quite unpleasant because of this fragmentation. Patients often do not have a named consultant or a named nurse.

Both politicians and leaders in the Royal College of Physicians have called for a greater emphasis on generalism.⁶ The former editor of the *BMJ* has stated that doctors and patients are heading in opposite directions, 'patients have multiple conditions whilst doctors are specialising not just in organ systems but parts of organs'.⁷ In the USA, the Council on Graduate Medical Education recommended an increase in the percentage of generalists among practicing physicians to increase from 32 to 40% in 2010 – not only is this target predicted to be unmet, but the percentage of generalists is likely to fall to 25%.⁸

The biggest difficulty for psychiatry is that the lack of clear delineation between diagnoses and patients could be passed between disagreeing teams. However, it is an option that needs consideration.

Minimise the use of local specialist teams and return to generalist mental health teams

This does seem somewhat backward, but may be a less-fashionable description of integrated services. After all, general adult psychiatry is a speciality in its own right, so why can't one team treat all diagnoses? Generic psychiatric skills require a holistic biopsychosocial approach and the incorporation of a full multidisciplinary team. The secondary-care generalist psychiatrist does not become deskilled when they are on call as they are used to diagnostic uncertainty and a broad view of aetiology and treatment.

Many specialist teams were introduced because of charismatic proponents claiming better outcomes but without evidence for effectiveness, and subsequent research failed to demonstrate efficacy. Just as assertive outreach teams have waned in the UK because of a lack of evidence of better outcomes, with patients returning to generalist teams, others may go the same way.⁹ Some staff might take on a specialist interest within a generalist team, although it is hard to meet and learn with specialist peers if they are separated between teams.

Have realistic and equitable estimates for all teams in terms of clinician case-load and team case-load

There needs to be equity in the commissioning of secondary-care mental health generalist and specialist services. Specialist teams often have tightly defined commissioning criteria whereas the criteria for generic CMHTs are not defined. The case-load size for different teams may not need to be equal, but they do need to be justified. Although generic teams exist, it is likely they will be the default service for complex patients with diagnostic uncertainty, and boundaries are harder to define than for specialist teams.

Generic CMHTs have tried to control their workload by defining inclusion and exclusion criteria and treatment pathways. However, commissioning needs to allow for the uncertainty of the interface between primary and secondary care. Patients and GPs get frustrated when criteria are so inflexibly followed that patients who are presenting in an unusual or atypical manner are refused care, or have to get worse before they are offered help. Some patients who are ill and at risk do not follow the pathway or treatments recommended. Mental health services are unique in being asked to be assertive in caring for reluctant patients and forcing care in certain circumstances.

Some suggestions

We believe that generic general adult psychiatric services are likely to be required because specialist-only services will not have the flexibility to roll with diagnostic uncertainty and changes in patient needs. In the past 30 years, new treatments have emerged for emotionally unstable personality disorder, which was once a diagnosis of exclusion and adult attention-deficit hyperactivity disorder, which was completely ignored (and still is in some places). Patients with high-functioning autism still tend to be pushed away, but treatments may emerge. Generalists are flexible and can think on their feet.

Somehow, we need to make working in a generalist CMHT attractive again. This may be through better management of expectations and case-load, career opportunities, pay or quality of life. We cannot lose good staff to specialist teams and leave more junior staff doing demanding generalist jobs.

Currently, the most pressing need is for equity between generic and specialist teams in terms of defined case-load. Staff/patient ratios are a cause of burnout, which increases staff turnover.⁵ Staff in generic CMHTs must have boundaries put on their patient case-load in the same way that specialist teams define their capacity. This does not have to be equal – it may be 35 cases compared with 15 for teams with more intensive input. There have been attempts to develop tools to promote equity between teams in Australia.¹⁰ Government policy and commissioners cannot continue to be inequitable in their expectations of generic and specialist teams, and as long as CMHTs are treated as inexhaustible, they will not retain the skilled clinicians they need.

1.5.79 Conversion therapy and the LGBT community: the role of the College now?

Annie Bartlett

date

2018-12

Contents

- *Conversion therapy and the LGBT community: the role of the College now?*

The history of the relationship between the LGBT (lesbian, gay, bisexual and transgender) community and psychiatry has not been a happy one, reflecting but also at times reinforcing hostile social attitudes. More recently, both psychiatry and psychological therapies have been at pains to distance themselves from previous discriminatory practice and align themselves with more contemporary understandings of diverse sexual identities and behaviour. The College and other bodies such as the UK Council for Psychotherapy have developed clear statements on sexual orientation and the issue of conversion therapy in particular, pointing out that it does not work, can create distress and should not be undertaken.¹

This position on conversion therapy is echoed in the raft of 75 measures announced recently by Women and Equalities Minister Penny Mordant, based on the results of the largest survey of LGBT people ever undertaken. The measures are designed to create a more inclusive society in which, among other things, individuals of any sexual persuasion may feel able to hold hands in public without fear of ridicule or attack (Hansard HC Deb, 3 July 2018, cWS). That a Conservative government has launched such an initiative seems remarkable to those of us able to remember Section 28, brought in by the Thatcher government 30 years ago (Local Government Act 1988).

However, we should be mindful as a profession that some practitioners may not be so sympathetic to this direction of travel. Not so long ago, a significant proportion of psychiatrists and therapists, 4%, were still prepared to treat individuals for their gay and lesbian identities.² It is not clear how much this has changed, if at all, on the ground. Equally, it is still very easy to locate reparative therapy options on the internet, a common port of call for those wanting some help negotiating same sex sexual preferences. A quick search picks up, among others, Nicolosi's website, which continues to say 'If gay doesn't define you you don't have to be gay,' accompanied by claims of treatment efficacy, in line with the views he so publicly expressed until his death in 2017 (<https://www.josephnicolosi.com>). He recommended reparative therapy, saying that it worked and should be offered as a psychological therapy. The number of individuals currently involved with reparative therapy is unclear and seems likely to be difficult to establish, as recent medical and political pronouncements may well drive it underground.

The College has an international reach. Many countries are still much more punitive to LGBT individuals than the UK; some have the death penalty on their statute books. Major world religions are internally divided on LGBT issues and can legitimise not only adverse social attitudes but also attempts at religious rather than medical cures. It remains to be seen how energetic the College feels it should be in sharing its liberal understanding of sexual preference. Its position on change-oriented treatments of any kind has international applicability. There may well be many individuals overseas who would thank psychiatry for taking part in this ongoing debate.

1.5.80 Review and update of the Health of the Nation Outcome Scales for Elderly People (HoNOS65+)

Mick James Bill Buckingham Gary Cheung Roderick McKay Jon Painter Malcom W. Stewart

Correspondence

Mick James via

(Emma.George@rcpsych.ac.uk)

date

2018-12

Abstract**Aims and method**

The Health of the Nation Outcome Scales for Elderly People (HoNOS65+) has been used widely for 20 years, but has not been updated to reflect contemporary clinical practice. The Royal College of Psychiatrists convened an advisory board, with expertise from the UK, Australia and New Zealand, to propose amendments. The aim was to improve rater experience when using the HoNOS65+ glossary by removing ambiguity and inconsistency, rather than a more radical revision.

Results

Views and experience from the countries involved were used to produce a series of amendments intended to improve intra- and interrater reliability and improve validity. This update will be called HoNOS Older Adults to reflect the changing nature of the population and services provided to meet their needs. These improvements are reported verbatim, together with the original HoNOS65+ to aid comparison.

Clinical implications

Formal examination of the psychometric properties of the revised measure is needed. However, clinician training will remain crucial.

Declaration of interest

 - * *Overarching rating guidelines*
 - * *Other issues*
 - *Summary*
 - *Supplementary material*

The Health of the Nation Outcome Scales (HoNOS) was originally developed for use with working-age adults.¹ Subsequent testing found that, in general, the scales also performed well with older people, but that some adaptations (especially relating to ratings of physical health and cognitive impairment) would be beneficial.² This resulted in the development of the HoNOS65+,³ which was validated against other established mental health measures used with older people and shown to have good interrater reliability.³ As well as this standardised version, a further version was developed with a tabulated glossary.⁴

Like the HoNOS, the HoNOS65+ was intended to: •be short and simple for routine use and acceptable to a range of mental health professionals;•have adequate coverage of clinical and social functions;•be sensitive to change over time;•have demonstrable and acceptable reliability;•have known relationships with more established scales.⁵

Since its development over 20 years ago, the HoNOS65+ has been translated into several other languages, including Spanish, Dutch, French, Greek and Italian, and is now routinely used in clinical practice and research around the world.⁶ Australia and New Zealand have mandated use of the original format of the HoNOS65+ scales for routine monitoring and outcome measurement across their mental health services,^{7,8} while across England both the original version and the more recently developed tabulated version are used to provide these nationally required data.^{3,4,9}

Experience of staff training and the evaluation of aggregated data-sets over this period, together with considerable advances in mental healthcare for older people, led to a recognition that the HoNOS 65+ required review and updating. As copyright holder for the HoNOS family of measures, the Royal College of Psychiatrists (RCPsych) elected to undertake a limited review that aimed to use expert opinion to improve the utility of the HoNOS65+ in contemporary older people's mental health services (rather than a full redevelopment and revalidation), while remaining true to its original aims and maintaining comparability with existing data-sets. This paper outlines the scope and process of the review, the issues identified and a revised set of scales (subsequently renamed HoNOS Older Adults).

Method

In recognition of their nationally mandated use of HoNOS65+⁷⁻⁹ and to ensure that each country's interests were considered, an advisory board (chaired by the RCPsych's National HoNOS Advisor) was convened with representatives from England, Australia and New Zealand. Each government nominated individuals with extensive experience in any of the following: HoNOS65+ staff training; using HoNOS65+ in practice; using aggregated HoNOS65+ data; or service-, professional- or governmental-level oversight. In addition to their own views, board members canvassed widely for clinicians' opinions regarding which aspects of the HoNOS65+ required refinement.

To ensure consistency with the concurrent HoNOS review, the same criteria were used to judge suggestions.¹⁰ These criteria were that for a change to be supported, it needed to result in a tangible improvement (e.g. simplification/clarification/removal of anachronisms) and: •maintain the original instrument's integrity as far as possible;•maximise comparability with existing individual and aggregated data;•support the use of HoNOS Older Adults as a summary of clinical assessment(s);•adhere to the HoNOS65+ 'core rules' i.e. each item is a behaviourally anchored five-point scale items are sequentially rated (1–12) all available information is used to make a rating information already rated in an earlier item is disregarded the most severe problem/worst manifestation from the preceding 2 weeks is rated problems are rated according to the degree of distress caused and/or its effects on behaviour problems are rated by a mental health professional trained in clinical assessment problems are rated regardless of cause.

In addition to these original HoNOS terms of reference, the board was keen to take this opportunity to consider whether there were opportunities to optimise alignment between the newly updated adult and older people's versions. The rationale for this was threefold. First, some of the HoNOS updates had come from the original HoNOS65+.¹⁰ Second, anecdotal reports suggested that some electronic patient record systems were unable to differentiate between the two versions and/or make both glossaries available to clinicians. Third, since the development of the HoNOS65+, the somewhat arbitrary age cut-off of 65 has become less justified given the increasing variation in functional impairment with age across different populations.¹¹

Using the collated feedback and the ensuing board discussions, a summary paper was produced by a board member with extensive experience in old age psychiatry. This highlighted some scales where alignment might be considered a viable option and those where alignment was unlikely owing to the nature of presenting needs in this population. This dictated the sequence of the board's teleconferences and its approach to each scale.

For the scales where alignment was considered to be potentially feasible and likely to improve utility, two questions were asked: first, does it resolve the concerns or problems with the scale reported by old age clinicians in the field; and, second, is the new HoNOS (2018) wording appropriate for older people's mental healthcare? Two positive responses resulted in the revised HoNOS scale being adopted for older people. A negative response led to an iterative process to produce a revised wording that was appropriate for the older people's version of the tool. During this process, consideration was given to whether these proposed changes could also be applied to the draft HoNOS (2018). Where

appropriate, to improve both, the draft HoNOS (2018) was aligned with the HoNOS older adult. Where this was not possible, the scale was grouped with items where full alignment had been deemed unfeasible.

For this second group of scales, the board considered both the new HoNOS and the original HoNOS65+ wording in the context of the collated feedback in order to produce a revised HoNOS65+ scale glossary.

Results

Upon completion of their discussions, the board was able to fully align seven of the 12 scales, with the remaining five having a high degree of similarity but also retaining some key differences. The revised tool (ultimately renamed HoNOS Older Adults) can be seen in Supplementary Table 1, available at <https://doi.org/10.1192/bjb.2018.68>. Each item's original wording is also included (in greyed-out boxes) to aid comparison.

Discussion

This publication follows the review of the original (working age) HoNOS.10 However, in reality, each review was informed by the other prior to each version of the tool being finalised. As a result, issues specific to older people will be discussed in full below, whereas those common to both tools (and hence previously discussed) will be summarised here purely for completeness. Readers are therefore advised to refer to James *et al* (2018) to gain an understanding of these common issues.

Overarching rating guidelines

After reviewing the HoNOS65+ introductory guidance, the board agreed that the issues were identical to those identified with respect to the HoNOS, i.e. that brevity had been prioritised at the expense of clarity. The board also agreed that the newly amended HoNOS guidance was entirely appropriate given that the two tools were intended to function in the same way. Consequently, the same guidance was used, as it: •clarified the severity threshold between subclinical (0–1) and clinical (2–4) ratings;•made an overt statement regarding the need for cultural competence on the part of assessors;•acknowledged the limitations of continuing to use the term ‘patient’.

Scale 1: overactive or aggressive or disruptive or agitated behaviour

There was agreement that the issues with this scale were similar, regardless of age, i.e. that: •raters should be encouraged to consider all four concepts in the title (rather than just focusing on aggression);•the issue of culturally sanctioned aggression was now satisfactorily addressed in the preceding, over-arching guidance.

However, some of the original HoNOS65+ examples were felt to be of continued value; hence, those pertaining to the following behaviours were retained: •restlessness/wandering•uncooperativeness/resistiveness and the need for persuasion•sexual disinhibition and deliberate incontinence.

There was some discussion about whether to contextualise inappropriate behaviours (i.e. in public *v.* in private); however, in keeping with the underpinning principles of the scales, it was agreed to simply focus on the behaviour itself. As a result, the two new versions of this scale are broadly similar, but not identical.

Scale 2: non-accidental self-injury

There was agreement that the issues with this scale were the same regardless of age, i.e. that the new scale should:

- consider risks, thoughts and behaviours
- rely on the over-arching guidance to ensure culturally competent ratings of some forms of ritualistic self-harm.

As a result, the newly revised HoNOS 2018 version of this scale was adopted without amendment.

Scale 3: problem drinking or drug-taking

There was agreement that the issues with this scale were the same regardless of age, i.e. that the new scale should:

- include descriptors of craving, dependency and behaviour that align with contemporary ratings of severity¹² and which accommodate rating individuals undergoing short-term, enforced abstinence;
- omit the subjective concept of 'social norms';
- exclude tobacco use unless it has led to problems over and above the detrimental effects traditionally associated with a person's physical health.

As a result, the newly revised HoNOS 2018 version of this scale was adopted without amendment.

Scale 4: cognitive problems

After an iterative process of revisions to both the original HoNOS 65+ and the draft HoNOS 2018 versions of this scale, a shared version of the scale was produced. The main issues addressed were therefore:

- the unhelpfully narrow focus on dementia
- the large step between the original ratings of 2 and 3.

A final review, however, identified the need to retain one example from a rating of 4 on the original HoNOS 65+, i.e. 'consistently unable to recognise or name close friends/family'. As a result, the two versions of this scale are almost, but not absolutely, identical.

Scale 5: physical illness or disability problems

The new HoNOS 2018 version of this scale was not suitable for older people, and alignment was not deemed viable owing to the effects of age-associated complexities including spectacles and hearing aids, as well as the differing clinical significance of minor falls for the two age groups. Hence, while some text is shared between the new versions of this scale, many of the original HoNOS65+ examples were retained to reduce ambiguity. The two new versions of this scale are therefore notably different.

Scale 6: problems associated with hallucinations and delusions

There was agreement that the issues with this scale were the same regardless of age. As a result, the newly revised HoNOS 2018 version of this scale (i.e. limited to minor linguistic changes) was adopted without amendment.

Scale 7: problems with depressed mood

There was agreement that the issues with this scale were the same regardless of age, i.e. that: •descriptors should be aligned with the scale's title to remove the current HoNOS65+ contradictions (helpfully, focusing on mood and excluding the wider symptoms of depression also avoided any need to accommodate the differing presentations of depression between the two age groups);•ratings should include a more balanced description of cognitive, affective and behavioural aspects of low mood (e.g. loss of interest, guilt and low self-esteem) to avoid unduly focusing on feelings of guilt.

As a result, the newly revised HoNOS 2018 version of this scale was adopted without amendment.

Scale 8: other mental and behavioural problems

There was agreement that the issues with this scale were the same regardless of age, i.e. the need to: •recognise the dominance of anxiety ratings in this scale, although the creation of a separate scale was deemed to be outside the scope of this work;•recognise the possibility that rating the most severe problem can lead to a failure to capture less severe issues, while electing to retain this approach;•add 'elated mood' to the list of options and re-code the options to accommodate this;•provide additional explanations of each option to improve consistency of ratings.

As a result, the newly revised HoNOS 2018 version of this scale was adopted without amendment.

Scale 9: problems with relationships

There was agreement that the issues with this scale were the same regardless of age. As a result, the newly revised HoNOS 2018 version of this scale (limited to minor linguistic changes) was adopted without amendment.

Scale 10: problems with activities of daily living

As with Scale 4, after an iterative process of revisions to both the original HoNOS 65+ and the draft revisions to the HoNOS 2018 version of this scale, a shared version of the scale was produced. The main issue addressed was therefore: •clarifying how to 'manage' the effects of any existing support the person is receiving.

A final review, however, identified the need to retain two examples from the original HoNOS 65+. 'Occasional urinary incontinence or continent only if toileted' was therefore included as an example for a rating of 3, while 'full supervision required with dressing and eating; frequent incontinence' was included to help illustrate a rating of 4. As a result, the two versions of this scale are almost, but not absolutely, identical.

Scale 11: problems with housing and living conditions

The new HoNOS 2018 version of this scale was found to be unsuitable for older people, and complete alignment was not deemed viable owing to the need to maintain references to the risks posed to older people by their environment. Removing this feature from the HoNOS65+ was judged to represent a major (and unhelpful) change. Therefore, much of the revised HoNOS 2018 version was adopted, i.e.: •clarification that the scale is intended to rate how well the person's current environment matches their needs/abilities, not their abilities *per se*;•clarification that when rating patients temporarily admitted to hospital their 'usual' place of residence should be considered;•updates to some of the terminology used.

However, in addition: •the original HoNOS65+ references to risk were maintained (and, for consistency, introduced to a rating of 1).•the original HoNOS65+ concept of patient satisfaction was removed owing to potential contradictions between suitability of and satisfaction with housing and living conditions.

As a result, the two new versions of this scale are similar, but not identical.

Scale 12: problems with occupation and activities

There was agreement that the issues with this scale were the same regardless of age, i.e. that there was a need to:

- clarify that the scale is intended to rate how well the person's current environment optimises opportunities to meet their needs or develop their abilities, not their abilities *per se*;
- clarify that when rating patients temporarily admitted to hospital their 'usual' place of residence should be considered.
- update some of the terminology used.

As a result, the newly revised HoNOS 2018 version of this scale was adopted without amendment.

Other issues

The advisory board was aware that since the publication of the HoNOS65+ there have been shifts in the well-being of older people, with frailty and disability tending to occur later in life.¹¹ With this has also come a shift in the focus of some services for this population. As a result, the existing title, with its focus on the over-65s, was felt to be unhelpful and slightly anachronistic. Increasing the age limit (e.g. to HoNOS 70+) may be more reflective of the group of individuals for whom the tool would be most appropriate in some countries, but still somewhat arbitrary. As a result, it was agreed to rename the scales HoNOS Older Adults, as this would allow clinicians and services to exercise their judgement about when it was appropriate to use each new version of the tool. This could allow the measures to be aligned with variations in the cut-off age for service organisations and practice in different countries and over time. While this variability may have some effect on the comparability of data internationally, it could significantly simplify utilisation of the measures in individual countries.

As with the review of HoNOS, 10 additional areas for development were identified that had merit, but these would have constituted substantial changes and required the development of a completely new instrument. These of course remain an option for future development, pending sector agreement, as well as government interest and funding.

Summary

The anticipated benefits of these changes should ideally be subject to empirical testing through assessment of interrater reliability and revalidation of the measure in the field. This type of study requires funding and preferably involvement from countries that have heavily invested in the HoNOS65+ to date. This issue is being actively pursued by members of the advisory board

It is also acknowledged that the different jurisdictions involved in the review (and others that have also invested in the use of HoNOS65+) may encounter a range of differing implementation issues. Training programmes in particular are likely to be affected, and while the proposed changes are intended to improve the ease and accuracy of using the scales, it must be stressed that these do not obviate the continued need for training in the use of the scales.

date

2018-12

Abstract

Aims and method

We aimed to evaluate clinical note documentation of valproate prescribing and establish the level of knowledge among women of child-bearing potential regarding valproate-associated adverse effects, including teratogenesis, in a regional Irish mental health service.

Results

Of the 42 women prescribed sodium valproate, 21.4% ($n = 9$) had some documentation in relation to associated risks and 33.3% ($n = 14$) described an awareness of these risks from consultation with their treating mental health team. On clinical interview, 9.5% ($n = 4$) of individuals with clear documentation of the risks of teratogenesis described no such awareness. Augmentation with lithium was associated with greater awareness of the teratogenic risks of valproate ($P = 0.011$).

Clinical implications

A clear description of the teratogenic risks of valproate and potential management strategies, including advice regarding contraception and supplementation with folic acid, should be clearly documented and provided repeatedly and in context to all women of child-bearing age who are prescribed valproate.

Declaration of interest

None.

Valproate is a broad-spectrum anticonvulsant with well-established efficacy for the management of partial and generalised seizures,¹ acute (hypo)mania and prophylaxis of (hypo)manic episodes both as a monotherapy or in combination with other psychotropic agents.² In addition, valproate can be utilised for the prophylaxis of depressive episodes in bipolar disorder,² although this reported therapeutic effect is of lesser magnitude.³

Risk of teratogenesis

However, valproate use in women of child-bearing potential is associated with a wide range of neurodevelopmental deficits,⁴ with an approximate risk of teratogenesis of 7%⁵ and 70% of teratogenesis malformations consisting of neural tube defects (NTDs),⁶ which is a 20-fold increase compared with the general population.⁷ NTDs occur when the embryonic neural tube fails to completely close during development, and include spina bifida and anencephaly.⁸ In addition to NTDs, valproate use in pregnancy is also associated with an increased incidence of cleft lip and palate, cardiovascular abnormalities, genitourinary defects, endocrine disorders, cognitive impairment, developmental delay and autism spectrum disorders in the foetus.⁹ A 'foetal valproate syndrome' has also been described and includes a constellation of physical traits consistently observed in foetuses exposed *in utero* to valproate such as a flat nasal bridge, epicanthal folds, small upper lids and a downward-turned mouth.^{10,11} Potential contributory factors to the teratogenicity of valproate have been reported and include the number of co-administered medications, higher dosages of valproate, differences in maternal and/or foetal metabolism, gestational age of the foetus at exposure to valproate and hereditary susceptibility.^{12,13}

The teratogenic risk associated with valproate has resulted in significant caution with its use, with the summary of product characteristics for sodium valproate and the related compound semi-sodium valproate and the National Institute of Health and Care Excellence (NICE) guidelines of 2014 stating that valproate should not be initiated in women of child-bearing potential without specialist advice or unless other treatments are not tolerated or are ineffective (<https://www.gov.uk/government/publications/toolkit-on-the-risks-of-valproate-medicines-in-female-patients>).

Awareness of teratogenic risk

Given the risks associated with valproate use during pregnancy, awareness of these risks and a consideration of what precautions are required in relation to the use of valproate in women of child-bearing potential is important. However, previous research has demonstrated low rates of documentation in clinical notes of advice from mental health staff regarding both the teratogenic risks of valproate and the importance of both contraception and folic acid use.¹⁴⁻¹⁷

Aims

Consequently, in this study we wanted to establish if women of child-bearing potential attending a mental health service in Ireland were prescribed valproate and ascertain the indications for this treatment. In addition, we wanted to assess the rate of documentation of advice relating to the teratogenic risks of valproate and importance of the use of contraception and folic acid. We wanted to establish the awareness of women of child-bearing potential who are prescribed valproate regarding the teratogenic risks of this agent, and the potential benefits of contraception and folic acid. We also wanted to enquire establish how those with such awareness attained this information.

Method

Participants

This study was undertaken in an Irish mental health service region with an approximate population of 250 000 people. All female adult patients attending this mental health service in January 2016 were screened ($n = 1620$) to ascertain if they were being treated with valproate. Community mental health team staff members, including consultant psychiatrists, non-consultant psychiatry hospital doctors, community mental health nurses, allied health professionals and administrators, were contacted to ascertain potential participants. Inclusion criteria included women aged 18-49 years who had been in receipt of care from the mental health service for >1 year and had been treated with valproate.

Exclusion criteria included individuals <18 years of age, the presence of an intellectual disability (IQ<70), a diagnosis of dementia and the presence of acute psychosis. None of the 42 individuals identified as receiving treatment with valproate fulfilled these exclusion criteria. Clinical diagnoses were attained utilising ICD-10 diagnostic criteria after consultation with the relevant treating consultant psychiatrist and a full clinical chart review.¹⁸

Ethical approval was attained from the Galway University Hospitals Research Ethics Committee (C.A. 841) and the study was conducted in accordance with the Helsinki declaration on research ethics. Written informed consent was attained from each participant for clinical note review, clinician contact and semi-structured interview. On completion of the semi-structured interview, psychotherapeutic support was offered to each participant.

Chart review

A retrospective chart review was undertaken of the lifetime clinical notes of included individuals. Clinical notes were examined in depth (by D.M., A.M. and S.F.) and included all handwritten, typed and electronically generated entries pertaining to in-patient admissions to one of three acute psychiatric in-patient units; attendance at the different day hospitals, day centres and out-patient clinics in the region;

Correspondence

and from general practitioners and specialists

(including neurologists) and all prescription records.

Demographic data collected included gender, age and socioeconomic, employment, marital and domiciliary status. Clinical data included diagnosis, prescription of valproate, time duration and dose of valproate prescribed and prescription of any concomitant psychotropic medication (mood stabilisers, anticonvulsants, antidepressants, antipsychotics, anxiolytics, hypnotics and anticholinergic agents). We also ascertained if children were conceived to patients when prescribed valproate, and if any foetal abnormalities were recorded. Data pertaining to the documentation of the risk of teratogenicity or congenital malformations secondary to valproate, and precautions including adequate contraception and use of folic acid were recorded.

Semi-structured interview

All 42 identified participants participated in a semi-structured interview. Information gathered included awareness of the teratogenic risk of valproate; how, when and by whom participants were first informed of this risk (if informed); advice regarding use of contraception; wishes regarding pregnancy before or during treatment with valproate; undertaking a pregnancy test before commencement of valproate and advice regarding, or prescription of folic acid. We also enquired if participants became pregnant or conceived when treated with valproate and ascertained what advice regarding treatment with valproate was attained from their treating clinician during their pregnancy (see Appendix 1, *Semi-Structured Interview Topic Guidelines*).

Data analyses

Statistical analyses were performed with SPSS 22.0 for Windows (SPSS Inc., New York, USA). We utilised the Student's *t*-test for parametric data and the χ^2 -test for non-parametric categorical data, where appropriate. Linear regression was conducted to ascertain the effect of age, dose of valproate and duration of treatment in relation to clinical documentation or awareness of the teratogenic risks of valproate.

Results

Demographic and clinical data

Demographic and clinical data are described in *Table 1*. Of note, the most common diagnosis was bipolar disorder (33.3%, $n = 14$) and the most common comorbid psychotropic medications prescribed were antipsychotic agents (71%). In addition, 16.7% of individuals ($n = 7$) were treated with valproate for prophylaxis of epilepsy due to treatment with high dosages of clozapine. *Table 1* Demographic and clinical characteristics

Sodium valproate dose, mg/day	923 (434)	[300–2000]
Duration of treatment, years	7.59 (3.92)	[1–14] ^{1,2,3}

Clinical documentation

Documentation of risks associated with valproate in pregnancy were present in 21.4% ($n = 9$) of the clinical files and included advice on contraception (16.7%, $n = 7$), the specific teratogenic risks of valproate (9.5%, $n = 4$) and use of folic acid (2.4%, $n = 1$). No individuals had a documented pregnancy test before initiation of valproate.

A range of sociodemographic factors, including maternal age at interview ($B = 0.101$, $P = 0.54$), or clinical variables, including dose of valproate ($B = 0.205$, $P = 0.21$) and treatment duration ($B = 0.127$, $P = 0.45$), were not associated with clinical documentation of the teratogenic risks of valproate. All nine individuals with a comorbid diagnosis of epilepsy had no clinical documentation of the risks of valproate, although this was not statistically significant when compared with those treated with valproate for a mental health disorder ($P = 0.17$, Fisher's exact test). Valproate augmentation with psychotropic medication was present in 95.2% ($n = 40$) of individuals. Three of the six individuals treated with lithium had written documentation of the risks of valproate.

¹ In this study, undertaking a university course.

² Socioeconomic class was scored based on NRS grading: I = upper-middle class/higher managerial, administrative or professional; II = intermediate managerial, administrative or professional; III = supervisory or junior managerial or skilled manual workers; IV = semi-skilled or unskilled manual workers, V = unemployed, on social welfare, minimum-wage workers.

³

Used as a prophylactic treatment for seizure control due to treatment of schizophrenia with clozapine.

Structured interview

On interview, 33.3% ($n = 14$) of participants demonstrated some awareness of the risk of valproate, with 19.0% ($n = 8$) aware of specific teratogenic risks, requirement for contraceptive use and need for a pregnancy test before valproate initiation, and 16.7% ($n = 8$) aware of the need for folic acid use when taking valproate. All but one of these participants stated that they had acquired this information from their treating consultant psychiatrist. Nine (64.3%) individuals who stated that they were informed of the risks of valproate as acquired from their treating clinician had no documented information detailing this advice/information in their clinical files. Overall, 18 (42.9%) individuals had either documented data in their clinical notes or stated that their mental health team had advised them on at least some of the risks of valproate for women of child-bearing potential. Four individuals (9.5%) had documented advice in their clinical notes but had no awareness of same (on clinical interview).

Regression analysis showed that younger age ($B = 0.315$, $P = 0.042$) was associated with a greater awareness of the teratogenic risks of valproate. Additionally, individuals augmented with lithium were more likely to be aware of the teratogenic risks of valproate (83 v. 25%, $P = 0.011$).

Pregnancies on valproate

Four participants had pregnancies (all uncomplicated) when treated with valproate. Three continued on the same treatment and dosage, with documentation that they should continue because of the risk of relapse of their seizure disorder. There was no documentation in these clinical files in relation to the risks of valproate in pregnancy or advice regarding contraception or folic acid use. The fourth participant had a diagnosis of bipolar disorder and had documentation to discontinue valproate (at 4 weeks' gestation), but there was no documented advice to commence folic acid. On structured interviews, in addition to the individual who discontinued valproate treatment, two of the other three participants stated that their consultant psychiatrist advised them to commence folic acid, but there was no documentation in the clinical files in relation to this.

Discussion

This is the first study to date, to our knowledge, to review both clinical documentation and undertake semi-structured interviews with women of child-bearing potential who were prescribed valproate. Either clear documentation of the risks of valproate or an awareness of these risks after discussion with their treating clinical team was present for 43% of individuals.

Our findings of poor clinical documentation of specific risks of valproate are consistent with previous research, with rates of 16–29% noted for documentation of risks of teratogenesis or the provision of advice in relation to contraception for women of child-bearing potential who are prescribed valproate.¹⁴⁻¹⁶ Similarly, documented advice in clinical notes relating to the use of folic acid has previously also been noted to be particularly low (4%).¹⁶ Our findings in relation to patient awareness of teratogenic risks of valproate are also consistent with previous studies (17–28%);¹²⁻¹⁷ however, awareness of the need for contraceptive use was lower in our patient cohort compared with a number of previous studies (55–67%).¹⁵⁻¹⁷

It is probable that the majority of patients examined in this study were provided with verbal advice regarding the risks of valproate. Two-thirds of patients who said they had been advised of the risks of valproate had no clinical documentation relating to this advice. Some participants, despite clinical documentation stating they had been informed of the risks of valproate, stated at the time of interview that they had no awareness of such a discussion (which may potentially be related to recall bias). This highlights the need for information (including in a written format) relating to the teratogenic risks of valproate to be provided repeatedly and in context to patients to ensure awareness of these risks. This may be particularly important for this cohort of patients who are being treated for bipolar disorder or schizoaffective disorder, where impulsive behaviour including risky sexual behaviour may occur during a (hypo)manic episode.¹⁴ The lack of documentation in mental health clinical notes of advice to individuals treated for epilepsy with valproate may be secondary to the fact that mental health staff had not initiated this treatment, with evidence suggesting that clinicians are less likely to inform patients of medications adverse events if they have not initiated the particular medication

themselves.¹⁷ However, three individuals diagnosed with epilepsy described being advised of the risks of valproate by their mental health team, and it is probable that some participants additionally attained advice from other clinicians (i.e. neurologists, general practitioner) relating to the teratogenic risks of valproate. The provision of written information, and advice on appropriate resources that gives accurate advice in relation to the risks and benefits of valproate and precautions required with its use is suggested. Information recently produced by the National Clinical Programme for Medicine Management is one potential option in this regard.¹⁹

This study highlights the low rates of documentation of contraceptive use or advice regarding folic acid. Consultations with mental health staff (preconception consultations) in relation to the risks and benefits of continuation or discontinuation of medications, including for women diagnosed with bipolar disorder, have previously been demonstrated to influence both choices regarding conception and treatment.²⁰ This study suggests that such consultations, focusing on issues of conception and pharmacotherapeutic treatment, should be considered for all women of child-bearing potential (even if not in a significant relationship) who are prescribed valproate. NICE guidelines²¹ state that valproate should not be offered to women of child-bearing potential for either the management of acute mood episodes or the long-term management of bipolar disorder, and if already prescribed, should gradually be discontinued because of the teratogenic risks of valproate. Additionally, folic acid should always be prescribed to women of child-bearing potential who are prescribed valproate,²² with levels to be undertaken both before commencement of valproate and on a 6-monthly basis.

Limitations

This study includes a number of limitations, including that females of child-bearing age who were under 18 years old were not included. Findings were attained from one region in Ireland and may not be representative of other regions or other jurisdictions; however, many of the findings are consistent with those noted in other jurisdictions and thus may indeed be generalisable. Clinical notes from other practitioners, including neurologists and general practitioners (excluding correspondence from them as detailed in the mental health clinical notes), were not examined or available. Finally, the semi-structured interviews conducted were retrospective in nature, and thus potentially liable to recall bias. Recall bias may partly explain the discrepancy we found, where documentation detailing the teratogenic risk of valproate was noted but not recollected by participants. It is probable that other non-mental health service clinicians may have disseminated information relating to the risks of valproate; however, this was not evident on clinical interview and this study principally investigated documentation in mental health clinical records.

Semi-Structured Interview Topic Guidelines

1. Are you aware of any risks associated with the use of sodium valproate? Please list these risks. Please identify how you became aware of these risks.
 2. Are you specifically aware of any problems this medication has in relation to pregnancy and foetal development? What have you been told? Who told you? When were you told?
 3. Was your wish or likelihood of becoming pregnant ascertained before commencing therapy?
 4. Was contraceptive advice offered?
 5. Was use of contraception confirmed before commencing treatment?
 6. Was a pregnancy test done before commencing sodium valproate?
 7. Were you advised regarding the use of folic acid supplementation?

2018-12

Abstract

The Five Year Forward View for Mental Health (FYFVMH) was a welcome development in the emerging 'Parity of Esteem' agenda, but focused mainly on a select few specialist services; much more limited attention was given to 'core' general adult and older age mental health services, such as community mental health teams, crisis teams and in-patient units. This relative policy vacuum, when combined with prolonged financial pressures and limited informatics, has left core services vulnerable and struggling to meet growing demands, with little sense of hope, in contrast to some of the newer, 'shiny' specialist services growing around them. Policy makers need to recognise the growing crisis and take action, ensuring that any sequel to the FYFVMH redresses this imbalance by clearly prioritising core services as the vital foundations of the larger whole-system. The potential benefits are huge and wide-ranging, but the harms of a second missed opportunity are perhaps even greater.

A.M. works in a National Health Service general adult community mental health team and is an elected member of the Royal College of Psychiatrists General Adult Faculty Executive Committee.

Contents

- *The forgotten foundations: in core mental health services, no one can hear you scream*
 - *Front-line messages*
 - *What to do?*

The Five Year Forward View for Mental Health (FYFVMH)¹ is now halfway through its lifespan, with policy makers assessing its early effects and pondering the sequel. Perhaps the biggest effect was simply having a specific mental health version of a Five Year Forward View. The 'Parity of Esteem' (for Mental Health) agenda is still relatively young, with considerable gaps between rhetoric and action, but the existence of a mental health version helped keep early momentum going. This must now accelerate, but with new priorities much more explicitly focused on 'core' general adult and older age mental health services, especially community mental health teams (CMHTs), crisis teams and acute in-patient units. Historically, these central foundations of the wider system have been vulnerable to ongoing, quiet erosion by chronic underfunding and systemic structural disadvantages (e.g. block contracts). The FYFVMH, despite enabling progress in some areas of its specific focus, was a painfully missed opportunity to take a more whole-service approach; this must not be repeated. There were some core service aspirations in the FYFVMH, such as enhanced 24/7 crisis teams, elimination of acute out-of-area placements and development of community pathways, but these were weakened by a lack of clear targets and/or specific ring-fenced funding. Despite early winners in the first FYFVMH, there are still some long-neglected losers. Future service planning urgently needs to redress this imbalance; systems are only as strong as their weakest parts, especially if they are core foundational components.

Quantitative analysis is dogged by informatics challenges. Despite a plethora of information sources, each has its limitations and none tell the whole story on their own. The National Health Service (NHS) England FYFVMH Dashboard² is good in principle, but is inevitably focused on select areas of current policy, with minimal content on core services.

Other sources include NHS Mental Health Benchmarking Data, 'Fingertips' Public Mental Health Data³ and a raft of *ad hoc* reports such as the Commission on Acute Adult Psychiatric Care,⁴ the Carter Report on Mental Health Services⁵ and Care Quality Commission reports.⁶ A 2017 Royal College of Psychiatrists survey of front-line clinicians, regarding perceived progress on the Acute Adult Psychiatric Care Commission recommendations, highlights deep and widespread concerns (personal communication). Combining all these, along with front-line experience, is not an easy task for dedicated researchers and policy leaders, and is almost impossible for busy clinicians. When attempted, an information bias emerges toward those areas that already have a national focus, making it all the harder for those services outside the current policy spotlight to make a coherent case for inclusion. Key information on core services can be hard to extract and harder still to interpret, giving a rather foggy, delayed view of a complex, changing landscape, leaving them vulnerable to institutional neglect, and easy prey for under-the-radar cost-savings.

Figures for total spending on mental health services vary depending on source and definition, inevitably leading to confusion, claim and counterclaim; although clearly of some importance, what matters more to core services is the detail. Nevertheless, analysis by the Royal College of Psychiatrists⁷ suggests that, despite claims that spending 'is higher than ever', total income (in today's prices) received by English mental health trusts in 2016–2017 was 1% less than in 2011–2012 (Scotland, Wales and Northern Ireland were 6, 0.3 and 1.3% less, respectively). An analysis by the British Medical Association⁸ concluded that despite geographical variations, there appears to be no obvious uplift in spending in recent years, noting concerns that government commitments to increased funding are not reaching front-line services, and a significant number of English Clinical Commissioning Groups are not meeting the Mental Health Investment Standard set out by NHS England. With the size of the overall cake barely changing, but several new and specialist ('non-core') services significantly expanding with 'new' investment, it seems likely that actual funding available to core services has decreased. Regarding the detail, what numerical and narrative features can be discerned within the core landscape, e.g. from NHS Benchmarking and the various other reports?

Between 2012 and 2017 there was a 17% reduction in adult acute beds, a 36% reduction in older adult beds and a 10% decline in acute adult admission rates.⁹ Average length of stay decreased slightly in adults and increased slightly in older adults. Adult bed occupancy (excluding leave) rose from 91 to 95% and involuntary admissions rose from 25 to 35%. In 2016–2017, delayed transfers of care increased to 5.4% of occupied bed days, up from 3.7% the year before. An analysis by the British Medical Association found that during 2016–2017, there were 5876 acute adult out-of-area placements for mental health treatment, a rise of 39% on 2014–2015.¹⁰ In May 2018, around 600 acute adult out-of-area placements, costing £9 million per month, were needed each month (in England) because of local bed unavailability.¹¹

FYFVMH did include crisis teams aspirations: by 2020–2021, NHS England 'should ensure that a 24/7 community-based mental health crisis response is available in all areas across England and that services are adequately resourced to offer intensive home treatment as an alternative to acute inpatient admission'.¹ The latest monitoring (2016–2017) shows that only 23% of crisis resolution team services were able to meet selected core functions.¹²

The NHS nursing workforce has grown between 2010 and 2017, but the number of mental health nurses has declined by 12%,¹³ mostly within acute in-patient care as bed numbers have reduced, whereas the number of (mental health) community nurses has increased slightly. In generic CMHTs, overall staffing levels per population, perhaps surprisingly, seem to have been relatively stable in 2014–2017, although with some changes to the skill-mix. Before this, however, were at least 6 years of austerity, during which an unknown quantity of 'easy, low-hanging fruit' workforce cost-savings were likely made. Community case-load figures per population have declined slightly in the past 2 years: by 10% in older age CMHTs and 5% in working age CMHTs. Current data shows that for every 100 patients in community teams, there are only two qualified community psychiatric nurses. Generic CMHT referrals peaked in 2015–2016, but waiting times vary considerably and seem to be growing. More data (due October 2018) is needed to clarify trends, but the general sense is of CMHTs struggling to hold back the rising tide of demand in all its forms.

There are further complexities: many assertive outreach teams were reabsorbed into generic CMHTs (only 25% of trusts still reported assertive outreach teams/data in 2017), increasing CMHT clinical case-load intensity; how many of the staff also transferred is simply unclear. Vacancy rates are not benchmarked at all, whereas generic CMHT 'cost improvement savings achieved' are, remaining steady at 2–6% for most trusts. These were likely achieved, at least in part, by holding vacancies, which the King's Fund reports as currently about 10% across all mental health services;¹³ it also notes, 'trusts must deliver annual cost-savings, and a key area for achieving this is workforce management'. Generic CMHTs, without any national policy priorities, no targets to measure and no 'safer staffing' safeguards, will

remain highly vulnerable targets for ongoing cost-savings.

Looking ahead, the latest Health Education England mental health workforce planning for FYFVMH14 estimates that an additional 20 900 posts will be needed nationally (across all professions: qualified, support and admin, including 700 medical staff). However, the only core service mentioned is crisis teams (with no increase in medical staff); there is no mention at all of in-patient or CMHT services.

Capacity, however, is a complex concept, depending not just on workforce, but on a multitude of inter-related factors, including demand, productivity and influences from other systems. The raw numbers rarely tell the whole story; narrative is needed, and the clear message from the range of commentators is of ever-increasing pressures within core services that were already operating on, or at the margins of, full capacity. The Care Quality Commission notes ‘an unprecedented set of challenges – high demand, workforce shortages, unsuitable buildings and poor clinical information systems’.⁶ Other sources include 2017 NHS Mental Health Benchmarking, available via www.nhsbenchmarking.nhs.uk, which reports, rather ominously, that: “‘In recent years, concerns have been raised that the levels of community care have not risen as quickly as may be required to match the reduction in acute inpatient beds, and that provision may still not be at the levels needed... whilst safe staffing level requirements have benefitted the inpatient environment, unfortunately they have not helped staffing in the community whose responsibilities have increased in terms of caseloads and having to care for more unwell patients in community.’”

With that background, caveats and all, what would front-line clinicians in core adult mental health services like the policy makers to hear, and do?

Front-line messages

One answer comes forcefully from a 2017 Royal College of Psychiatrists survey of front-line clinicians, regarding perceived progress on the Acute Adult Psychiatric Care Commission recommendations (personal communication). It describes an ‘overwhelming consensus that the provision and quality of care is declining’, highlighting deep and widespread concerns over core services, including in-patient care, crisis teams and particularly CMHTs. There is a clearly perceived chronic and growing lack of service capacity, when matched to increasing demands (clinical, operational and regulatory).

The issues are familiar by now: raised clinical thresholds to enter services, and increasing severity and complexity within them; growing waiting times for CMHT care coordination; bed shortages and increasing use of the Mental Health Act 1983 (possibly linked to health inequalities for Black and ethnic minority groups¹⁵); increased acute out-of-area placements (<https://www.bma.org.uk/news/2016/october/plan-to-reduce-discharge-distances>); an increasingly stressed workforce and flagging morale.¹⁶ System changes compound the pressures, such as shrinking social care services and expanding roles like safeguarding. Attempted mitigation measures usually have a modest effect at best, whereas their unintended consequences can sometimes make things worse. Creative service redesigns have mostly confirmed that whatever the model, capacity (and probably continuity¹⁷) trumps configuration. Quality and productivity improvement activities, although clearly valuable, usually produce more gradual, longer-term gains, but too slowly to turn the current tide.

The FYFVMH simply did not take a whole-systems view of mental health services. Instead, it focused heavily on specialist areas such as liaison psychiatry, perinatal mental health, early intervention in psychosis services, child and adolescent mental health services, forensics and primary care psychological therapy. To their credit, these typically generated significant political attention through a clear and up-to-date evidence base (especially health economics research) or public attention via the media. In contrast, core severe mental health services seemed less newsworthy, less politically appealing and had a more limited, historical evidence research base (itself symbolic and symptomatic of long-term relative neglect). Yet it is precisely these core services where the vast majority of care for severe mental illness is delivered, forming the backbone and foundation of the whole service; if they are struggling, and overwhelming evidence and opinion suggests that they are, then the whole system will inevitably struggle too because sufficient capacity is needed in every part of the system.

Currently, the FYFVMH’s blind-spot over core services risks a lack of Parity of Esteem within mental health going undetected under the policy radar. Furthermore, early progress in many of the more specialist areas may become undermined because core and specialist services are inevitably linked and interdependent. Child and adolescent mental

health services patients grow up, with many still needing care; acute hospital liaison patients may be followed up in CMHTs; early intervention in psychosis often becomes ongoing intervention within a generic CMHT; perinatal care does not stay perinatal forever and acute mental health in-patient units and forensic services transfer patients both ways. Each recipient of specialist services should later be able to swiftly access quality care within a core generalist service, when needed, as should those who are referred straight from primary care, yet this is becoming more and more challenging, given the growing core pressures.

Finally, it is worth reflecting on why the core services, particularly CMHTs, currently feel so neglected. Historically (1990s), they were once the new expanding services, following the shift from asylums to community care, and they were considered progressive and attractive to work in. Around 2000, new investment was linked to new services (National Service Framework¹⁸ teams: crisis teams, assertive outreach and early intervention in psychosis), making these now the exciting teams to work in, with attention, enthusiasm and talent shifting away from the core CMHTs and in-patient wards.

Following the onset of austerity after 2008, alarm bells soon rang for the already drifting core, with senior clinicians noting that ‘demographic trends ensure that demand will rise and harsh economic realities dictate that resources will in real terms shrink’.¹⁹ Cost improvement plans inevitably followed, and rationalisation took place, with many assertive outreach teams merging back with CMHTs.²⁰ The search got underway for any new service configurations that might be inherently more efficient; they were not especially (as noted before²¹), at least not in the prevailing climate.

Finally came the paradoxical pairing of ongoing austerity and an emerging Parity of Esteem agenda, both within a confusing commissioning environment, hampered by immature information systems. Priority areas grew, with commissioners and senior managers more focused on newer, ‘shiny’ services, whereas the older core, typified by CMHTs and in-patient units, were quietly considered ‘fair game’ for ongoing cost-savings (typically 3–6% each year), systematically slicing them to part fund the newer services. This gradual shift of resources away from core areas went largely unreported, hidden by limited informatics, minimal relevant national core targets, a chronic accommodation to the growing clinical risks and a lack of media appeal. Much like their patients, most core services, and CMHTs especially, have quietly remained out of sight and out of mind, a no-show in the FYFVMH calls for evidence, and therefore not making the policy cut. Front-line core staff were optimistically exhorted, ‘We’ve always made annual cost-savings before, so we know we can do it again’. But as with most simplistic rules of thumb, it only works for so long, and up to a point. Like anorexia, there comes a time when further safe reduction is simply not possible. For many core services, that point was probably reached some time ago.

What to do?

Policy makers now need to publicly recognise the burgeoning crisis in core services. Any FYFVMH sequel must refocus policy more explicitly on CMHTs, crisis teams and in-patient care, rescuing, resuscitating and relaunching them all, along with improved information systems to support and monitor their regeneration.

There are glimmers of hope: the National Collaborating Centre for Mental Health ‘Mental Health Care Pathway: Community Mental Health Services’ project,²² nearing completion, arose from an FYFVMH recommendation to ‘establish comprehensive pathways and quality standards for the rest of the mental health system’. But it came with worrying limitations: they were last in line for development, waiting times were to be informed by clinical evidence (not targets), and they can be implemented as funding becomes available. Urgently addressing this wooliness would be a welcome start.

The potential benefits of reinvestment (and the risks of not reinvesting) are not limited to the core services, but extend to the whole wider system, even beyond mental health into general society.²³

For too long now core services have been allowed to struggle along in a relative policy, priority and informatics vacuum, through which only muffled cries have so far travelled. Please, finally and quickly, will someone see the signs, hear their voice and begin to restore the foundations?

This book is the fruition of an idea by the author that has germinated since the 1970s. It was largely inspired by his concern with unfair discrimination against people with mental illness. From its evocative title to its thought-provoking review of 200 years of mental health legislation (both in the UK and globally), this is a book that should appeal to a wide audience. It has been deliberately written to include patients and family ('experts by experience') as part of a multidisciplinary audience. The fluent and conversational writing style, the purposeful use of 'typical' case histories, the text being well signposted with subheadings, and references being readily accessible at the end of each chapter certainly help in this respect.

There are two main themes – the use of coercion in mental health practice and an equally interesting bold and well-thought-out exposition of a proposed new mental health legislation termed a 'Fusion law'. This law is non-discriminatory and generic for all specialties, with no need for specific mental health law, the framework being based on decision-making capability and a modified best interests approach to involuntary admissions and treatment decisions.

The book has five parts and comprises 13 chapters. Part I considers problems associated with involuntary detention, which the author believes actually contributes towards discrimination against people with mental illness. Part II offers an exciting solution to involuntary detention and treatment and proposes in-depth new legislation. This part has a more theoretical or academic feel, but this is where the author elucidates and validates his proposed reforms. A visual flowchart of these reforms may have been helpful to help understand these better. The author does acknowledge that there would need to be some initial interim measures in the forensic setting were these reforms enacted. Part III analyses coercion and treatment pressures in everyday clinical practice and provides ideas to try and reduce recourse to coercive measures in both detaining and treating people. This part would be particularly useful for junior doctors of all specialties. Parts IV and V are about translating the theoretical basis of new reforms into the reality of clinical practice across all physical and mental health settings.

Given that mental health law has not fundamentally changed for around 200 years (essentially still being based on the two criteria of having a mental disorder and posing a risk of harm, but *not* including any form of capacity criteria) it would surely be an epoch-making quantum leap in mental health legislation to enact this Fusion law. However, the author opines that 'change is now essential' and is optimistic that such legislation favouring patient empowerment will continue to emerge globally, citing a version of Fusion law and its principles having been passed in the Northern Ireland Mental Capacity Bill 2016. This was an invigorating read, challenging the long-held orthodoxy of mental health law. It is a text that will surely resonate with all clinicians involved in the application of the Mental Health Act.

I quite understand Jennifer Smith's concern. It seems, on the face of it, silly to suggest that the age of consent be reduced when the great majority of people, including me, think it is unwise for adolescents to engage in full sexual intercourse at least until their late teens. But, once one has considered how the existing law is flouted, it no longer seems at all silly. The idea that changing the law will encourage 50-year-old men to seduce 14-year-olds rather than 16-year-olds seems highly improbable. The reality is that the best safeguards against premature sexual activity are those that emphasise much better sex education for children and young people who would thus be empowered to say 'no'. And lowering the age of sexual consent would allow parents and teachers to engage in imparting meaningful information earlier than is currently the case.

1.5.84 Against the Stream: lowering the age of sexual consent

Jennifer Smith

date

2018-12

Contents

- *Against the Stream: lowering the age of sexual consent*

I read with unease the Special Article by Philip Graham in the August 2018 edition of the *BJPsych Bulletin*. His counter arguments seem insufficient. He argues that existing law has had no effect on young people's sexual behaviour over the previous 50 years, but doesn't take into account changing social, cultural and religious attitudes over that period. He references a survey of American school students who failed to cite the law as a reason for abstinence. However, conservative beliefs and promotion of abstinence before marriage are likely to be much more significant factors in the USA than in the UK. With respect to arguments about physical and physiological maturity, these seem largely irrelevant either way as these attributes bear no firm relationship to cognitive maturity.

Regarding cognitive and emotional maturity, while those aged 14 to 16 may be able to recognise the risks of sexual activity, as he points out himself, their ability to evaluate the risks can be compromised by other factors.¹ Life experience and perspective are also imperative when making potentially life-changing decisions; an extra two years in adolescence

is a significant amount of time. Graham's assertion that the law is unlikely to be used as a reason to refuse consent seems speculative, and even if only a small proportion feel empowered that is surely important.

In my opinion, the most worrying aspect of lowering the age of consent is the legalisation of adults of any age having sexual relationships with children under 16. Consider a 50 year old with a 14 year old; it is obvious that the power dynamic is unhealthy even if the person isn't in a trusted position. Worse still is the risk of greater difficulties in prosecuting cases of vulnerable children involved in prostitution, sex abuse rings or forced marriage.

We also have to consider children below 14. It is currently an offence for a person (A) aged 18 or over to intentionally engage in sexual touching of a child under 16. Where the child is aged 13 to 15, the prosecution must prove that A did not reasonably believe that he was 16 or over (Sexual Offences Act 2003). If the age of consent was 14, presumably prosecutors would have to prove that A did not reasonably believe that the child was 14 or over. Logically, that would likely lead to claims that people thought children under 14 were at or above the age of consent.

To address Graham's arguments in favour of lowering the age of consent, he himself points out that where both parties are below the age of consent there is little likelihood of prosecution. There is also no current reason that 14- to 16-year-olds cannot access sexual health services, as is made clear by the National Health Service (<https://www.nhs.uk/live-well/sexual-health/>). Similarly, sex education is already compulsory from the age of 11 (<https://www.gov.uk/national-curriculum/other-compulsory-subjects>).

In conclusion, I see no compelling argument to lower the age of consent; we should instead be taking inspiration from other countries like France that are strengthening their existing inadequate laws.

1.5.85 Street triage services in England: service models, national provision and the opinions of police

Abirami Kirubarajan Stephen Puntis Devon Perfect Marc Tarbit Mary Buckman Andrew Molodynski

Correspondence

Stephen Puntis

(stephen.puntis@psych.ox.ac.uk)

date

2018-12

Abstract

Aims and method

Street triage services are increasingly common and part of standard responses to mental health crises in the community, but little is understood about them. We conducted a national survey of mental health trusts to gather detailed information regarding street triage services alongside a survey of Thames Valley police officers to ascertain their views and experiences.

Results

Triage services are available in most areas of the country and are growing in scope. There is wide variation in levels of funding and modes of operation, including hours covered. Police officers from our survey overwhelmingly support such services and would like to see them expanded.

Clinical implications

Mental health crises now form a core part of policing and there are compelling reasons for the support of specialist services. Recent changes to the law have heightened this need, with a requirement for specialist input before a Section 136 is enacted. Those who have experienced triage services report it as less stigmatising and traumatic than a traditional approach, but there remains little evidence on which to base decisions.

Declaration of interest

None.

 - * *Implications*

Law enforcement officers routinely come into contact with members of the public who have mental health problems. In the UK, estimates of police incidents linked to mental health crises have increased over recent years.¹ Within England and Wales, Section 136 of the Mental Health Act 2007 allows police officers to detain people who are experiencing a mental health crisis and who are considered to pose a risk to themselves or others.² Although this measure may be unavoidable, it is often distressing, expensive and labour-intensive.³ In addition, police officers often feel that they lack the training to appropriately support those in mental health crisis.⁴

In response to the increasing use of Section 136, the Department of Health funded several regional pilots of street triage for mental healthcare in 2013.⁵ Triage models typically involve mental health professionals working in partnership with police officers, providing expertise through a telephone service or an in-person mobile unit.

More services have now been commissioned at a local and regional level by mental health trusts and police forces. The provision of triage services nationally, however, remains unknown and there is a lack of information regarding the operational models used. There is also no systematic information regarding police officer opinions of such services.

Recent changes to the Policing and Crime Act 2017 made it a legal requirement to consult, where practical, with a mental health professional before instigating a Section 136.⁶ Street triage schemes, whose primary function is to introduce mental health expertise during police incidents, may be ideally placed to do this. As mental health police partnerships become more vital at the point of crisis, information on service models will enable better planning of services to meet the requirements of the legal changes.

Our study aimed to determine the prevalence of mental health street triage services in England and to characterise their operational models. We asked whether services were predominantly mobile- or control room-based, how they were staffed, which vehicles and locations were used, the hours of operation and the reasons cited for use.

Our second aim was to systematically collect the views and experiences of police officers who have used services. We identified how regularly officers had contact with individuals experiencing mental health crises, whether they frequently used Section 136 and their confidence levels when dealing with mental health crises. We also asked whether police officers were aware of local street triage services, their preferences regarding their model and whether they found them beneficial.

Method

Survey design and samples

We conducted two surveys. Data were collected between June and October of 2017, using an online survey tool (www.surveymonkey.com). The first was a cross-sectional survey of all 55 National Health Service (NHS) mental health trusts in England.

The second was a survey of operational police officers in the Thames Valley police force. Thames Valley Police provide police services for 2.1 million people residing in Berkshire, Buckinghamshire and Oxfordshire. Street triage services have been available in the region since 2013 because of collaboration between Thames Valley Police and Oxford Health NHS Foundation Trust. The street triage service provides telephone support and a co-response mobile unit (where a police officer and mental health worker respond to incidents in a police vehicle) between the hours of 18.00 h and 04.00 h.

Both surveys met Health Research Authority criteria for a service evaluation and were approved by Oxford Health NHS Foundation Trust.

Procedure

For the NHS trust survey, letters were sent to every trust's Chief Executive. Non-responders were followed up twice when necessary, at 4 and 8 weeks. For the police survey, surveys were emailed to all response police constables and police sergeants employed by Thames Valley Police in September 2017, with responses collected until October 2017. A single reminder was sent out to all officers 2 weeks after the initial request.

Survey questionnaire

The surveys were constructed to address the primary and secondary aims of the project. The surveys took up to 30 min for participants to complete, and were conducted solely online. We collected demographic information and length of service for all respondents. The survey questionnaires are available from the corresponding authors upon request.

Results

Identifying and characterising NHS street triage services

Prevalence of street triage services

A total of 40 out of 55 (73%) mental health trusts in England responded to our survey. Of the 40 respondents, 28 (70%) offered street triage services. Of those that had services, the mean length of provision was 2.9 years, with wide variability from 6 months to 5 years of operation. Most areas reported that services had been available for 2–4 years.

Of those that did not provide a service, two (17%) had definite plans for introduction. Seven trusts reported having more than one street triage service, crossing different jurisdictions (police and/or social services) in their geographical area, giving a total of 41 street triage services represented in the survey.

Models of street triage

Eight out of 41 (20%) of the services described a telephone support only street triage service, 19 (46%) reported a mobile unit and 12 (29%) reported they had both means of response (*Fig. 1*). Two respondents (5%) did not specify. *Fig. 1* Reported frequencies of models of triage.

Staffing

A total of 28 out of 36 respondents (78%) reported their service was staffed by police officers and mental health staff, and eight out of 36 (22%) reported it was staffed by mental health staff only (a model in which mental health staff provide telephone support or attend police incidents after a referral from the police at the incident).

Services were overwhelmingly led by health staff (27 out of 41; 82.5%), although several services had police officers as lead (five out of 41; 12.5%) or a combined leadership model (six out of 41; 12.5%). One of the services (5%) did not have a designated lead. Two respondents (5%) did not specify. On average, there were 2.05 whole-time equivalent staff on duty per shift.

Vehicle and location

Of the 31 reported mobile services, ten (32%) used marked and 11 (36%) used unmarked police vehicles. Four (13%) used personal vehicles or ambulances and six (19%) respondents reported that they used a combination.

A total of 38 services reported on their main location for street triage services, with 28 (74%) services located at police stations and ten (26%) located at mental health sites.

Hours and days of operation

There was a wide range of reported hours and days of operation. Only three of the 28 trusts (11%) offered 24/7 availability, with the majority (79%) typically only providing night shifts (usually between late afternoon or early evening and a few hours past midnight).

Methods of contact

Street triage teams were contacted in a variety of ways, including 999 emergency operators (10%) and from the police control room (18%). The most common method, however, was a combination of means (72%), including 999 calls, control room, individual police officers and other emergency services.

Reasons cited for service use

Service providers gave a number of reasons for street triage call-outs: 98% (39 out of 41) reported that call-outs had been made for cases of self-harm and there were also high figures for other reasons, as shown in *Table 1*.

Reasons cited	Percent of respondents
Deliberate self-harm	98%
Previous mental health history	80%
Substance misuse	20%
Psychosis	50%
No alternative support available	10%
Support Section 136 decision-making	8% ¹

The views and experiences of police officers regarding street triage services

Demographic information

The police survey was sent out to 579 officers, of whom 264 responded, for a response rate of 45.6%. *Table 2* presents service and demographic results of respondents.

Mental health training

A total of 207 out of 256 (81%) of respondents reported they had received formal mental health training in the past 3 years, often in more than one form. Eight respondents did not respond. This training was generally mandated (181 out of 221 respondents; 82%).

Contact with mental health crises

A total of 87% (222 out of 255) of respondents reported regular (approximately every shift) face-to-face contact with the public, with 79% (202 out of 255) reporting weekly or more frequent contact with people in mental health crises; within this subset, 115 (45%) reported daily or more frequent contact (*Fig. 2*). Respondents reported that on average, four out of their past ten incidents involved mental health crises. *Fig. 2* Frequency of contact with members of the public with mental health problems.

Officers' confidence regarding mental health incidence varied: 71% (178 out of 252) reported they were at least fairly confident, whereas 10% (25 out of 252) described themselves as unconfident.

Awareness and use of street triage

Levels of awareness of the service were high at 97% (249 out of 256): 92% of respondents who answered this question had used street triage (234 out of 257) and 92% of these respondents described the triage service as helpful. Sixty per cent (145 out of 245) had used both mobile units and telephone support.

Respondents were further asked for their experiences of and preferences for the two systems. There was a clear preference for response in person, with 47% (68 out of 145) reporting this as being more helpful and only one respondent feeding back that telephone support was better. The remainder (52%; 76 out of 145) reported that both were equally helpful. A total of 98% of respondents (240 out of 245) overall felt that the service has been beneficial in the Thames Valley area and 71% (173 out of 245 respondents) felt that it should be available 24 hours a day.

Use of Section 136 and interactions with street triage

More than half of respondents had used Section 136 of the Mental Health Act 2007 (58%; 146 out of 251) and only 52% of those using the powers (76 out of 146) had involved the street triage service in the process. The most common reason cited was the unavailability of the street triage service because of hours of operation or other demands on it (83%; 58 out of 70).

Officers' free-text responses and feedback

Sixty respondents made comments in the free-text section, with 58 (98%) commenting that the service was highly beneficial. Officers noted that the service was 'long overdue' and 'one of the best decisions made by Thames Valley Police and NHS in recent years'. One officer directly commented on its necessity: '[Mental health] is a specialist area and police officers are not mental health specialists'. Additional reported benefits included saving police time and reducing stigma.

Many stated that they wished that the service was available 24/7 or at least extended hours. One officer wrote 'the only downside is that it is not already a 24-h service'. Additional comments referenced the lack of availability of child mental health workers and social workers, as '[police officers] seem to come across a lot of younger people with mental health issues too'.

Discussion

These surveys are the first attempt to characterise street triage services nationally since the launch of the pilot projects in 2013, and to get a detailed snapshot of police attitudes toward them. It is clear that street triage services, although still a relatively new model of care, are now widespread across England. They have continued to expand in spread and scope since their introduction, understandably given the increasing contact between police officers and those with mental illness. This is also reflected in the changes to the Policing and Crime Act, which will necessitate better police–mental health interagency collaboration;⁶ street triage is best prepared to fill this gap in service.

Our National NHS survey highlights significant variations in street triage models. Hours of operation vary, although usually with an emphasis on evenings, night-times and weekends, with little or no cover during the daytime. Levels of investment vary substantially and are reflected in staffing numbers and types of model; a mobile in-person response is inevitably initially costlier than telephone support. However, the former service is more valued by officers and may be more effective at freeing up police time and allowing for appropriate interventions, and as a result may be more cost-effective. We simply do not know. Future research must concentrate on what the effective elements of street triage are that improve patient experience, reduce ‘wasted’ police time and improve outcome in terms of health use, functioning and criminal justice interactions.

Most services are located on police premises, but are led by NHS staff. This may be appropriate in the short-term, but there needs to be consideration of whether a merger of personnel would be more effective. There is similar lack of clarity in many funding models, with the key question being ‘who should pay for these services?’. We did not specifically explore this in our study, but opinions seem to differ between the three main agencies concerned (the police, health and social care). A hybrid funding model involving the interested parties would likely be most appropriate but this requires negotiation and thought; in these austere times this will not be easy. Future work to determine how to best navigate such financial and institutional barriers to interagency cooperation between the police and health sector is needed.

Police officers from our survey are overwhelmingly supportive of street triage. There was a clear preference for services to exist and to be provided in-person. There was strong support for 24/7 services. There was a high frequency of responding to mental health incidents described by participants, supporting the view that mental health work is now ‘core police business’.⁷ This underpins the need for triage services, heightened by recent changes to legislation that require officers to seek qualified mental health advice before using Section 136, rather than seeking guidance retrospectively.⁶ As mental health crises occur at any time of the day, it was not surprising that the majority of officers in our survey believed that street triage should be available 24/7. Longer hours of operation, more integration and a higher profile may help to improve the training and confidence of officers.⁸ We do not know whether face-to-face triage is more effective than telephone triage. Only one previous study has compared these models.⁹ Their analysis suggested that a face-to-face model can reduce the overall use of Section 136 and increase the proportion resulting in hospital admission, while the telephone-only service did not.

Limitations

Both surveys may include some selection bias, in common with any survey of this type. However, the respondents in our police survey were fairly large in number, there was a reasonable response rate and they appear representative. Our national NHS survey achieved an excellent response rate of 73%, unusually high for such a survey and likely to be protective against selection bias.

Implications

In conclusion, street triage services are widespread across England and increasingly seen as a permanent part of our response to mental health crises. Despite this, models vary significantly and there is little or no evidence on which to base good practice or commissioning decisions. Outcome data is almost non-existent. Our surveys show a clear appetite for services to exist and to be strengthened. Recent changes to the Police and Crime Act will almost certainly stimulate this, with officers being required to seek advice in real time. Public concerns regarding civil liberties and the unacceptable cases of people being stranded in police cells while arrangements are made also make the case that mental health expertise during these crises is vital.

However, the increase in use of street triage will require greater resources and further investment. Questions should be asked as to how services can be organised most effectively and efficiently and how they can most benefit those experiencing mental health crises. Evidence is urgently needed regarding the effects of street triage services and, crucially, what elements of the service are effective in reducing risk and improving outcome. Future studies could also investigate mental health staff or patients' perceptions regarding the quality of triage care.

This research was funded by the National Institute for Health Research (NIHR) Collaboration for Leadership in Applied Health Research and Care Oxford at Oxford Health NHS Foundation Trust (grant number BZR00180). - *Even more against the stream*

We all know the law is an ass, but when it comes to defining an age of consent it is more like a badly assembled chimera. You can become criminally responsible at the age of 8 or 10, liable to criminal prosecution from the age of 12, legitimately have sex at the age of 14 while on holiday in Germany, join the Army at 16 and perhaps later die for your country, vote and purchase alcohol or cigarettes at the age of 18, but not hire a car until the age of 25. What an Alice in Wonderland world we live in! Logic would suggest a similar age for all of these activities, perhaps with some allowance for variation justifiable by the extent of risk involved.

The appropriate legal age of sexual consent is not immediately obvious. However, as sexual intercourse with a child under the age of 13 amounts to statutory rape, this might provide a logical starting point. Incidentally, when I last checked, the lowest age of sexual consent in a European country was actually 12 (in Vatican City, somewhat ironically).

Of course, in reality, the limited availability of parliamentary time will make a logical alignment of the various ages for consent a complete non-starter. So perhaps a better question is 'Why have an age of consent at all?' This allegedly offers protection but in reality mainly just criminalises a substantial proportion of the juvenile population and potentially even criminalises an underage victim of a sexual assault. Surely criminal responsibility should only rest with the perpetrator? In this scenario, a perpetrator would commit a crime if, and only if, a sexual act occurred in the absence of consent,

and not simply by reason of some arbitrary age. Can we not trust our children to reach their own decisions and just make consent, or rather lack of consent, the sole reason for engaging criminal law?

1.5.87 Men in eating disorder units: a service evaluation survey regarding mixed gender accommodation rules in an eating disorder setting

Akira Fukutomi Frances Connan Anthony P. Winston Pia Ghosh

Correspondence

Dr Akira Fukutomi (fukutomiakira@gmail.com)

date

2018-12

Abstract**Aims and method**

This service evaluation was conducted to find out: (1) if mixed gender accommodation in eating disorder units is perceived to be helpful or unhelpful for recovery, and (2) if men were being discriminated against by the implementation of the 2010 Department of Health (DoH) guidelines on the elimination of mixed gender wards. All 32 in-patient units accredited on the Quality Network for Eating Disorders were contacted via a survey.

Results

We received 38 responses from professionals from 26 units and 53 responses from patients (46 female, 7 male) from 7 units. Four units had closed admissions to male patients due to DoH guidelines.

Clinical implications

We found that it is possible to provide admission for men with eating disorders, while respecting the single gender accommodation rules, and that doing so is likely to be helpful for both genders and prevents discrimination against men.

Declaration of interest

None.

 - *Supplementary material*

In 2010, the Department of Health (DoH) set guidelines for all hospitals to eliminate mixed gender wards to preserve privacy and dignity for patients.¹ In specialist eating disorder services, all-male wards do not exist due to the low prevalence of the disorder in males compared with females. This leads to the paradoxical situation where men have difficulty accessing an eating disorder bed under these DoH guidelines. Some hospital trusts have modified their accommodation or procedures in light of Care Quality Commission (CQC) guidelines set by the DoH to accommodate men; however some have had to close admissions for male patients as the trusts believed they would be fined for breaching single gender accommodation rules.

Anecdotally, there has been positive feedback from having men in eating disorder wards: they provide a less competitive atmosphere, a different perspective in group treatments and reduce the institutional nature of the environment. A survey performed by Mezey *et al*² in a medium secure forensic setting found similar results, where most female patients preferred to be among male patients. A small qualitative study interviewed male in-patients with eating disorders and one participant said that eating disorder is ‘gender-excluding as a disorder’ and ‘reasons why you get there are probably slightly different but in the end all roads lead to Rome’,³ suggesting that the same treatment applies to both genders. There has yet to be any evaluation of patient perceptions on mixed versus single gender environments in an eating disorder setting. We therefore collaborated with National Health Service England to conduct a service evaluation survey, gathering information from patients and professionals.

Method

All 32 in-patient units accredited on the Quality Network for Eating Disorders (QED) in the UK were contacted via email, using an electronic survey (Supplementary Appendix 1 available at <https://doi.org/10.1192/bjb.2018.51>). The individuals contacted were those registered on the QED network and included consultant psychiatrists, psychologists, senior nurses and occupational therapists. The survey for the professionals asked for feedback on three themes: (1) if they were a single or mixed gender unit and how they arranged the ward to accommodate both genders; (2) if the trust, commissioners or the CQC had ever commented on or stopped admission of male patients; (3) if the professional had any views on recovery of patients in same or mixed gender environments.

The third point was conducted by asking positively and negatively framed questions with a five-point Likert scale and mean scores were then calculated. The points ranged from 1 for strongly disagree to 5 for strongly agree. A ‘free comment’ box was placed at the end for added opinions.

In-patients were asked to provide feedback on their experience of single or mixed gender environments and similar scores were then calculated (Supplementary Appendix 2). Male patients had extra questions to complete. Data were

collected between October 2016 and August 2017.

Results

Professionals

A total of 38 eating disorder professionals registered on the QED network responded from 26 different units across the UK. Six of these units did not admit men: three of these units had stopped admitting men after a CQC inspection and one had been advised similarly by Health Improvement Scotland. *Figures 1 and 2* show the responses to questions on perceptions of mixed gender wards. In general, professionals thought that mixed gender units carried more benefit than harm to patients. There was a general agreement that eating disorder units should be mixed gender wards (mean score 4.37 out of 5) and that it was easy to ensure safety and dignity in mixed gender wards (4.11). Most did not think that mixed gender wards discriminated against women (1.63), nor did they think that having one male patient was detrimental to that man's care (1.71). There were mixed responses about whether it has been difficult to find a bed for male patients since the single gender rule was introduced (3.24). *Table 1* highlights some comments that were provided in the free-text box. *Fig. 1* Survey for professionals: positively framed questions. *Fig. 2* Survey for professionals: negatively framed questions. *Table 1* Comments by professionals in the free-text box

Themes
Response from professionals
Is mixed gender accommodation helpful in eating disorder units?
On the whole we have found having a male on the unit quite refreshing and beneficial to both client sexes... We have only had a small number of males admitted to the unit but on the whole our experience so far is positive.'

'Mixed sex units for ED are a necessity. Both sexes benefit from having the other gender on the ward. ED units attempt to support individuals in recognising what is "normal" this includes being in an environment with members of the opposite sex.'

'We tailor our groups to accommodate the needs of all patients, and dynamics that arise around gender, as with any other issue, would be explored through the group process and in community group settings where appropriate.'
Are men being discriminated against due to single gender accommodation guidelines?
The concern seems disproportionate and the impression is that the response from CQC varies dependent upon the individual assessor on the day.'

'I believe it could be quite tricky to manage the issue of having different corridors for male and females especially if you are not a purpose built unit. The feedback from males during their stay is they prefer to be included in the group as it often makes them feel awkward and isolated from peers.'

'There needs to be some work done to alleviate blanket rules around single sex wards. Some elements ought to be ward or unit specific.'

Patients

A total of 53 patients (46 female, 7 male) from 7 eating disorder units responded to the survey. Three of these surveys were partially incomplete; however the scores and comments that were provided have been included in the results. A total of 49 participants (92%) had experienced admission on a mixed gender unit and 29 (56%) had experienced both single and mixed gender environments. *Table 2* shows the distribution of services from which the patients responded, although many had experience of admission at a variety of other centres. *Table 2* Sources of responses

Figures 3 and 4 shows the attitudes from patients towards mixed gender accommodation. Most patients agreed that men were being disadvantaged (75.5%). Nearly the entire patient group (98%) answered positively or neutrally to whether having a mixed gender accommodation was helpful for their recovery. A total of 45 participants (85%) gave a similar (positive or neutral) response to 'I've learnt helpful things about myself by having male patients'. There were minimal safety issues noted, most participants (75.5%) disagreed to being 'intimidated by male patients on the ward'. *Fig. 3* Patients' responses scoring above 3 (neutral). *Fig. 4* Patients' responses scoring below 3 (neutral).

Figure 5 shows the responses from the seven male patients. Of these, six agreed to the statement 'I don't mind if I'm the only male patient on an eating disorder ward' and five agreed to 'As a man I feel accepted on a mixed gender ward'. Six men said that they would not want to be treated on an all-male ward if it were far from home. Fig. 5 Perceptions from male patients.

Of the 41 patients who wrote in the optional free-text box (see Table 3), 36 (88.8%) were in favour of having a mixed gender unit. Many voiced that having a 'mixed unit is reflective of the outside world' and that mixed wards were 'healthy for dynamics' and 'reduces competitiveness'. A male patient thought it was 'crucial' to his recovery that he was on a mixed gender ward and believes his presence 'was a benefit to others on the ward'. Only three participants (8%) had negative feelings towards this (one male, two female); however both female patients with this opinion had not experienced a mixed gender eating disorder ward. The male patient voiced strong concerns about feeling 'isolated and slightly intimidated' as the only man because 'many groups were geared towards females'. Table 3 Comments by patients in the free-text box Themes Response from patients In favour of having mixed gender wards 'Mixed unit is reflective of the outside world.'

'Having a male upon the ward allowed me to see from a different perspective during therapy groups which helped me to understand the illness from this kind of viewpoint and hence supported my treatment.'

'All female wards can be stifling and very competitive.'

'I feel sure that had I been forced to be on an all-male ward that I would have found it much harder. I also believe that my presence as a man was a benefit to the others on the ward.'

'I think it's not a problem having male patients on the ward too. It's not fair to restrict their treatment options.' In favour of having single gender wards 'I see that there will be fewer wards for men which is unfair but also there is a percentage of women with eating disorders who have PTSD or have suffered from sexual abuse that need to be taken into account.'

'Many groups were very geared toward females and I have often felt isolated and slightly intimidated in both units. I have often felt that my recovery, or lack thereof, has been in part not helped by being the only male in treatment at in-patient units, although I would still rather be the only male than have no treatment or community based treatment only which for me is ineffective.'

Discussion

The results show that the majority of both patients and staff believe mixed gender units work just as well as, if not better than, single gender units for patient recovery in both genders. Some of the original thoughts behind segregating the genders, such as having to dress differently or having separate lounges, were not deemed very important by the patients. Unfortunately we confirmed that a handful of units have closed to male admissions due to interpretation of DoH regulations. Drawing parallels from the study by Mezey *et al*,² it may be that due to the long-stay nature of the ward and treatment duration, having a sense of normality and the reduction in competitiveness by having a mixed gender unit helps to provide a more therapeutic setting. This survey suggests that both professionals and patients believe that eating disorder wards should be open to males, and that patients will have a better recovery journey as a result of the mixed gender environment. We hope that research will now follow to better understand the risks and values of a mixed gender treatment environment.

Recommendations

With the support of QED, clarity was sought about how the DoH single gender guidelines apply to settings such as eating disorder services. The following guidance has been approved by the CQC as entirely consistent with the DoH single gender accommodation guidance and should make possible male admissions to every in-patient eating disorder service: •A risk assessment has been carried out to ensure that the male patient does not pose a specific risk to female patients. •There is an agreement in place with National Health Service England commissioners on the admission of male patients and the admission is consistent with this agreement. •Appropriate arrangements have been put in place to ensure that female patients do not feel unsafe or compromised in terms of privacy. •Male patients are accommodated in single bedrooms with en-suite bathroom and toilet facilities, if possible. •If this is not possible, male patients occupy a single room with use of male-only bathroom and toilet facilities. •Patients do not have to walk through a sleeping area or a bathroom occupied by another gender. A sleeping area is a bedroom or a bay of beds. Men can walk through a corridor, off of which there are doors to female bedrooms and bathrooms, to access a male bathroom. •A women-only day room is available.

- *Dhirendra Nath Nandi, FRCP (Edin.) FRCPsych*

Formerly Psychologist, Psychoanalyst and Psychiatrist

2018/S205646941800058X_inline1.jpg

Dhirendra Nath Nandi, who passed away quietly aged 98 on 26 March 2017, was Head of the Department of Psychological Medicine at the University of Kolkata and a prominent leader of Indian psychiatry. Assisted by a team of several postgraduate students, he carried out significant epidemiological research in different tribal groups in villages of West Bengal. His research findings, which included important longitudinal data, were published not in just Indian but several British and US journals. One important finding related to a dramatic fall in hysterical and anxiety disorders with an equal rise in affective illnesses.¹ His papers were used as standard texts in several educational programmes.

Professor Nandi had a strong interest in raising public awareness of mental health problems. He organised several public awareness programmes on his own and with the Indian Red Cross Society in different parts of Kolkata and other districts of West Bengal. He was frequently invited to be a speaker on various television shows and radio programmes to talk about mental health. In 1990 he wrote a book in Bengali on psychiatry, *MonerBikar o Pratikar*, which was very popular with the general public, and postgraduate students in psychology and psychiatry. In the later years of his life, he founded the Girindra Sekhar Institute of Psychological Education and Research, where he started a counselling course affiliated with a recognised university of West Bengal for graduates in basic and social sciences. He also established a popular quarterly journal in Bengali, *Moner Katha*, as well as running an out-patient clinic for the poor and underprivileged mentally ill, which retains its reputation to this day.

Born on 13 August 1918, in a remote village of a district of West Bengal to a poor family and losing his mother in his early childhood, Dr Nandi showed early promise in his studies. He struggled considerably in early life but showed indomitable energy in the pursuit of knowledge in medicine and psychology. After graduation from Carmichael Medical School, then the R. G. Kar Medical College and Hospital, Kolkata, in 1945, he obtained an MSc in psychology in 1950, and a PhD in psychology in 1958 from the University of Calcutta. He trained in clinical psychiatry and psychoanalysis with Professor Girindra Sekhar Bose, the eminent psychiatrist and founder of psychoanalysis and psychiatry in India, and with Professor N. N. Dey, his own maternal uncle and first editor of the *Indian Journal of Psychiatry*. He began his career in 1948 as a teacher, examiner and researcher in physiology at NRS Medical College and Hospital, Kolkata, where he worked for nearly 10 years.

Marrying in 1949 into a business family, he went abroad in 1960, leaving his wife and three children in Kolkata with his in-laws. He obtained his Scottish Diploma in Psychological Medicine in 1961 and became a Member of Royal College of Physicians (Edinburgh) with a special paper in psychiatry in 1963. In those days, there was no postgraduate training in psychiatry available in India. Returning to Kolkata he was appointed Associate Professor of Psychiatry at R. G. Kar Medical College and Hospital, Kolkata. In 1970 he became Head of the Department of Psychological Medicine at the University of Calcutta. He retired in 1979 as Professor of Psychiatry from R. G. Kar Medical College and Hospital, Kolkata. During his professional life he held a number of important positions in Indian psychiatry, including being President of the Indian Psycho-analytical Society for more than 20 years, and President of the Indian Psychiatric Society and Indian Association of Social Psychiatry. His contributions to the advancement of the fields of psychiatry and psychoanalysis were recognised by numerous awards and prizes.

Professor Nandi had an active interest in cooking, fishing and hunting, and travelled widely with his family and friends. It is noteworthy that his two sons are consultant psychiatrists, his daughter and younger daughter in-law are psychoanalysts, one grandson is undertaking a post-graduate degree in psychiatry, a second grandson is a graduate in medicine, and a third is a final-year medical student.

1.5.89 The Risk Reference Panel: a thematic analysis of a multidisciplinary forum for complex cases

Alec Thomas Ian Evans Gaynor Jones

Correspondence

Alec Thomas (alecthomas@doctors.org.uk)

date

2019-4

Abstract

Aims and method

To describe the functions of the Aneurin Bevan University Health Board Risk Reference Panel and characterise the typical referrals presented and outcomes from the panel. A structured thematic analysis was performed on verbatim transcripts of 48 panel sessions.

Results

The 79 codes identified were grouped into 16 subthemes. Four principal themes were identified: two characterising cases brought to the panel (childhood risk factors and current presenting difficulties) and two describing advice given (risk management and wider organisational issues). Quotations are given to illustrate cases presented and advice given by the panel.

Clinical implications

The panel provides a valuable source of special expertise in the management of complex and exceptional cases where risk of harm is significant and clinical teams have ongoing concerns. This paper describes a model of peer-working to support staff and may further reduce the risk of harm associated with mental illness.

Declaration of interest

None.

Background

The assessment and management of the risk that a patient poses to themselves and others is a core duty for psychiatric services. There are several ways in which this is achieved, depending on the complexity of the case, the configuration of local services and resources available. In many cases, issues around risk are managed effectively by individual practitioners or teams on a day-to-day basis, using evidence-based guidance from national bodies such as the Royal College of Psychiatrists¹ or the Department of Health,² as well as locally agreed policies and procedures and clinical supervision. However, in some circumstances the risks posed may be exceptional or unclear, and individuals can engage in high levels of self-harm or antisocial behaviour. This can be analysed retrospectively by complex case reviews to reduce risk of recurrence,³ but prospective prevention or minimisation of harm is clearly preferable.

The Risk Reference Panel

Multidisciplinary working is a key strategy for particularly risky cases, which can take various forms. From 2008 the Aneurin Bevan University Health Board Risk Reference Panel was developed by Dr Alan Wright, Forensic Psychologist, and author I.E., Forensic Psychiatric Nurse, as a local response to the public and professional anxiety surrounding exceptionally risky cases. The panel is intended to provide a pool of multidisciplinary expertise with representation from social work, nursing, forensics, intellectual disability and general adult psychiatry. To date, the panel has not included patient representation, but this could be considered in future. This paper offers an analysis of a way of addressing risk and management of complex cases by describing the types of cases that have been presented and the outcomes of panel meetings. A retrospective thematic analysis of the meetings was conducted.

Method

Thematic analysis

Our aim was to describe the typical cases presented to the panel, the discussions that took place and the advice given. To best produce this narrative from the data available, we felt a qualitative approach was appropriate. We required a method of qualitatively analysing transcribed data, such as the meeting transcripts that formed our data-set, and decided on thematic analysis. This provided a framework with which to identify and organise the discrete ideas within the transcripts, outlining patterns in the data but also indicating their relative frequency within the meetings as a whole.

Although qualitative research uses many specific, prescribed techniques to evaluate non-empirical data, there has historically been some discrepancy as to what strictly constitutes thematic analysis and its methodology. For our purposes, we have followed the model proposed by Braun and Clarke,⁴ which describes six discrete stages of thematic analysis.

The stages of the above method as applied to our analysis are described in the Appendix.

Discrete ideas (referred to in the process as ‘codes’) and broader groupings of these ideas into key patterns (‘subthemes’) were identified. The subthemes can then be grouped together to identify the main themes within the data.

Data collection

The Risk Reference Panel meetings are attended by a secretary who records what is said by typing verbatim as far as is possible; there is no audio recording of the meetings. These transcripts are then used to produce letters to the referring team, outlining what was discussed and the recommendations of the panel.

A pilot analysis was conducted whereby authors A.T. and G.J. independently applied the method described below to a sample of original transcripts for 8 of the 48 cases that had been presented to the Risk Reference Panel between May 2010 and April 2016. Ethical approval was not required as our study is a retrospective service evaluation where no change to the service was implemented and no service users were interviewed. All reported data are anonymised. Anonymised samples of the transcribed data, as well as examples of the codes generated from them and how they were recorded, are given in *Boxes 1* and *2*. Box 1 Sample transcription and coding process '... [I] can count on one hand how often [she's been] seen, very difficult to engage¹⁹, [she] abuses drink and drugs³⁶, chaotic lifestyle, she has several relationships with different men³⁵... [The house] is a very dangerous place to visit.'¹⁹ Lack of engagement/difficult to engage

³⁵ Vulnerable adult

³⁶ Substance misuse issues '... in the first instance, refer to [Learning Disability Consultant]⁷⁰ as it was recognised that [he] needs to be embedded in LD services, [but] it was suggested that LD services will not accept responsibility for his care ... [they] should be contacted regarding the interface between the relevant services⁷⁸.'⁷⁰ Refer to specialist

⁷⁸ Funding/responsibility issues '... it sounds like it's taking quite a toll on [his] CPN, what support is there for her⁷⁶? In these cases rotation of staff⁷⁷ can be helpful in preventing burnout and getting a fresh perspective on things.'⁷⁶ Extra support for staff involved

⁷⁷ Suggest rotation of staff Box 2 Box 2 Sample of code database Code G.J. frequency A.T. frequency Total frequency Theme Subtheme History of being in care 21311 Aggressive as a child 12312 History of sexual abuse 561113 History of neglect and witness of violence and physical abuse 951413

The pilot analysis generated an initial list of codes that were used as the basis for coding the rest of the transcripts, as well as demonstrating an acceptable consensus on what constituted individual codes. The remaining 40 transcripts were then coded, 20 each by authors A.T. and G.J., and the frequency of codes were recorded. The resultant database allowed the rest of the thematic analysis to be completed. A thematic map provided a diagrammatic representation of the various themes, subthemes and relationships between them (*Fig. 1*). Fig. 1 Thematic map of Risk Reference Panel meeting transcripts. CJS, criminal justice system.

A feedback form allowed participants to indicate, via a Likert scale, the degree to which they agreed with a number of statements (outlined under 'Feedback' within Results) and to provide free-text feedback.

Results

Using this method, 16 subthemes were identified to group similar codes. The subthemes were further grouped into four principal themes: childhood risk factors, current presenting difficulties, assessment and management of risk to self or others and team or wider organisational issues. The first two themes encapsulate information presented to the panel during presentations by referrers; the latter describe recommendations made or issues identified by the panel.

The subthemes are organised by frequency of codes, referred to hereafter as occurrences, with absolute frequencies (i.e. the number of times a code occurred in the whole of the transcribed data, given as *n*) and the proportion of occurrences within that theme (given as a percentage). Percentages are rounded to the nearest 0.5%. There were a total of 522 occurrences of codes throughout the 48 transcripts analysed.

Childhood risk factors

The first theme contains codes pertaining to the history of the case, outlining risk factors pertinent to the current problem. There were four individual codes that accounted for 31 of the 522 occurrences (i.e. 6% of all occurrences). These were primarily adverse experiences that the person had endured in childhood, but also included childhood traits that are associated with subsequent antisocial behaviour.

The most common childhood adverse experience was being a victim of physical abuse ($n = 14$, 45% within theme) or sexual abuse ($n = 11$, 35%), followed by having been in care ($n = 3$, 10%). A history of aggressive behaviour as a child was also identified in a number of individuals ($n = 3$, 10%).

Current presenting difficulties

This theme accounted for the greatest proportion of individual codes, with 245 occurrences (47%). Five subthemes were identified within current presenting difficulties, namely nature of offences, problematic behaviour, factors affecting current presentation, police/criminal justice system involvement and established diagnoses.

The nature of offences subtheme explored the various types of offences committed, if applicable (only some of the cases presented had criminal convictions, hence their low frequencies). The offences captured in the transcripts included arson ($n = 3$, 1%), non-assaultive sexual offences ($n = 3$, 1% within theme), threats to kill ($n = 1$, 0.5%) and sexual assault (1, 0.5%).

The most common problematic behaviour was suicide attempts/self-harm ($n = 32$, 13%), which was often seen to be chaotic and instrumental. However, there were several cases where severe self-harm without suicidal behaviour was the primary problem. The next most frequent was a lack of engagement with services ($n = 19$, 8%). The remaining codes within the problematic behaviour subtheme were sexually inappropriate behaviour ($n = 7$, 3%), antisocial behaviour ($n = 7$, 3%), disruptive behaviour ($n = 6$, 2.5%), harassment of care-giving staff ($n = 6$, 2.5%), multiple contacts by phone ($n = 6$, 2.5%), absconding risk ($n = 6$, 2.5%), complaints to health board/Welsh Assembly Members/counsellors ($n = 5$, 2%), false allegations ($n = 4$, 1.5%) and litigation ($n = 1$, 0.5%). Although the most prevalent individual code was risk of self-harm or suicide, the combined frequency of codes relating to risk to others was around 1.5-times as high.

Another subtheme was factors affecting current presentation, which captured issues in the person's life at present that were affecting their level of risk. Substance misuse was the most prominent among these ($n = 27$, 11%). Other codes within this subtheme were chronic pain/illness/physical issues ($n = 7$, 3%), social isolation ($n = 7$, 3%), multiple admissions to psychiatric hospital ($n = 7$, 3%), homelessness/moving area frequently ($n = 6$, 2.5%), family history of mental health issues ($n = 5$, 2%), admissions under the Mental Health Act ($n = 5$, 2%) and lack of insight ($n = 5$, 2%).

Less commonly, people had problems with anger ($n = 3$, 1%), bereavement ($n = 3$, 1%), sexuality ($n = 3$, 1%) and personality traits without a diagnosis of personality disorder ($n = 2$, 1%). There was police involvement in nine cases (3.5%) and the person was subject to the criminal justice system in 15 cases (6%).

Most of the cases presented to the panel had an established diagnosis, although within the 60 code occurrences in this theme, 'conflicting/unclear diagnosis' occurred 13 times (21.5%). These subthemes grouped the diagnoses by psychopathology.

'Developmental disorders' were the most common presentation and included autism spectrum disorder ($n = 8$, 13%), intellectual disability ($n = 5$, 8%), attachment disorder ($n = 5$, 8%), 'Special needs' ($n = 3$, 5%) and attention-deficit hyperactivity disorder ($n = 3$, 5%). Emotionally unstable personality disorder (EUPD) was the only specified personality disorder diagnosis ($n = 9$, 15%) and the most common individual pathology. This was followed by psychotic illnesses, with 'treatment-resistant psychosis' accounting for seven cases (11.5%). Schizophrenia was only given as a named diagnosis in one case (1.5%). Lastly, affective/anxiety disorders included depression ($n = 3$, 5%), eating disorders ($n = 2$, 3%) and post-traumatic stress disorder ($n = 1$, 1.5%).

Risk assessment and management

There were 31 occurrences of codes (6%) related to an assessment of the level of risk posed to others by the individual. Three of these (9.5% within theme) were an observation that there was a poor understanding of the risks posed and that specific further information was required.

Much more of the output from panel meetings was regarding the management of specific risks to the person or others, with 95 code occurrences. Within this theme, four subthemes were identified: need for further assessments, specialist care plans, capacity/placement factors and responsibility of other services.

Most commonly, the panel advised that specific assessments would be beneficial to manage risk. In disorders that modulated risk, such as autism spectrum disorder, the panel would often suggest 'expert/specialist opinion required' ($n = 17$, 18%). If the risk was more general, then suggestions of which avenues to pursue included a need for HCR-20 (Historical Clinical Risk Management-20; an established actuarial tool for assessment of violence risk) ($n = 3$, 3%); legal advice ($n = 4$, 4%) and a need for more background information ($n = 11$, 12%) or updated formal risk assessment ($n = 8$, 8%).

Issues regarding the assessment of capacity, or the established lack of capacity, were also commonly cited. There were 14 occurrences (15%) of recommendations that a Mental Health Act assessment had not been considered and could be of use in containing the risks posed. Further to this, there were 13 recommendations (13.5%) that the acute problems should be managed as an in-patient.

Several of the cases indicated longer-term in-patient or other compulsory interventions were necessary, such as the need for low secure placement ($n = 5$, 5%) and management under guardianship ($n = 2$, 2%) or Protection Of Vulnerable Adults scheme ($n = 2$, 2%).

Team issues within the context of risk management were need to improve engagement ($n = 1$, 1%), need to take positive risks ($n = 1$, 1%) and need for child protection training for team members ($n = 1$, 1%).

In eight cases (8%) the panel identified that responsibility for the patient's actions did not lie with health services as they were independent of mental health issues. These were divided into a recommendation that their behaviour be dealt with under the criminal justice system ($n = 4$, 4%), or an acknowledgement that although there is no criminal element to pursue in some cases, all appropriate actions to reduce risk have been considered and there is no more that the team can realistically do ($n = 4$, 4%).

Occasionally, the panel recommended specific management plans to manage particular disorders. Most frequently this was stated as a need for a specialist care plan ($n = 24$, 77%), incorporating advice from specialist assessments. The need for structure in the patient's life was identified ($n = 3$, 10%), as was the need for family work/family meeting ($n = 1$, 3%). More specifically, clozapine for treatment-resistant psychosis ($n = 2$, 6%) and dialectic behaviour therapy for EUPD ($n = 3$, 10%) were suggested.

Team/wider organisational issues

The final theme generated by the analysis contained 29 occurrences (0.5%) between five codes, and was subdivided into team working issues ($n = 8$, 27.5%), funding issues ($n = 7$, 24%), need for special staff/staff rotation ($n = 6$, 20.5%), need extra support for the staff involved ($n = 5$, 17%) and trust management issues/needs escalation ($n = 3$, 10%).

Team working issues captured differences within the team that may have hindered progress in the management of particular behaviours. For example, the panel acknowledged that because of splitting in the context of EUPD, it was necessary to establish a clear and consistent boundary narrative. However, outright disagreement within teams, over significant issues such as primary diagnosis and level of risk posed, was identified as an issue.

Funding issues identified that responsibility for funding was not always clear and had delayed the provision of appropriate placement. This was particularly relevant where the person had moved frequently between areas or was of no fixed abode.

The panel stressed that the staff who were dealing with particularly demanding individuals needed extra support themselves, which can often be neglected, and suggested rotation of staff to prevent burnout. In a small number of cases

it was identified that the particular service or treatment indicated for a person's condition, such as dialectic behaviour therapy, was not available, and it was suggested that this was escalated on a trust level on the basis that this would reduce risk of harm.

Feedback

Feedback was overwhelmingly positive, with 20 out of 22 respondents (91%) indicating agreement or strong agreement with the following statements: 'New ideas were generated in the session', 'The case feels safer as a result', 'I learned a great deal during the session', 'The questions I brought were answered' and 'I would recommend the process to a colleague.'

Discussion

The Royal College of Psychiatrists has highlighted a need for improved, tiered risk assessment and interventions on both a local and national level.⁵ A qualitative analysis of the content of Risk Reference Panel meetings has illustrated how it provides a potential model for services to address this need. The panel is an innovative service model that was set up to provide a further level of support for teams who had been looking for support in managing very complex individuals with high-risk behaviour and has provided new direction and specialist advice in the management of these cases.

Most cases described physical or sexual abuse, with many experiencing multiple adverse childhood events (ACEs). These findings support the existing body of work on the relationship between multiple ACEs and subsequent morbidity and risk behaviours, such as that by Bellis *et al*,⁶ which showed that individuals with four or more ACEs were several times more likely to smoke, drink heavily, have low mental well-being and chronic health conditions. This also correlates with well-documented risk factors for self-harm,⁷ suicide⁸ and interpersonal violence.⁹ These data have more general implications on history-taking in risk assessment, with the inclusion of this background information crucial to the working of the panel. The potential for referrers to exaggerate the risk, both consciously and unconsciously, to encourage acceptance by the panel should be acknowledged.

Although a person's risk of harm cannot be entirely removed,⁵ particularly in such complex cases, a thorough understanding of risks posed and their severity is crucial. The panel often identified areas where risk was not fully understood and suggested specific assessments or specialist opinion that would be beneficial. Having said this, the responsibility for risky behaviour, particularly in a capacitous patient, does not lie entirely with mental health teams and it is prudent to identify when all reasonable steps have been taken, or if involvement of the criminal justice system is more appropriate. Taking the case to such a panel allows an independent debate and makes this decision more defensible.

For patients who remain in the community, it is particularly difficult for teams to provide care and ameliorate risk if engagement is poor. Surprisingly, the meetings often highlighted that capacity assessments and use of the Mental Health Act beyond admission for brief assessment had not been considered. This may reflect a lack of appropriate placements available to community teams, particularly long-term in-patient services when patients cannot be managed in the community.

This model provides a valuable multidisciplinary source of special expertise in the management of complex and exceptional cases, where risk of harm is significant and clinical teams have ongoing concerns. The format may not be appropriate for every service and there is also a place for improved training in formulation and management of patients with complex personality difficulties, but model could certainly be reproduced in other areas where clinical teams feel it would have a beneficial role, particularly to inform Care Programme Approach unmet needs, training needs within the staff workforce and service development needs.

Lastly, it is pertinent to consider alternatives to such a panel. As the heaviest burden appears to be personality pathology, these would primarily consist of improving training in managing patients with personality disorders. In some cases, it may be that this is the better and more economical option, although it has been acknowledged that the panel approach uses relatively few resources in terms of clinician sessions while providing an additional tier of support for community teams to reduce the risk of harm associated with mental illness.

Limitations

This study is only able to describe the function and output of the panel in question, rather than give a rigorous analysis of this model in comparison with other models, and there were no available data on matched people who were not referred. We were also unable to comment on the make-up and training of the teams referring into the panel; it is possible that the referrals represent professional anxiety that stems from sources other than the patient in question, such as gaps in senior management or reluctance to engage with complex individuals with personality pathology, although the panel meetings analysed cover a period of 6 years where it is likely that there would be some fluctuation in team make-up.

All referrals to the panel are made via a written referral letter, which details the history of the case, the assessments that have previously been conducted, a risk assessment and concerns that the referrers wish to address. As the panel will already be familiar with this information, some of it may not have been verbalised at the meetings and thus not captured by the transcription. However, it was noted that there was a verbal presentation of each case and that the relevant history was given.

We would like to thank Dr Alan Wright, Forensic Psychologist with the Gwent Forensic Psychiatry Service, without whose work the Risk Reference Panel would not have come to exist, for information on the formation and workings of the Panel. We would also like to acknowledge the contribution of Jen Strange, Team Secretary, toward setting up and maintaining the Risk Reference Panel.

Alec Thomas is an ST4 in forensic psychiatry at Abertawe Bro Morgannwg University Health Board, Wales, UK. **Ian Evans** is a forensic community psychiatric nurse with Gwent Forensic Psychiatry Service, Aneurin Bevan University Health Board, Wales, UK. **Gaynor Jones** is a consultant forensic psychiatrist at Caswell Clinic, Abertawe Bro Morgannwg University Health Board, Wales, UK.

1.Familiarisation with the data-set: All transcripts were read and re-read by authors A.T. and G.J., considering the application of the coding process to the data and noting initial observations.*2.Generating initial codes:* Each transcript was read line by line and discrete ideas within the data were identified and systematically coded. Eight cases were coded by both A.T. and G.J. and the remainder were divided in half between these two authors. Each occurrence of a code was recorded as a simple tally. For example, the history of the patient in question would be given and each feature would be assigned a different code, such as ‘history of being in care’, ‘history of sexual abuse’, ‘diagnosis of schizophrenia’ or ‘poor engagement with the CMHT.’ Individual risks identified and management suggestions offered by the panel would all produce individual codes.*3.Searching for themes:* Codes were reviewed and collated into potential themes. It was decided whether each code represented, for example, a demographic feature, a specific risk to his or her self or others, or a suggestion for managing a particular risk. All data relevant to each theme were identified, as some ideas could be given two distinct codes or fit into two or more themes.*4.Reviewing themes:* Consideration was given to whether the identified themes adequately captured and collated the data in relation to both the individual coded transcripts (i.e. the narration of each Risk Reference Panel meeting) and the entire data-set (i.e. the overarching patterns of input and output for the Risk Reference Panel meetings as a whole). A ‘thematic map’ was generated.*5.Defining and naming themes:* After satisfactory completion of stage four, each theme was analysed to refine its specific categorisation and the overall ‘story’ that the analysis has produced. Clear names and definitions were produced for each theme.*6.Producing the report:* Writing the present report provided the final opportunity for analysis of the insights gained from the process. The analysis was used to address the initial research questions.

1.5.90 Follow-up study of 6.5 years of admissions to a UK female medium secure forensic psychiatry unit

John Tully Alessandra Cappai John Lally Maria Fotiadou

Correspondence

John Tully (john.tully@kcl.ac.uk)

date

2019-4

Abstract

Aims and method

We aimed to examine clinical and risk outcomes at follow-up, and reoffending and readmission rates, for a sample of 50 admissions to a female medium secure unit (MSU). Demographic, clinical risk assessment (HCR-20 and HoNOS-Secure) and quality of life data were collected using validated measures for all admissions to a female MSU ward in London, UK, between April 2008 and November 2014.

Results

All clinical and risk assessment scale scores had improved at follow-up. Quality of life compared favourably to community samples and was good for physical, social and environmental factors and acceptable for psychological health. Twenty-six per cent had at least one readmission, while 17.5% reoffended in the period studied. A longer duration of admission and use of restrictions on discharge was associated with reduced reoffending, but not readmission.

Clinical implications

Admission is associated with improvement on clinical risk assessment at follow-up. Longer hospital admissions and use of restrictions on discharge may be necessary to prevent reoffending in this group.

Declaration of interest

None.

 - *Results*
 - *Discussion*

Forensic psychiatry services are low-volume, high-cost services which seek to balance clinical treatment for public protection with caring for vulnerable patient groups.¹ In the UK, forensic psychiatric in-patient care is organised into three levels: high, medium and low secure facilities.² Patients are admitted to a specified level of security based on forensic history, level of risk to self or others, and diagnosis of a mental disorder. On discharge from in-patient services, many patients are subject to conditions under a Community Treatment Order (CTO), or 'restrictions' under Section 41 of the Mental Health (MHA) 1983, as amended in 2007 (for England and Wales), known as 'conditional discharge'. After discharge, such patients may leave hospital, but if they breach conditions or restrictions, they may be recalled to hospital. Examples of conditions and restrictions include being resident at a specified address, medication adherence, or cooperating with supervision by mental health services. Prevention of reoffending after discharge and reduction in readmission rates are key roles of forensic services. It is therefore essential that services be aware of factors involved in reoffending and readmission.

In the past decade, there has been a six-fold increase in the number of women admitted to medium secure forensic psychiatry services (MSUs³). Approximately 12–15% of medium secure beds in the UK are occupied by women.^{2:4:5} Despite this, there remains a paucity of demographic and clinical data on female MSU patients, particularly in relation to progress after discharge. Using a longitudinal cohort design, we assessed clinical risk assessment follow-up data and quality of life, using validated measures, in a female MSU sample. We also sought to identify clinical and demographic factors associated with reoffending and readmission rates following hospital discharge.

Methods

Sample and study setting

This study comprised all patients admitted to Spring Ward, the female ward of River House MSU in South London and Maudsley Foundation (SLaM) Trust, between April 2008 and November 2014 (6.58 years). Spring Ward contains 16% of the beds within the unit. The service covers a population of 1 090 544 people in London, approximately 50% of whom are female. Spring Ward opened in April 2008 and employs a multidisciplinary biopsychosocial approach to support women in their pathway of recovery and reintegration into the community. Ethical approval for this project was sought and obtained from the SLaM Trust Research and Ethics Committee.

Data collection

We examined the electronic clinical records of all patients. Demographic, clinical and risk assessment data are collected routinely at admission and throughout the course of admission. Standard risk assessment during MSU admission in the UK includes the Historical Clinical Risk Management-20 (HCR-20), Health of the Nation Outcome Scale (HoNOS), and Health of the Nation Outcome Scales for Users of Secure and Forensic Services (HoNOS-Secure⁷). The predictive validity for violence of the HCR-20 has been established in female patients in medium secure settings,⁸ and HoNOS has previously been used to identify clinical improvements following admission to female MSUs.⁹ All patients were assessed using these scales at the time of their admission, or shortly after. All patients were reassessed using the HCR-20, HoNOS and HoNOS-Secure scales between April and October 2015. Readmission and reoffending rates following initial discharge were collated, based on SLaM data. Quality of life was measured using the World Health Organization Quality of Life Scale, brief version (WHOQOL-BREF¹⁰), which has been validated in large international samples, including those with mental illness.¹¹ One assessment was obtained for each patient, close to or soon after discharge.

Statistical analysis

Comparisons between the groups were conducted using χ^2 -tests for categorical variables and t -tests for continuous variables. All statistical tests were two-sided, and the level for statistical significance was 0.05. All analyses were conducted in SPSS version 22.0.

Results

Within the study period, 50 female patients were admitted to Spring Ward. The mean age was 37.5 years (s.d. 11.17). The sample comprised 20 (40%) White, 26 (52%) Black and four (8%) individuals of 'other' ethnicity. The most common primary diagnoses were schizophrenia spectrum disorders ($n = 38$; 78% of sample) (International Classification of Diseases (ICD-10) category F20–29) and personality disorders (category F60–F69) ($n = 36$ patients, 18%). Nine patients (18%) with a schizophrenia spectrum disorder had a secondary diagnosis of a personality disorder. A diagnosis of a schizophrenia spectrum disorder was associated with non-White ethnicity ($\chi^2 = 8.059$, d.f. = 1, $P = 0.005$), while a diagnosis of personality disorder was associated with White ethnicity ($\chi^2 = 4.678$, d.f. = 1, $P = 0.031$).

A history of physical or sexual abuse or neglect was present in 26 (52%), and 22 (44%) had a history of self-harm. Twenty-three patients (46%) had a history of alcohol and/or drug misuse, with those of White ethnicity having increased alcohol misuse compared to those of non-White ethnicity (alcohol: $\chi^2 = 6.63$, d.f. = 2, $P = 0.036$; drugs: $\chi^2 = 7.49$, d.f. = 2, $P = 0.024$). Eighteen patients (36%) had no index offence, 17 (34%) had a violent index offence (actual or grievous bodily harm, manslaughter or murder), eight (16%) had committed arson and seven (14%) had a non-violent index offence.

The median length of hospital admission was 503 days (1.39 years). As of November 2014, 46 of the 50 patients were discharged at least once following admission; four were still in hospital following their first admission. Thirteen patients (26%) were readmitted once or more during the study period. The median follow-up period was 1390 days (3.8 years) for the 46 patients who were discharged. Of this group, five (10.8%) were discharged to prison; 32 (69.5%) were subject to a CTO, probation, or section MHA restriction order; and nine (19.5%) were not subject to conditions or restrictions.

Table 1 shows outcome data on the HCR-20, HoNOS and HoNOS-Secure scales. There were significant improvements on each of these scales at follow-up. Quality of life outcomes on WHOQOL-BREF were 'good' (60–69) for physical (mean 66.2), social (mean 64.3) and environmental domains (mean 67), which compared favourably with international samples of individuals with mental illness.¹¹ The mean score for psychological health (mean 58.9) was 'acceptable' (50–59), which was comparable to that of patients with psychotic disorders in international samples.¹¹ Table 1 HCR-20, HoNOS and HoNOS-Secure scales: mean differences between initial assessment and follow-up assessment. Initial assessment mean score Follow-up assessment mean score Mean differences. d.95% CI d.f. Sig. Of 41 discharges to a hospital or community setting, data on reoffending were available for 40. In this group, seven patients (17.5%) reoffended (four with violent offences). Those who reoffended had a significantly shorter hospital stay (mean days 231.7, s.d. 226) compared with those who did not reoffend (mean days 631.7, s.d. = 326; $t = 3.701$, d.f. = 12.66, $P = 0.005$). The length of stay of those who were readmitted did not significantly differ compared with those who were not readmitted ($t = 0.215$, d.f. = 27.05, $P = 0.831$). Likewise, use of conditions, restrictions or probation was not associated with readmission ($\chi^2 = 4.66$, d.f. = 2, $P = 0.097$), but was associated with reduced reoffending ($\chi^2 = 43.14$, d.f. = 6, $P < 0.001$). Alcohol or drug use was not found to be associated with readmission ($\chi^2 = 0.02$, d.f. = 1, $P = 0.887$), but was associated with increased reoffending ($\chi^2 = 4.49$, d.f. = 1, $P = 0.034$).

Discussion

We report clinical characteristics and follow-up outcomes on 50 female MSU patients, a group that has been underrepresented by research to date. Studies of this group have focused primarily on readmission and reoffending only, and there have been few new published data in the past decade. Our study provides an update in this important area of forensic psychiatry, including clinical outcome measures. This is also the first study in this group to include self-reported quality of life data.

A key finding of our study was that women discharged from hospital maintained their improvement for the follow-up period and reported good outcomes. Reduction in clinical and risk items on HCR-20 suggests both clinical improvement for patients and reduction in risk of future violent offending in the community. Overall quality of life measures (WHOQOL-BREF) were grossly comparable to a population of individuals with mental health problems.¹¹ Quality of life is an important outcome for patients and their family following discharge. Lower scores on physical and psychological domains were a concern, although this is perhaps to be expected given the complexity of our population.

As with previous studies, we found that a longer hospital stay was associated with a lower rate of reoffending. While forensic services have been criticised for longer periods of stay in hospital,¹² it has also been argued that this is necessary for patient recovery and public protection.¹³ Our findings provide support for this hypothesis, and are in keeping with results from a previous large-scale study showing that a longer in-patient stay was protective against reoffending following discharge.⁴ The use of restrictions in forensic services is also controversial, but has also been shown to be associated with reduced reoffending following discharge.⁴ This was also the case in our sample. These results suggest that longer stays in hospital and judicious use of restrictions on discharge are necessary to prevent reoffending in this patient group.

In our sample, alcohol and drug use were also associated with increased reoffending. The largest study of reoffending following discharge from MSU settings did not identify this association, demonstrating only an association between alcohol use and arson.⁴ However, this association may also be due to distinct clinical characteristics of our sample and warrants further exploration.

Our sample's demographic characteristics were similar to those of previous studies which have examined female MSU patients.^{4,5,9,14} There were high rates of abuse and neglect, alcohol and substance misuse and self-harm, emphasising that this is a vulnerable group, and supporting the view that there is a need for specialised MSU services for women.^{2,9} There were higher rates of psychotic disorders than in previous samples, and lower rates of personality disorders.⁴ This may be due to a tendency in some settings to diagnose personality disorder, rather than psychosis, on the basis of the presence of self-harm, impulsive behaviour and substance misuse, an issue that has been identified as a concern in clinical guidelines.¹⁵ Our exclusively urban sample may also contribute to the discrepancy.

There was a high representation of ethnic minorities within our female forensic service. Black women admitted to MSUs have previously been shown to be more likely to have diagnoses of psychotic disorder or drug misuse, and to be less likely to be diagnosed with depression, alcohol misuse and borderline personality disorder than White women.¹⁴ In the current study, ethnicity was also associated with different clinical profiles in our patient group. Owing to our small sample size, we limited our categorisation of ethnicity to White and non-White. In keeping with previous research, non-White ethnicity was associated with increased rates of schizophrenia spectrum disorders, while White ethnicity was associated with increased rates of personality disorder.¹⁴ This tentatively supports the hypothesis that there is a deficit in adequately providing appropriate non-forensic services to non-White women with psychotic disorders, leading to escalation to offending and admission to forensic services. Also in keeping with previous studies,¹⁴ White ethnicity was associated with increased alcohol misuse. However, in contrast to previous findings, White ethnicity in our sample was also associated with increased drug misuse. This suggests a potential shift in clinical characteristics of White female patients being admitted to medium secure settings. Inferences are limited, however, by our small sample size and exclusively urban population.

The study was limited mainly by a relatively small sample size, although this needs to be considered in relation to the relatively small female MSU population, and the lack of relevant data on this group. The study benefited from robust data collection – very few data were missing – and from the use of standardised and objective measures of outcomes.

In conclusion, admission to female MSU is associated with improvement on clinical risk assessment outcomes at follow-up. Longer hospital admissions and the use of restrictions on discharge may be necessary to prevent reoffending

in this group. Further research on the role of ethnicity in this group is warranted.

We would like to thank all staff on Spring Ward, River House MSU, for assistance with data collation and acquisition.

Abstract

Humans have always used mind-altering drugs. However, in 1961 the United Nations approved the Single Convention, under which the production, sale or possession of a number of drugs, including heroin, cocaine, ecstasy and cannabis, became illegal. The prohibitionist regime was then introduced by most countries around the world and has substantially remained in place ever since. Some countries, particularly those in Latin America, have never criminalised the use of cannabis. A small number of countries have introduced more liberal policies. This article examines the evidence of the consequences of policy liberalisation and argues that there is now a clear case for every country to examine its drug policies and to introduce evidence-based policies with a public health focus.

- *Against the stream: drugs policy needs to be turned on its head*

Human beings have taken mind altering drugs since the Stone Age, but the current global ‘war on drugs’ dates only from 1961. At that time, the addictive qualities of drugs like heroin and cocaine led the United Nations Member States

to conclude that drastic action had to be taken as they were ‘concerned with the health and welfare of mankind’¹ – the objective of the United Nations Single Convention on Narcotic Drugs. The assumption at the time was that a drug-free world could be created if those who produce, sell, possess or use certain addictive drugs were severely punished. Currently, in the UK, those arrested for possession of a controlled drug (e.g. heroin, cocaine, ecstasy or cannabis) can have a maximum prison sentence of 7 years under the UK Misuse of Drugs Act 1971. Producers and suppliers can be put behind bars for a maximum of 14 years.

A policy objective to advance the health and welfare of mankind is fine if the policy makers know the consequences of their proposed policies. In fact, instead of advancing the health and welfare of mankind, the drug laws that followed the United Nations Convention have led to untold violence and corruption in the producer countries, drug-related deaths, the accumulation of wealth worth billions of dollars by terrorists and violent criminals, the non-availability of essential pain-relieving medicines in many developing countries and the emergence of an extremely dangerous online market for synthetic psychoactive drugs. Of course, none of these consequences was predicted in 1961. It is not that the policy makers at that time were bad, they were simply ignorant of the consequences of their policies.

For political reasons, two of the most dangerous drugs widely used across the globe – alcohol and tobacco – were excluded from the Convention. Although rated as less dangerous than heroin and cocaine on a carefully devised scale of harm, both these drugs have been rated well above cannabis and ecstasy in their potential danger to the individual.² A Royal College of Psychiatrists Working Party report³ concluded that, ‘In the long run, society will only be at ease with its drug control policies if they are based on a rational assessment of the risks associated with the different psychoactive substances and an objective appraisal of the consequences of previous policy changes, rather than on moral postures, the mistaken assumptions of the past and the accidents of history’ (p. 259).

This suggests we need an entirely new approach to controlled drugs. The starting point must be a clear definition of the objectives of drug policy. The All Parliamentary Group for Drug Policy Reform⁴ proposed the following objectives to the United Nations: (a) to ensure the adequate availability of essential controlled medicines to those who need them (relevant to the many developing nations who have minimal or no access to morphine);(b)in production and supply countries, to prioritise education, community development, infrastructure development and employment in vulnerable communities;(c)in user countries, to minimise addiction and the harms associated with drug use.

In 1961 there was widespread consensus that a criminalising approach to the sale and use of heroin, cocaine and cannabis was appropriate, but this is no longer the case today. Now, even the Global Commission on Drugs Policy reports that the prohibitionist approach has failed.⁵ Arguments for and against drug prohibition in relation to heroin and cocaine may be more finely balanced, but there has been a major swing both among scientists and politicians toward the view that the illegal status of less harmful drugs, especially cannabis, does more harm than good.

Considerable concern has been raised concerning the decriminalisation of cannabis as a result of studies showing links between ‘skunk’ (high-potency cannabis) and the onset of psychosis. An influential study has shown that people who use skunk daily are five times more likely to develop psychosis than those who do not.⁶ However, the same study showed that, when the effects of low-potency cannabis were examined, hash users did ‘not have any increase in risk of psychotic disorders compared with non-users, irrespective of their frequency of use’. Further, although it is now widely accepted that there is a causal relationship between regular high-potency cannabis users and psychosis, the possible importance of the effect of confounding factors makes the significance of even this finding for drugs policy unclear. It has been estimated, for example, that 98% of regular cannabis users will not develop a psychotic disorder.⁷ Further, decriminalisation would allow much more effective control, especially of high-potency cannabis, than is the case at the present time.

The uncertainty regarding the effects of decriminalisation can only be resolved by examining the effect of decriminalising legislation where it is occurring elsewhere in the world. There are now a number of studies examining the effects of drug law liberalisation, especially, but not only, in relation to cannabis. A recent review suggested that liberalisation of cannabis laws is associated with a slight increase in use of cannabis among the young.⁸ A cross-national study of 38 countries confirmed this finding, noting that the increase was only detectable after 5 years and then mainly in girls.⁹ Further, although adolescent use remains criminalised in US states where marijuana use has been legalised for adults, decriminalisation has led to decreases in possession and felony arrests among adolescents as well as reduction of associated juvenile-justice involvement.¹⁰ It has also been shown in a 20-country comparison that cannabis law liberalisation leads to increased help-seeking behaviour for people with drug problems, an encouraging finding suggesting that if some of the savings made as a result of the discontinuation of prohibition policies were put into increasing and

improving drug services, any negative effects might be significantly reduced.¹¹

It has recently been suggested that positive experience from cannabis law liberalisation might lead to some countries looking more critically at their laws relating to other potentially more dangerous drugs.¹² There is already some evidence to suggest this might have beneficial effects. In 2001, Portugal changed its approach to the possession of all drugs. The drugs remained illegal, so the policy did not resolve the problem of illegal drug dealers enriching themselves by selling contaminated drugs. However, children and young people who go through a drug-taking phase do not end up with a criminal record and can much more easily give up the habit and progress with their education and employment – the best protections from addiction.

This policy is not ‘soft’ on drug users. If a police officer finds a young person with drugs, they will be taken to the police station and required to hand over the drugs, they are then referred to a Commission for the Dissuasion of Drug Addiction or tribunal including a legal, health and a social work professional. The tribunal will determine whether the drug possessor is addicted to drugs. If so, they will be referred for treatment. The treatment becomes the basis of a contractual agreement between the drug user and the tribunal. If the drug user breaks the contract, they could receive an administrative penalty, although this rarely happens. Importantly this has no implications for their future employment. A casual user is sent on their way by the tribunal and strongly told not to continue using the drug. Portugal invested heavily in prevention, treatment, harm reduction and social integration services. The combination of decriminalisation with improved health and social care services probably account for the good results.

Importantly the policy has been extensively evaluated.¹³ Portugal now has levels of drug use well below the national European average. The numbers sent to the criminal courts in Portugal fell from more than 14 000 to 5000–6000 a year after the policy was introduced. The proportion of offenders for drug-related offences fell from 44 to 21% between 1999 and 2012. The numbers of addicted children and young people has decreased. All the same, critical analysis of studies of those who claim that the Portuguese drug policy has been a resounding success or, in contrast, a disastrous failure suggest that the evidence does not support either extreme view.¹⁴

Switzerland has shown how to replace drug dealers with heroin treatment services. The services largely cater for poly drug users. The service has three parts: the drug consumption room (DCR), the heroin clinic and the methadone clinic. The service providers have an agreement with the police that anyone approaching the DCR will not be arrested for drug possession. The DCR is a vital part of the service. A doctor spends time there each week, treating ulcers and other health problems, and a social worker is available to help with housing, financial and other social issues. Addicted clients who come in off the street with their illegal drugs are welcomed and cared for. Over about 3 weeks these two professionals encourage the street drug users to come along to the clinic and have clean heroin in exchange for agreeing to a demanding contract. These chaotic individuals are required to hand over their benefits in the early stages, to make sure their rent and bills are paid. They are given back the money they need for food or other essentials, but not enough for them to buy drugs.

The constraints are worth it in return for the clean heroin as well as the psychological and social care. The Swiss heroin treatment programme has been rigorously evaluated.¹⁵ The results are impressive. Until they arrived at the clinic these individuals were committing an average of 80 crimes a month to feed their addiction. After 18 months in treatment, one third are entirely drug-free and leading normal lives; a further third are leading their lives within the law, but still taking some heroin or methadone. The last third need more time to achieve their objectives. The savings to the tax payer and the benefits to the community from reduced crime levels are huge. The estimate is that for every franc spent on this service, two francs are saved for the taxpayer. The cost of the service per person is 15 000 euros. Not cheap but well worth it.

In the meantime, in England, the Durham Police are beginning to use the Swiss route for users of all narcotic drugs and even for low-level drug dealers and traffickers.¹⁶ Their Check Point programme recognises that many who are arrested for theft motivated by drugs and other less serious crimes have underlying mental health and social problems. The programme offers drug-related offenders and others a 4-month contract. This requires them to engage with treatment and not to reoffend. If they succeed on their contract then no further criminal justice action is taken. If successful in rehabilitating drug users and cutting reoffending, this will surely be an important policy across the country. The government will be funding 10 pilots of Checkpoint and 25 police forces are wanting to apply to be involved.

To conclude, an independent review of UK drug policies is urgently needed. Each drug needs to be individually considered. Regulation of heroin, for example, needs to be very different from the regulation of cannabis or ecstasy.

The objectives must be to reduce addiction and limit as far as possible the harms associated with drug use. Drug policy reform would also dramatically reduce the ill-gotten gains from the drugs trade of terrorists and violent criminals.

In fact, we need to turn, not just policy about cannabis, but our whole drugs policy in its head. Opponents of the legalisation of cannabis, who suggest that this might well represent a slippery slope leading to the legalisation of other, currently proscribed drugs are right. But that is exactly what needs to happen.

1.5.92 Making up symptoms: psychic indeterminacy and the construction of psychotic phenomena

Huw Green

Correspondence

Dr Huw Green (huw.green@gmail.com)

date

2019-4

Abstract**Summary**

Psychotic phenomena include a far wider range of experiences than is captured by the brief descriptions offered in contemporary diagnostic guides. Given the richness of historical clinical phenomenology, what can account for the recent ascendancy of relatively impoverished descriptions of psychosis? One possible explanation is provided by Hacking's notion of dynamic nominalism, where human categories change over time in tandem with those who they classify. But although dynamic nominalism makes sense of changes in behaviour, it fails to account for change at the level of subjective experience. In this paper, psychotic symptoms are addressed in the light of the indeterminacy of subjective mental content. A naïve-introspectionist approach to mental symptoms assumes that, notwithstanding practical difficulties, such symptoms are reliably describable in principle. Contemporary philosophy of mind challenges this assumption. Lighting upon a verbal description for ineffable phenomena changes their nature, resolving them into new forms.

Introduction: historical moving targets

The DSM-5 provides brief descriptions of the central positive psychotic symptoms of delusions, hallucinations and disorganised thought. In this schema, delusions are defined as ‘false beliefs’ and hallucinations are defined as ‘perception-like experiences’. It is to this framework that patients’ experiences are matched to make a psychiatric diagnosis. The dissemination of such definitions and criteria has pervaded society’s understanding of what psychosis is like. Their influence can now also be seen in the push for the re-description of psychosis in terms not of symptoms, but as ‘unusual beliefs’ or ‘hearing voices’.¹ However, it is not always clear that delusions are best characterised as beliefs,^{2,3} and auditory hallucinations can include experiences that do not resemble ‘hearing’ and do not involve voices.⁴

Historically, delusions, to examine just one of these symptoms, were not necessarily defined as beliefs. Tracing the conceptual history of this particular symptom, German Berrios⁵ has argued for the falsity of what he calls the ‘received view’ that delusions are beliefs, and detailed its emergence. Berrios suggests that historical intellectual processes shape delusions, although it is not clear whether he intends to suggest that this shaping affects only the received clinical view or also the symptom itself. Berrios argues that the received view was in place by the end of the 19th century. However, a more complex picture of delusions can be seen in the work of two prominent psychopathologists of the early 20th century.

In his original description of the features of the group of schizophrenias, Eugen Bleuler’s⁶ overview of delusions includes no explicit requirement that they be beliefs. At many points he seems to be describing a wider variety of mental states. Patients with delusions are described as being unconcerned with evidence or reasons for their ideas, “‘It is just so”, and with this he appears to be quite satisfied’ (p. 118). Additionally, delusions are described – unlike a dogmatically held belief – as sitting comfortably alongside other inconsistent ideas: ‘Unconnected or even mutually contradictory ideas can be maintained simultaneously or appear one after the other within a short interval of time’ (p. 125). Bleuler includes false statements that might not be held with any conviction: ‘A catatonic’s bed is a polar bear. “I lay on it and it seemed like a bed, but it was nevertheless a polar bear”’ (p. 126). Additionally, Bleuler explicitly extends his description of delusions into cases of non-belief-like states: ‘The delusions can appear in the form of “hunches,” “intuitions,” etc., which can persist permanently in their indefinite forms’ (p. 135).

Karl Jaspers, in his seminal description of the phenomenon of delusions,⁷ does not speak of them in terms of belief, but rather builds a complex picture through case examples and phenomenological descriptions. For Jaspers, contrary to modern psychological theorists,^{8,9} delusions proper (what Jaspers terms ‘primary delusions’) are not belief-like inferences that have been made from an anomalous perceptual input, but form part of the direct experience itself. Jaspers emphasises the immediacy of a delusional interpretation. A delusional patient sees their delusion in their experience of the world in the same way as ‘If I see a knife, I see a tool for cutting’² (p. 99). The word ‘belief’ does not appear in this part of his discussion.

Compare these rich and heterogeneous descriptions with the formal definition of delusions provided in the DSM-5:¹⁰ ‘Delusions are fixed beliefs that are not amenable to change in light of conflicting evidence. Their content may include

a variety of themes (e.g., persecutory, referential, somatic, religious, grandiose)' (p. 87). This historical transmutation of psychotic symptomatology is a curious phenomenon. I suggest that it represents something potentially significant, occurring not only in the literature but also in the patients. Paraphrasing the philosopher of science Ian Hacking (who referred to 'making up people' 11), I call this 'making up symptoms'.

Dynamic nominalism

Historical variation in psychiatric presentations has been understood in terms of bidirectional feedback loops between the patient and world that shape the patient's expression of symptoms.¹²⁻¹³ Consider the phenomenon Hacking terms 'dynamic nominalism', the process he posits whereby people come to fit the categories they are assigned. A classification or description of people is created on the basis of some observed regularity or classificatory principle (autistic, anorexic, gay). Observations about this classification are then made by academics, journalists, medics and so forth. Because the individuals classified are people, and not rocks or trees, they can become aware of the classification, and of various facts, fashions and stereotypes associated with it. Such knowledge is apt to change people as they behave increasingly in line with the way that they have come to see themselves described. Hacking has suggested that entire disorders ('transient psychiatric illnesses') can be brought into existence by interactive processes he calls 'looping effects'.¹²⁻¹⁴ Plainly there are hard limits on the influence of looping effects (people cannot, for example, become taller just because they have been classified as belonging to a group that is stereotypically tall), but the more plasticity there is associated with important elements of a classification, the more we might expect looping effects to exert their influence.

Thus, as clinical phenomenologists produce ever more succinct descriptions of psychotic experiences, people may have come to experience themselves as actually having these simpler symptoms. This, in turn, would have changed the psychiatric classification of psychosis, confirming ever more specific and limited definitions of the phenomena at hand. This story is powerful, but – at least in Hacking's telling – it leaves an explanatory gap in between the world and the patient's symptoms. Dynamic nominalism can readily account for changes in historical behaviour (the culturally determined manifestations of psychiatric distress) because we can readily intuit the ways that behaviour can be influenced by expectations. But there is more to psychosis than behaviour. Mental symptoms feel a particular way, and it is intuitive to suppose that the way they feel is a 'bottom-up' result of internal illness processes. We need more detail about how personal mental experiences could be subject to the same sorts of external influence.

We cannot account for symptom variability without appeal to an important but unacknowledged feature of the mental experience: its ethereal nature. Unlike livers and larynxes, subjective conscious experiences can never be directly observed by another person. Moreover, despite our casual intuitive sense that we have direct access to our subjective experience, it can be uncannily difficult to pin that experience down, even for ourselves. Consciousness is messy, inchoate and often ineffable. It may even be that its contents are indeterminate, and even indeterminable.

Psychic indeterminacy

The indeterminacy of mental content has been perhaps most thoroughly explored by the philosopher Eric Schwitzgebel.¹⁵ Schwitzgebel articulates scepticism about the possibility of accurate introspection on one's perceptual experiences. We might think that we know what our perceptual experiences are like in some detailed and accurate way. At first blush, what could be more immediately knowable? But subjectivity is often transient and difficult to pin down. We are not always clear whether an impression (the impression, for example, that one is looking at a scene that contains spatial depth) arises from something that is more directly perceptual or more inferential in character. For Schwitzgebel, questions like 'Do you always have a constant tactile experience of your feet in your shoes?' and 'What do you see when your eyes are closed?' are not as readily answerable as they might appear.

Schwitzgebel provides an example of a historical change that he takes to reflect this indeterminate nature of subjectivity.¹⁴ Multiple researchers examining reports of dreams in the early 20th century found that a minority of respondents' dreams (9–41%) involved the experience of colour. Since the 1960s, however, that figure changed and research participants reported that the majority of their dreams (74–100%) included the experience of colour. Schwitzgebel takes this to suggest that 'I don't know, and you probably don't know, whether we dream in color or not' (p. 3), and suggests that the dramatic change in people's assumptions about their dreams reflects the emergence of widespread access to colour

television and films. Dreamers changed their assumptions about the nature of visual experiences and translated this into a judgement about the quality of their dreams.

Schwitzgebel's pessimism about the reliability of introspection has obvious implications for the assessment of psychiatric phenomena. If he is right about the unreliability of naïve introspection, then the assessment of experiences like hallucinations and delusions is open to variability and influence. To ask whether someone is hearing voices or whether they believe in a given proposition is doubly problematic. Such queries presuppose that there is a fact of the matter, and create unwarranted certainty as respondents confabulate an account of their subjective impressions.

Something like this indeterminacy of the subjective has already been posited in the realm of psychiatric symptoms. Citing Dennett's¹⁶ scepticism about the possibility of relying on inner experience, Stephens and Graham¹⁷ note that not all auditory visual hallucinations are voice-like, and suggest that individuals who come to hold certain ideas may sometimes engage in a sort of *ad hoc* confabulation about their origin. The result of such confabulation might be a conclusion that an idea came to be held because a voice was heard⁸ (pp. 26–31). The psychoanalyst Roy Schafer¹⁸ has also explored the indeterminacy of psychiatrically relevant symptoms, pointing out that inquiring about certain vague experiences (e.g. the location of a felt mental presence) can alter the nature of the experience itself⁹ (p. 123).

Does this not lead us to phenomenological nihilism? If our mental life is indeterminate, is there any value in asking people about their inner lives? What about asking people whether they are in pain? (I am grateful to an anonymous reviewer for raising this question.) I think we can fruitfully distinguish more or less fine-grained aspects of experience, with greater difficulty attendant on making determinations about more detailed phenomenology. It is relatively straightforward to say, 'I'm in pain', but far more complex to make detailed descriptions of the nature and quality of that pain. Physicians also ask questions like 'is the pain sharp or dull?' or 'is it a shooting pain?'. Some people, lacking a clear idea about how to answer, could have their experience of the pain changed by the question. Equally, it may be possible to establish the presence of a hallucinatory experience, but harder to describe its form without contamination by interrogation.

If subjective experiences are indeterminate in this important way, then there are grounds to worry about the emphasis on specific symptoms in contemporary psychiatry and clinical psychology. Over the latter half of the 20th century, psychiatry saw a push toward more precise measurement of psychiatric phenomena. A loss of confidence in diagnostic categories shifted attention to the observation and measurement of specific symptomatic experiences.

Paradoxically, however, this focus on symptoms (and especially the use of familiar terminology like hearing voices or unusual beliefs as opposed to the vaguer and more clinical hallucinations or delusions) may be taking us further from the individual experience of people in profound states of disturbance. When we ask people whether their experience is like hearing voices, they may be inclined – when confronted with the immense difficulty of describing what it is really like – to accede that it is.

Take a question like 'Do you ever seem to hear noises or voices when there is no one about, and nothing else to explain it?' from Wing *et al*'s Present State Examination.¹⁹ A person answers yes. In response to the follow-up question ('Do you ever seem to hear your name being called?'), they also say yes. It is possible that this individual does not, in fact, have those experiences (they do not actually hear noises or voices, they experience something else that feels impossible to describe in other terms), and that they do not actually hear their name being called. Perhaps they just have some sense that there are voices or noises in the vicinity that are having some kind of a perceptual effect on them. Perhaps there is a sense in which they are feeling called, but they never actually have the perceptual experience of a voice calling their name.

I have administered this kind of a questionnaire to people, and it is true that they can prompt the interviewee to provide reflections on how, no their experience is not 'quite' like that being described in the question. Interesting discussions about personal phenomenology can ensue. However, people also have difficulties articulating their experience. People have more or less ability to communicate, and more or less interest in getting the nature of their experience precisely articulated ('I don't really hear the voices but, ah, close enough!').

Making up their minds

The myth of measurable and determinate psychotic symptoms neglects entire aspects of people's experiences and recent research has revealed that some people with psychiatric illness can come to feel alienated by the discipline's failure to encompass the variety of phenomenology.⁴ 19 Jones and Shattell²⁰ describe the experiences of people who have had psychotic experiences that 'simply did not map onto available terms and constructs' (p. 769). These authors find participants afraid of describing their experiences to doctors in case they were dismissed, and others who had been told there was 'no such thing' as non-auditory voices: 'It was not that the textbooks were wrong ... her experiences were' 19 (p. 769). Too tight a focus on preordained symptom categories (the core positive symptoms of the DSM-5) omits those experiences that do not readily fit them. Psychiatric symptom erasure is a systematic failure to take seriously an individual's own account of what is happening to them.

But perhaps more fundamentally, the process of making up symptoms unwittingly shapes people to clinician expectations. Anyone is potentially vulnerable to introspective error and this vulnerability is compounded by the frightening, unusual and private nature of a psychotic symptom. The clinicians who assess such experiences ask specific questions and have diagnostic expectations, thereby providing a particular framework for their patients to fit into. It is a mistake to minimise the potential power of such shaping.

In his discussion of multiple personality disorder,¹² Hacking outlines the moral hazard involved in the inadvertent creation of psychiatric subjectivity by reference to a Marxist concept. To create and impose new ways of being psychiatrically disturbed, he says, is to subject people to a form of false consciousness. If my argument here is correct, we cannot successfully demarcate false from true consciousness. If there is no plain fact of the matter about the nature and contents of mental states to begin with, there is no 'pure' unobserved form of consciousness to compare against a putatively 'false' form. Nonetheless, I submit that Hacking is on to something significant. When psychiatrists come into contact with disturbances of consciousness, they cannot hope to only observe them. The mind is not infinitely malleable (it would salve much therapeutic angst if it were), but encounters with others – especially powerful professional others – can be expected to influence the form that peoples' thoughts can take.

Abstract

Current neuroscience suggests that although short-term memory difficulties frequently occur immediately after electroconvulsive therapy (ECT), longer-term problems are less common. However, gaps in our knowledge remain regarding longer-term cognitive problems after ECT, including memory function. Some of these relate to the complexities surrounding cognitive testing and interpretation of test results. An important question in clinical decision-making is why, despite current evidence suggesting long-term memory problems are less frequent, some patients still report subjective memory difficulties. To further advance clinical practice and the neuroscience surrounding post-ECT cognitive function, assessment of cognitive function, possibly including neuropsychological testing, should potentially become more routine as part of clinical practice.

- *Depression, memory and electroconvulsive therapy*
 - *Memory complaints post-ECT*
 - *Assessing cognition post-ECT*
 - *Remaining questions*

Measuring treatment response after depression is often not entirely straightforward in clinical practice. What matters to clinicians might not always perfectly align with what is important to their patients. For example, the DSM-5 lists a combination of physical, cognitive, affective and behavioural diagnostic criteria representing major depressive disorder (MDD).¹ For patients with MDD, subjectively, fatigue is sometimes the most disconcerting symptom, whereas for others it might be impaired concentration or the persistent feelings of sadness and hopelessness, resulting in a range of subtly different presentations. Similarly, a wide range of effective treatments for MDD are now available, depending on patients' clinical presentation. Treatments range from pharmacological approaches, talking therapies and physical exercise, to electroconvulsive therapy (ECT) or a combination of these, among others. Treatment approaches all have different levels of efficacy, potential side-effects, and accordingly their acceptability to patients with MDD varies.

A recent retrospective study found that patients were generally satisfied with ECT as a safe and effective treatment for depression.² Nevertheless, one of the suggested adverse side-effects of ECT concerns possible memory problems. Whether ECT can have a deleterious effect on memory presents an important question for both the clinician and patient when discussing treatment options. An appraisal of the current neuroscience knowledge on memory and ECT can provide some guidance to further inform clinical decision-making, including addressing patients' concerns regarding treatment choice. Lezak *et al*, reviewing neuropsychology and other neuroscience findings concerning ECT and memory, conclude that memory difficulties immediately post-ECT can be present in some patients, but that it is less common beyond this period, even in patients who have had longer-term treatment.³ Similarly, Kirov *et al* conclude that long-term memory effects are rare and that ECT appears to be safe as regards adverse neuropsychological outcomes.⁴ Furthermore, a recently published, large cohort study found that the risk of developing dementia in patients previously treated with ECT was not significant.⁵ These findings might reassure clinicians, but what about patients' views? Understanding patients' preferences and concerns as regards treatment choice is an important aspect of clinical decision-making and ultimately for determining overall treatment response.

Memory complaints post-ECT

Vann Jones and McCollum⁶ report the findings from their systematic review of ECT and subjective memory complaints. Although there were methodological limitations to some of the included studies, which made definitive conclusions difficult, their review does suggest that generally subjective memory ratings improve over time, and that ultrabrief-pulse ECT potentially has less side-effects. Interestingly, another study not included in their review reported that although cognitive function appears to be largely unchanged in many (but not all) areas of neuropsychological functioning, improved depression long-term post-ECT appears to be associated with improvement in some cognitive functions.⁷ Vann Jones and McCollum's review raises some interesting questions for clinical practice and neuroscience. In particular, if the above (and other) findings from the research literature is correct in concluding that ECT is safe as regards memory functions, why is it that a number of patients consistently continue to report longer-term subjective memory difficulties after ECT?

Addressing the above question is potentially of considerable relevance not only to patients, but also clinicians. For example, from a policy and practice perspective there is an acknowledgement of the importance of considering cognition as part of ECT service delivery. The Royal College of Psychiatrists Statement on Electroconvulsive Therapy advises that cognitive functioning should be assessed before ECT and monitored after every three or four ECTs, and also after the final ECT.⁸ Furthermore, the Statement indicates that in addition to orientation being assessed after each ECT, retrograde amnesia, new learning and subjective memory complaints should be tested more than 24 h post-ECT. However, exactly how to perform testing of these functions is not specified. Interestingly, looking at some current National Health Service ECT policies fails to identify a consistent and clearly defined approach to assessing cognition in ECT services. To summarise, although the relevance of assessing cognition after ECT is clearly acknowledged, how to do this remains less clear. At present, there is not a straightforward answer doctors can give to patients receiving ECT, if they ask exactly how their memory functions will be monitored.

Assessing cognition post-ECT

Assessment of cognition can be performed at different levels, providing objective or subjective data. Patients can be asked about their own views on their cognitive functioning, which provide subjective data. Objective testing can be performed at the bedside, or can constitute formal neuropsychological testing. In the latter case, the patient's results are compared against standardised norms as well as their own predicted premorbid level of functioning. Patient effort is also measured to identify any underperformance that might influence the interpretation of test results. Cognitive domains assessed generally include information processing, language functions, new learning and retention, construction, visual-spatial abilities and executive control functions, among several others. Kolar suggests that neuropsychological testing should be an integral part of ECT service provision.⁹ In ECT services, testing will most likely focus on cognitive domains such as new learning and retention, as well as information processing. Although the assessment of cognitive functions appears straightforward enough, interpretation of the results is not. This may be one of the reasons why wider implementation of cognitive assessment post-ECT has not occurred.

Returning to the relevance of diagnostic criteria as outlined at the beginning of this editorial provides a good example of some of the complexities surrounding post-ECT cognitive assessment. Cognitive symptoms of MDD, such as poor concentration, can be affected by some of the other features of the disorder. For example, insomnia can adversely affect concentration, which will have a negative downstream effect on memory (new learning and retention). The same applies to fatigue. In terms of the statistical interpretation of neuropsychological test results, one example would be that consideration should be given to the possibility that when compared with standardised norms, depressed patients may already (before ECT) be underperforming, or even be near floor level (a score that is too low to reliably identify any further decline in performance). This is one of the reasons why the individual patient's neuropsychological profile ideally should be interpreted against their own predicted premorbid level of cognitive function by using, for example, demographic data or formal tests of premorbid intellectual function. Other issues related to interpretation of test results concerns for example determining what constitutes a reliable clinical change during serial testing, or identifying what represents an impairment versus a below average performance of a given cognitive function in a test protocol.

There are also non-cognitive factors to consider when interpreting data. Particularly relevant to Vann Jones and McCollum's study would be the effect of patients' self-awareness (or 'insight') on their subjective judgements of memory function. Problems in this area can influence how patients rate their memory performance and result in very different

scores from actual objective test performance. For example, a small study looking at repeated neuropsychological testing about 3 weeks after ECT found objective as well as subjective memory difficulties to be present, but the authors cautioned that subjective post-ECT reports of memory problems may be influenced also by problems of awareness, questioning their reliability.¹⁰ Perhaps if routine standard cognitive assessment were available in ECT services, patients could be reassured that in addition to their own 'report back' opportunities to identify their concerns about memory problems with their doctor, their cognitive functions (including memory) would be closely monitored for objective change.

Remaining questions

Although current research appears to indicate that ECT in most patients does not appear to have lasting adverse effects on memory, we can, of course, not be entirely sure that this is always the case for all patients. For example, prospective studies that look at ECT effects on cognition, where baseline neuropsychological testing including consideration of premorbid intellectual ability is included and compared with a control group, could help to further advance our understanding of the cognitive neuroscience surrounding this topic. However, of particular relevance to Vann Jones and McCollum's interesting review, to help address patients' concerns expressed through their subjective reports of ongoing memory difficulties, the following could possibly be helpful to think about. Future research in the area may wish to consider more closely which specific non-cognitive factors, including self-awareness, might account for a discrepancy between actual and reported cognitive impairment. For example, a recent study of patients with acquired brain injury found that most of the variance between actual and perceived cognitive impairment was explained by affective factors such as anxiety or low mood.¹¹ Conversely, it may be helpful to also look more closely at which specific symptom(s) of MDD improve post-ECT. As an example, one interesting hypothesis to test would be to determine how much of improvement in depression can be accounted for (or not) by a specific improvement in patients' ability to think or concentrate post-ECT.

As regards clinical practice, one of the possible implications from Vann Jones and McCollum's study is that there may be a need to consider if it is necessary to determine recommended standards of cognitive testing or clearer guidance on testing for UK ECT services. It may, of course transpire, that routine standardised cognitive testing of all patients receiving ECT would possibly be unhelpful or even harmful, raising anxiety-provoking questions in patients' minds that were not there before. However, if standardised testing were deemed necessary to implement, close consideration might need to be given to factors such as which cognitive functions are most relevant to test in the ECT situation, the length of such assessments and, closely related to the latter, what type of assessment (bedside, formal neuropsychological testing or a hybrid approach), among other questions. To conclude, several recent papers illustrate the essence of some of these questions. Although the Montreal Cognitive Assessment¹² is considered to be useful in monitoring cognitive function after ECT,¹³ on the other hand, cognitive assessment after ECT is also presently thought to not be comprehensive enough, especially if limited to bedside testing only.⁹ As with many of the questions surrounding the clinical practice and neuroscience of ECT, this is not an easy one to provide a definitive answer to.

Abstract**Aims and method**

The OPTIMA mood disorders service is a newly established specialist programme for people with bipolar disorder requiring frequent admissions. This audit compared data on hospital admissions and home treatment team (HTT) spells in patients before entry to and after discharge from the core programme. We included patients admitted between April 2015 and March 2017 who were subsequently discharged. Basic demographic data and numbers of admissions and HTT spells three years before and after discharge were collected and analysed.

Results

Thirty patients who completed the programme were included in the analyses. The median monthly rate of hospital admissions after OPTIMA was significantly reduced compared with the rate prior to the programme. HTT utilisation was numerically reduced, but this difference was not statistically significant.

Clinical implications

These results highlight the effectiveness and importance of individually tailored, specialist care for patients with bipolar disorder following discharge from hospital.

- *A new inner-city specialist programme reduces readmission rates in frequently admitted patients with bipolar disorder*
 - *Method*
 - *Results*
 - *Discussion*

The period immediately following hospital admission for mania or bipolar depression is an important opportunity to optimise treatment and to prevent episode recurrence and readmission.¹ Studies show that this period is one of high risk of readmission and episode recurrence.²⁻⁴ It is also a period of high suicide risk.⁵ The OPTIMA mood disorders service was established in 2015 in the South London and Maudsley (SLaM) NHS Foundation Trust.⁶ OPTIMA's core programme aims to consolidate recovery for people with bipolar disorder who have recently required a hospital admission or home treatment team (HTT) care for an episode of mania or depression. Importantly, the core programme focuses particularly on those who have required frequent hospital admissions. In a preparatory audit of admissions for bipolar disorder in the Trust, over a three-year period, there were approximately 500 admissions per year for bipolar disorder. Two-thirds of these were readmissions, emphasising the need for better preventive strategies. Approximately 150 people were admitted more than once a year: this group accounted for a quarter of the total number of admissions for patients in this diagnostic group.

The OPTIMA core programme offers an individually tailored treatment, comprising ongoing psychiatric assessment and review, the prescribing of psychotropic medication, specialist nursing, occupational therapy and individual psychoeducation.

This preliminary audit assessed the effect of this programme on readmission rates by comparing median admission rates before and after engagement with OPTIMA. A similar comparison was made with rates of HTT episodes.

Method

Approval for this audit was obtained from the SLAM Mood, Anxiety and Personality Clinical Academic Group Governance Committee. The audit focused on patients who had been admitted to the OPTIMA core programme between April 2015 and March 2017.

The core programme began with an assessment appointment with a consultant psychiatrist or senior trainee, and a key worker (a senior nurse or an occupational therapist). When the patient entered the programme, they were offered a period of engagement in which goals were agreed. Psychiatric review and medication changes were made to address ongoing affective episodes or subsyndromal symptoms. 'Key working' was offered: this was an individually tailored psychoeducation programme which aimed to reinforce prevention strategies. It included sensitive work, such as the identification of past episode triggers and early warning signs of mania and depression. Self-management skills, early intervention strategies and crisis planning were taught to prevent full episode recurrence.⁷

The programme also offered specialist nursing interventions and occupational therapy. Appointments were offered at times and at a frequency convenient to the patient to encourage attendance. Initially, it was planned that the core programme should last 12 weeks, followed by less frequent contacts prior to discharge to the patient's community team. However, in practice, a more flexible approach was used, and the duration of the core programme was adapted in each case to allow for individual variation in the time needed to engage patients and to address ongoing affective symptoms.

Basic demographic data were collected. The number of hospital admissions and HTT episodes in the three-year period before entering OPTIMA were extracted from electronic health records. Similarly, the number of hospital admissions and the number of HTT episodes in the (shorter) period following discharge were determined. Monthly rates of admission and HTT episodes in the 36 months before OPTIMA were calculated. For the period following discharge from OPTIMA, rates of admission and HTT contacts were calculated by dividing the number of admissions/HTT contacts by the number of months since discharge from the programme. Descriptive statistical analyses were used to characterise the audit sample. A Wilcoxon signed-rank test (Shapiro–Wilk, $P = 0.001$) was used to conduct comparisons of pre- and post-OPTIMA admission and HTT rates.

Results

At the time of this audit, 30 people had engaged with and had been discharged from the OPTIMA core programme; a further 22 patients remained in the programme. Of the group of 30 discharged patients, 20 were female and 10 were male. The median age was 40.5 years, with an interquartile range (IQR) of 25.

The median number of months since discharge from OPTIMA was 9.5 (IQR 8). Eighteen people did not complete the whole programme for the following reasons: recurrence of illness ($n = 4$), personal issues ($n = 6$) and lack of engagement ($n = 8$). For purposes of our analysis, these 18 patients were included in the analyses as they received at least one therapeutic intervention during their stay in the programme.

The median monthly rate of hospital admissions after OPTIMA was 0.00 (IQR 0.00), which was significantly different from the median monthly rate in the three years prior to OPTIMA (0.04; IQR 0.06; Wilcoxon signed-rank test $Z = 3.1$; $P = 0.002$). The post-OPTIMA median monthly rate of HTT episodes (0.00; IQR 0.02) was numerically reduced compared with the rate prior to OPTIMA (0.03; IQR 0.06), but this difference did not reach statistical significance (Wilcoxon signed-rank test $Z = 1.5$, $P = 0.136$).

Discussion

These results provide preliminary evidence of the effectiveness of the OPTIMA core programme in reducing hospital readmissions in a group of frequently admitted patients from an inner-city catchment area.

There was no statistical difference in HTT spells of care required before and after the programme. This may reflect the limited sample size and the short follow-up period of this early audit. However, it is possible that when OPTIMA ‘graduates’ do suffer recurrence, symptoms are recognised earlier, and patients are better able to use home treatment, and so hospital admissions are avoided.

The role of specialised programmes has been debated in recent years. Do the long-term benefits of specialised services justify the resources they require and their costs? A growing body of evidence supports the need for and the effectiveness of specialist services, particularly in the case of complex and disabling illnesses, such as bipolar disorder.⁹ In a recent study, Kessing *et al*¹ randomised 158 recently discharged patients with bipolar disorder to the treatment arms of a specialised bipolar clinic or standard care. The specialised intervention consisted of a two-year comprehensive programme that combined individual and group treatments, including group-based psychoeducation, provided by psychiatrists, psychologists, nurses and social workers with relevant training and experience in the treatment of bipolar disorder. Over a period of almost six years, a significant reduction in the rates of readmission was found in the group receiving specialist care. Importantly, there was a significant associated reduction in the financial costs to the care provider, as well as higher patient satisfaction rates. The OPTIMA mood disorders programme used a similar approach, but there were several important differences. First, the OPTIMA mood disorders service provided intensive clinical care to recently discharged patients at any stage in their bipolar illness, but selected them on the frequency of their admissions; the Kessing study focused on those early in their bipolar course. Second, the OPTIMA programme was designed to recruit the Trust’s most frequently admitted patients to our core programme. Third, patients on our core programme were often symptomatic and could not attend our structured group psychoeducation programme; in these cases, individual psychoeducation was provided instead.

Specialised programmes such as OPTIMA provide opportunities for education and research.^{8,10} The South London and Maudsley NHS Foundation Trust comprises a number of clinical academic groups which aim to facilitate the provision of evidence-based treatment, research and training in its clinical services. The OPTIMA programme hosts students, postgraduate students and trainees who wish to learn more about bipolar disorder.

Interpretation of the results of this early audit of a new service is subject to several limitations. The number of patients who completed the programme was small, and the period since discharge is short. Our results are based on an observational design with intra-individual comparisons: there was no control group to compare effects with standard treatment offered by the Trust. Despite these limitations, our initial findings support the importance of frequent specialist post-episode psychiatric review and maintenance phase interventions to stabilise bipolar disorder in frequently admitted patients. Future work will include the expansion of this model of care in the development of an OPTIMA ward liaison service to improve continuity of care from the in-patient to the community setting, and recruitment to the OPTIMA core programme.

1.5.95 Decision-making in crisis resolution and home treatment teams: The AWARE framework

Chiara Lombardo Mónica Santos Tine Van Bortel Robert Croos Ella Arensman Manaan Kar Ray

Correspondence

Dr Manaan Kar Ray

(manaan.karray@health.qld.gov.au)

date

2019-4

Abstract

Aims and method

The aim of the study is to improve patient safety by identifying factors influencing gatekeeping decisions by crisis resolution and home treatment teams. A theoretical sampling method was used to recruit clinicians. Semi-structured interviews to elicit various aspects of clinical decision-making were carried out. The transcripts were thematically analysed using a grounded theory approach.

Results

Patient needs (safety and treatment) was the primary driver behind decisions. The research also revealed that information gathered was processed using heuristics. We identified five key themes (anxiety, weighting, agenda, resource and experience), which were constructed into an acronym 'AWARE'.

Clinical implications

AWARE provides a framework to make explicit drivers for decision-making that are often implicit. Incorporating these drivers into reflective practice will help staff be more mindful of undue influences and result in improved clinical decisions.

Declaration of interest

None.

Crisis resolution and home treatment teams (CRHTTs) are the interface between acute and community mental health services. Focused on patients' recovery and empowerment, they are an alternative to hospital admission, providing treatment in a less restrictive environment. They are the gatekeepers for in-patient admissions and enable early discharge, reducing hospital bed use.^{1,2} Patients experiencing mental health crisis are assessed by CRHTT practitioners. Outcomes may include home treatment, admission to hospital, back to referrer in secondary or primary care or signposting to other appropriate services.^{3,4}

Now an integral part of mental health services in the UK,⁵ they were introduced in 1992 through the National Service Framework for mental health in England. Similar teams have been implemented in other European countries.⁶ Research has primarily focused on their value as admission prevention service. Some,⁷⁻⁹ but not all,¹⁰ studies indicate reduction in bed use. National guidance¹¹ on acute service provision recommends CRHTTs. A systematic review of 69 studies¹² identified elements influencing CRHTT service quality through models of care and implementation guidelines. Hunt *et al*¹³ has noted that suicide rates in crisis teams are higher than in in-patient settings. CRHTT decisions are at a critical juncture in the care pathway and have a major impact on patient outcomes, but research is scarce and needs development.

Clinical decision-making is a contextual, continuous, evolving process, where data is gathered, interpreted and evaluated to select evidence-based actions.¹⁴ Understanding the rationale behind CRHTT assessment outcomes, such as whether to admit a patient, is pivotal to improving patient safety. We conducted a qualitative study with the aim of identifying intuitive factors influencing clinical decision-making following CRHTT assessments, as a service improvement project.

Method

Setting and participants

A theoretical sampling method was used to identify qualified multidisciplinary team members in a CRHTT of working-age adults in East Anglia. Eighteen interviews were carried out across 12 multidisciplinary team staff (10 nurses, 2 social workers; post-qualification experience: 10–25 years; 6 men, 6 women), who were primary assessors. Six participants were interviewed once and six participants were interviewed twice.

Psychiatrists were not included as their involvement in clinical decision-making in the initial assessment was not routine in this team. Participants volunteered after being informed of project objectives and procedures and provided verbal informed consent. It was only after the conclusion of the clinical interaction that assessors participated in the study, thus there was no direct or indirect influence on patient care. As part of the consent process, interviewees were given specific

instructions not to use any patient-identifiable information. This was in keeping with the organisation's confidentiality policy.

Ethical approval was not deemed necessary and the study was registered within the trust as a service improvement project.

Interviews

Semi-structured, face-to-face interviews (supplementary interview schedule available at <https://doi.org/10.1192/bjb.2018.94>) with open-ended questions to elicit various aspects of clinical decision-making were carried out separately by two psychiatrists working in the CRHTT (M.S. and R.C.). Participants were asked to discuss an assessment from the past 24 h. The interview schedule provided general structure but the discussion was fluid based on the responses, which were probed to gain a deeper understanding of the themes and theories being generated. Each interview lasted about 1 hour. Interviews were audio-typed, transcribed and conducted until saturation of themes was reached.

Data analysis

A grounded theory approach was taken.^{15,16} Data was thematically analysed by the researchers (M.S. and R.C.) working independently, following recommendations by Ritchie *et al.*¹⁷ Initial transcripts were coded manually to support development of a coding framework that was subsequently refined by additional interviews. Codes included purely descriptive ones arising directly from the transcript and more interpretive codes. Then, to ensure trustworthiness of the data, the authors met and agreed themes. Any differences in interpretation of statements was resolved by discussion with the wider research team until consensus was reached. The coded data was synthesised into the final framework. Further confirmation of themes took place through team discussion, with themes validated by an independent researcher (C.L.) and the principal investigator (M.K.R.).

Results

Of the 18 assessments, low mood and suicidality appeared to be the primary cause of referral to CHRTT. Information gathered relating to symptom severity and risk appeared to be the primary basis for decision-making. Information from the referrer was supplemented by electronic patient records or past knowledge about known patients. The principal source was the face-to-face assessment with the person and their carer/s. Patient need (actual or perceived) appeared to be the primary driver behind decisions. This was evidenced in statements such as: 'For her own safety, she was unpredictable, it would have been difficult to manage that in the community at that time... Admission was the right decision' (01). (For all quotations, the numeral refers to the interview serial number.)

However, interviews revealed that the extensive information gathered was not processed in a uniform manner, but often by heuristics (common sense, rule of thumb, stereotyping, educated guess, intuitive judgement). These were noted to be part of the decision-making toolbox for all practitioners and were related to more than just patient presentation (symptoms, risk, aetiology). Below, we describe the most commonly expressed heuristic themes that influenced decision-making (*Table 1*). *Table 1* Heuristic themes (with subthemes) that influenced information processing

Theme	Subtheme
Anxiety	(generated/diffused in)
Patient	Friends/family/carer/Referrer
Triaging/assessing	practitioner
Weighting	(of symptoms elicited)
Diagnosis	(co-morbidity – personality disorder/alcohol or substance misuse)
Course of illness	(acute/chronic/acute on chronic)
Factors considered outside core remit	(relationship/finances/accommodation/employment/family – carer availability)
Agenda	(elicited in)
Referrer	Patient/Family/Practitioner/Team/
Resources	(identified or not)
Beds	Home treatment capacity/
Experience	(of)
Same patient	Other patients from same diagnostic group/
Other patients	from different diagnostic group

Anxiety

Interviews clearly showed the dual role of practitioners. First, to assess and plan the next steps, and second, to diffuse anxiety relating to the crisis under assessment. For the patient and family the anxiety settled when they felt that they got the right support, the referrer felt less anxious knowing someone else was dealing with the crisis and the assessor's anxieties settled if they felt they had brought matters to a safe conclusion either through capturing hope or blanket safety reassurances. In the case of a young, agitated suicidal male with limited protective factors who was referred back to locality team, the practitioner stated, 'Well it was straightforward, he was able to engage in it (the assessment) despite the difficulties with his anxiety' (03). The patient's willingness to engage was indicative of a safe conclusion. It diffused everyone's anxiety and trumped symptoms of agitated depression and the rationale for the decision not to provide additional support. A similar presentation with an ambiguous commitment resulted in higher anxiety all around, bringing forward the diametrically opposite decision to admit: '... There was obviously some urgency to it (admit). He had strong thoughts of taking an overdose the previous day... and his wife had to take time off work because she was concerned about his help-seeking' (15).

Practitioners were consciously eliciting predisposing, precipitating and perpetuating factors as part of exploring risk (increases anxiety), as well as protective factors and the potential willingness to safety plan (decreases anxiety). It was noted that in patients with similar presentations and risk profiles. there could be diametrically opposite clinical decisions. For risk-averse decisions, the focus was on anxiety increasing perpetuating factors. In contrast, anxiety decreasing protective factors were emphasised by the assessor. where they had taken positive risks: '... He was staying with his parents, they were quite supportive, ... housing was a big concern. ... but he's got a good job, and his employer had been really supportive. He also identified his daughter and his father as protective factors' (14).

Weighting

In the decision-making process, weighting of symptoms and risk was influenced by pre-existing diagnosis (personality disorder/substance misuse), course of illness (acute, acute on chronic, chronic) and presence or absence of social factors that were considered to be outside the core remit of CRHTT work. For example, in a suicidal patient who was not taken on, the practitioner stated: 'Not much had changed. He had previously been referred to the [...] service and the [...] service... he'd already been signposted, nothing had changed' (12).

Patients with alcohol and/or substance misuse fell into a similar bracket, with the understanding that these issues needed to be addressed first by other agencies: 'He's a heavy cannabis user, which he uses to self-medicate with his anger difficulties. We gave him advice on alcohol making him impulsive, what else can we do' (02). Nevertheless, substance misuse issues were consistently assessed for, and when identified, appropriate onward referral/signposting took place. In the presence of clear-cut major psychiatric illness, comorbid substance misuse was taken very seriously as it is a factor that significantly contributed to increased risks: '... She has been abstinent for [...] years now but with all the stress going on in the family she had turned to drink, it's only when she drinks she takes an overdose. It makes her feel lower and more impulsive, we had to do something to break the spiral' (05).

The course of the illness also strongly influenced the outcome. Generally, an acute presentation appeared to trump an acute on chronic presentation, which was higher on the pecking order to a chronic deterioration irrespective of the presentation and risk being quite similar; the expectation in the latter being that more should be done by the referrer. 'Acute: '... She was presenting as quite labile... was quite unsettled, agitated, disinhibited... we have to do something' (01). Acute on chronic: '... She's got chronic thoughts of ending her life by an Insulin overdose. There's a change to wanting to put herself in front of a train... previously what stopped her acting was her sons, however this had changed. The intensity had changed and a change in nature. Her protective factors have reduced' (15). Chronic: 'I didn't think it was an appropriate referral because this was a guy who'd only been seen in an out-patient appointment with long-term ongoing problems and I felt more could have been done by the locality team, before referring' (03). 'Although practitioners fully recognised the impact on risk of social factors (accommodation, finances, relationships, employment, carer/family support and availability), those presenting primarily with these issues were often not taken on for acute care interventions. In these circumstances, often the social aetiology behind the crisis was given more weighting than the risk: '... Social support impacted the decision-making... no significant friends or family. She receives no support

from care services with regard to her son...She is single, financially lacking and on benefits, lacking social support. She has physical illnesses with a lot of symptoms...but not for us really...' (16).

Agenda

Agendas (desire to achieve a particular outcome), both stated and perceived, influenced information processing. If an agenda was picked up in a referrer/patient/carer by a practitioner, they often responded to it. This was most obvious when judgement calls were being made about the appropriateness of the referral: '...I felt that the reasons for the referral weren't really appropriate. He was someone that they'd (Locality Team) only seen twice, the reason for referral was that he was being actively suicidal. But I felt the risk was kind of raised so we'd go and see him...' (06).

Sometimes agendas were picked up in patients and carers. There was evidence to suggest that practitioners responded (taking seriously or dismissing) with their gut instinct to the agenda that they perceived: '...Suicidal ideation, in the context of depression...because she has a child, so I think it's always worth having a look when there's a child, I got the clear sense that she was downplaying it as she did not want social services involved, we needed to do something...' (13). Generally carer concerns particularly relating to burnout were taken quite seriously, as delivering successful home treatment is often quite difficult without their support: 'I think her husband felt that she needed to come into hospital...he was quite distressed by what she had done again. He felt it was a heavy load to carry at the moment. Too much to cope with...' (01).

Resources

The research revealed that most practitioners were conscious about the impact of resources on decision-making. Most took the stance that they tried their level best to carry out the assessment independently of the bed state. When directly asked about bed pressures influencing decisions, most practitioners said no; however, most would be aware of it when doing the assessment. Practitioners indicated that if a patient was very unwell they would ensure that they get a bed, but it was also apparent that the threshold for admission dropped if more beds were available: 'We knew there was a bed, actually we knew there were plenty of beds on the ward, so we kind of thought, you know what this lady could just do with a break and some more assessment of her depression' (04).

There were similar findings relating to home treatment capacity, where practitioners denied the effect of resource limitation: 'It had no bearing on the decision (not to take a suicidal patient on for home treatment). What does that mean if we were short staffed we wouldn't have taken him? No it had no bearing on it whatsoever' (03). However, thresholds were noted to fluctuate in a similar fashion to beds when the home treatment team was less busy.

Experience

Past experience of unsuccessful home treatment or an admission that did not benefit the recovery journey of the patient influenced the practitioners reading of current risk. The rationale for not taking a suicidal patient on to home treatment was as '...There were no changes in his social situation from when I'd last seen him [...] years ago...if he feels that the situation is not validated then he will increase his risk behaviours... I felt that we needed to validate his level of distress over that and try and keep it compact (not get another team involved)' (17). It was also apparent that the team put a far higher premium on knowledge held within the team from previously working with a patient than what was being handed over to them in the here and now by the referrer.

Discussion

MacNeela *et al*¹⁸ concluded that nurses strive to ‘know the patient’, while having to ‘work the system’, with implications for patient care and decision-making quality. Interviews revealed that assessing practitioners are often put in very difficult scenarios and need to respond to multiple pressures. It would be unrealistic to expect that they will not be influenced by this. It could lead to formulation of an opinion about what a good outcome would look like early in the process. They try to remain in a rational space and make decisions based on information that they have collated. However, the pressures set up a rationalising environment in which facts get highlighted selectively to rationalise the decision that has been already formulated. This is often an unconscious process and the purpose of the study was to identify and make explicit drivers for decision-making that are often implicit and are captured in hard-to-define terms like ‘gut’ or ‘instinct’. To help assessing staff become more mindful and stay in a rational space rather than rationalising (we see what we want to see to help us deal with our cognitive dissonance¹⁹), we have framed the findings from our qualitative study in an easy-to-remember acronym, AWARE (Anxiety, Weighting, Agenda, Resources, Experience).

If a practitioner is anxious about adversely affecting the balance of hope versus risk and decides not to tease out triggers extensively, this decision should be a conscious choice (rather than unconscious). One can then document the same and handover to the next person, making it clear that there is an outstanding piece of work. The assessor can then mindfully safety plan and systematically attend to warning signs²⁰ that may rise until the next appointment. Further work relating to fluctuating risk can then be taken up when the crisis is more contained at the follow-up. Seeking blanket reassurance by asking patients ‘Can you keep yourself safe?’ only decreases anxiety in the practitioner and does very little to enhance safety.

Embedding reflective practice will keep clinicians mindful about these heuristics. Bhugra *et al*²¹ found in a qualitative study that expert psychiatrists relied upon intuitions and novices took a more analytical approach in making clinical decisions. CRHTTs are multidisciplinary in nature: front-line assessments are done by team members from different backgrounds with different levels of experience. Given the variation, decision-making standardisation becomes a key service issue. Bhugra *et al*²¹ found that uncontrollable factors (time pressures, cost, resources) influenced decisions. This is highly relevant as CRHTTs are often managing bed pressures. It is a highly dynamic setting, and thorough conscious deliberation on findings may not be possible.²² Hunt *et al*²³ reported suicide rates of 14.6 per 10 000 CRHTT episodes compared with 8.8 for in-patient episodes. The national reduction of 17% in mental health bed numbers from 2012 to 2015²⁴ has meant that CRHTTs have an ever-increasing importance in care delivery of acutely unwell patients. Therefore the higher suicide rate in CRHTTs compared with in-patients needs urgent attention. The AWARE framework may provide the foundation for safer care as it seeks to keep assessors in a mindful and reflective space.

Hunt *et al*¹³ found that 49% of CRHTT patients who took their own life had adverse life events, and a further 44% were living alone. Preconceived notions about what is core CRHTT work could be taken up in case-based discussions in a supportive fashion. This could also help reframe the CRHTT gatekeeping agenda. Assessments are about admitting at the appropriate time so that the shortest in-patient stay may be followed up by prompt home treatment. It is not about keeping everyone out. Resource-led decisions²¹⁻²⁵ are never ideal but are inevitable in the real world. Naming the decision for what it is will ensure that practitioners then consciously work toward mitigating the risk the resource-led decision has created, rather than justify (deal with cognitive dissonance¹⁹) their action by selectively highlighting aspects of the presentation.

Given that suicide is a rare outcome, assessors often feel that their judgement calls are safe, and so the threshold for admission/home treatment unconsciously creeps up. Reflective practice could keep staff mindful about small increments in risk-taking. Serious untoward incidents have a considerable detrimental impact on the confidence of practitioners to take positive risks. Threshold awareness supports safety and patients’ recovery journeys in the long run, as without risk there is no recovery.

Limitations

The study findings, particularly in relation to anxiety, are limited to the CRHTT setting as crisis referrals often have an urgency and acuity that might not be present in routine assessments. As an improvement project, the findings are relevant to the service. Before generalising findings to all assessments, AWARE as a framework needs further research. It is also important to acknowledge that, for practical reasons, study participants were recruited from a single team. Although not unusual for CRHTTs, there were no front-line assessors working who had less than 10 years post-qualification experience. Research into decision-making shows that experience level has a bearing.²¹ Also, in most crisis services, initial assessments are carried out by nurses and social workers; however, there are teams where psychiatrists might have oversight. Inter-team variability of this nature limits the generalisability of this study. Another limitation is that interviews were carried out by CRHTT psychiatrists, introducing a potential bias in responses. This was mitigated by assuring participants that this was not an assessment of their decision-making skills and that their participation was voluntary and they could withdraw consent at any point.

Clinical decisions not only affect patient outcomes but also have significant medicolegal implications. Mulder *et al* point out the futility of risk categorisation and how it may confuse clinical thinking.²⁶ This study proposes AWARE as a theoretical framework that supports safer clinical decision-making. To substantiate this claim, research across various contexts and different CRHTT settings is needed in which AWARE is empirically tested and refined.

In conclusion, there is a subjective element to clinical decision-making, as it involves clinical judgement and interpretation of information. However, there needs to be a balance between fact and intuition, and dissecting out intuitive processes might help eliminate certain unhelpful biases. AWARE provides a framework to make explicit some of the drivers for decision-making that are often implicit. This can be used in reflective practice groups as well as for a quick, internal crosscheck post-assessment. It may reduce bias and inter-assessor variability, improve consistency, lead to a more systematic approach and help staff be more mindful of how they could be subject to undue influences, and therefore result in improved clinical decisions and patient safety.

We thank the home treatment staff who were interviewed for this study, and Mrs Mary Henniker for transcribing the interviews. We acknowledge scholarly contributions from Dr Golam Khandaker and Dr Claire Dibben.

1.5.96 The banality of counterterrorism “after, after 9/11”? Perspectives on the Prevent duty from the UK health care sector

Charlotte Heath-Kelly Erzsébet StrauszCONTACT Charlotte Heath-Kelly c.heath-kelly@warwick.ac.uk¹

date

2019

Abstract

Since 2015, the UK healthcare sector sector has (along with education and social care) been re-responsibilised for noticing signs of radicalisation and reporting patients to the Prevent programme. The Prevent Duty frames the integration of healthcare professionals into the UK’s counterterrorism effort as the banal extension of safeguarding. But safeguarding has previously been framed as the protection of children, and adults with care and support needs, from abuse. This article explores the legitimacy of situating Prevent within safeguarding through interviews with safeguarding experts in six National Health Service (NHS) Trusts and Clinical Commissioning Groups. It also describes the factors which NHS staff identified as indicators of radicalisation – data which was obtained from an online questionnaire completed by 329 health care professionals. The article argues that the “after, after 9/11” era is not radically distinct from earlier periods of counterterrorism but does contain novel features, such as the performance of anticipatory counterterrorism under the rubric of welfare and care.

Introduction

The question “is there an after, after 9/11?” forces us to address whether there has been any return from the exceptionalised, emergency frame which dominated international politics in the aftermath of 9/11. At face value, the direction of travel in Europe and North America is unchanged. The immediate legislative responses to international terrorism of the twenty-first century – the Contest Strategy (UK) and the Patriot Act (USA) – have not been repealed, and the technological advance of counterterrorism surveillance continues unabated.

However, this article argues that Countering Violent Extremism (CVE) policies do represent a distinctive development in the post-9/11 counterterrorism repertoire. CVE frameworks are now employed across the globe by actors such as the United Nations, the European Union as well as individual nation states (Kundnani and Hayes 2018). Their unique selling point is the prevention of terrorism through interventions in “radicalisation processes”, before criminal conspiracy occurs (in the so-called “pre-criminal space”). Here, the resources usually associated with social welfare policies (like mentoring, housing and education) are reframed as terrorism prevention assets (Home Office 2017, 2018). In contradistinction to the emergency criminal justice measures of the immediate 9/11 era, this article focuses on the banality of the Prevent Duty in the UK where social care, education and health care workers are now engaged in the prevention of terrorism (Ragazzi 2017).

The Counter-Terrorism and Security Act of 2015 placed a statutory duty on specified authorities within the UK’s public sector to have “due regard to the need to prevent people from being drawn into terrorism” (Home Office 2015: 2). In practice, this has meant that schools, colleges, universities, prisons, social services, National Health Service (NHS) trusts, NHS Clinical Commissioning Groups² (CCGs) and private health care providers on the NHS standard contract now perform counterterrorism – under the rubric of safeguarding. These providers deliver Prevent-related training to their staff, promote the importance of the Prevent Duty to their staff, and process Prevent referrals made about colleagues, students, patients and clients.

The use of health and education sectors to support counterterrorism is unique to England, Wales and Scotland. The Prevent Strategy has not even been rolled out to the entire UK (given the specific provisions of Good Friday Agreement, the Prevent Strategy does not apply in Northern Ireland). While some European nations utilise community policing and prison services to identify and deter potential radicals, it is much rarer for the non-judicial sectors to be involved in counter-radicalisation. The Netherlands is an exception and has begun encouraging youth workers and educators to promote counter-radicalisation³ agendas. But Britain is alone in making its educational, health and social care sectors legally responsible for counter-radicalisation.

In this unique context of policy implementation, this article explores how counter-radicalisation has been integrated into the health care sector. The authors conducted a 12-month pilot study, funded by the Wellcome Trust, which evaluated the performance of Prevent Duty safeguarding by NHS trusts and CCGs in the Midlands region of England.⁴ Using expert interviews with NHS safeguarding professionals, discourse analysis of the Workshop to Raise Awareness of Prevent (WRAP) training DVD and a survey of staff attitudes ($N = 329$) towards the Prevent Duty, we explored how Prevent is performed within the NHS’ safeguarding remit.

Our study showed that NHS staff are, on the whole, accepting of their new responsibilities under the Prevent Duty and comfortable with the training provided. However, our survey also revealed that staff knowledge of specific “radicalisation indicators” is drawn not from official training but from popular culture representations of ISIS and radicalism. WRAP training encourages staff to intuit the presence of radicalisation in staff and patients, rather than providing details of explicit “signs” to be reported. We found that this has led NHS staff to rely on the media for their understandings of terrorism and radicalisation. Furthermore, despite the popular acceptance of the Prevent Duty as a form of safeguarding, our expert interviewees unanimously commented on the imperfect fit between the Prevent Duty and other forms of safeguarding expected of the NHS.

² Clinical Commissioning Groups (CCGs) are NHS organisations set up after the Health and Social Care Act of 2012 to organise the delivery of healthcare services. Each CCG includes all of the General Practitioner groups in its geographical area, so that GPs and clinicians can influence commissioning decisions for their region.

³ The Netherlands’ “Integrated Approach to Combatting Jihadism” [Actieprogramma Integrale Aanpak Jihadisme Overzicht maatregelen en acties] policy of 2014 outlines the potential for youth workers and educators to prevent radicalisation: <https://www.tweedekamer.nl/kamerstukken/detail?did=2014D2934&id=2014D29343> (last accessed 3 November 2017).

⁴ The Midlands has a population of over 10 million people and is constituted by the counties of Derbyshire, Herefordshire, Leicestershire, Lincolnshire, Northamptonshire, Nottinghamshire, Rutland, Shropshire, Staffordshire, Warwickshire and Worcestershire. The biggest cities in the Midlands are Birmingham, Coventry, Leicester, Nottingham and Stoke-on-Trent.

Unlike broader safeguarding protocols, Prevent safeguarding is not restricted to adults with “care and support needs”. NHS England therefore defines all citizens as potentially vulnerable to radicalisers and opens the possibility for care practitioners to intervene upon their lives. This extension of interventions across the entire population (rather than limiting them to those persons with care and support needs) creates a tension with the liberal foundations of British political life. A distinctive feature of counterterrorism “after, after 9/11” is, then, that care can be positioned as an anti-terrorism measure – and counterterrorism as a care intervention; such is the normalisation of the counterterrorism within society “after, after 9/11”.

Prevent in the NHS: academic studies

The majority of academic literature on Prevent in UK public services addresses the performance of the duty in the particular contexts of education (Choudhury 2017; Miah 2013; Thomas 2016), youth work (Lynch 2013; McDonald 2011) and social work (McKendrick and Finch 2017). Studies exploring the role of the health care sector in Prevent are beginning to emerge, but at a slower pace. Research access to the NHS can be a lengthy and complicated procedure involving a primary application to the Health Research Authority, unfamiliar terminologies (social scientific research is often not recognised as “research” but as a “service evaluation”) and secondary research access applications to each local NHS Trust’s Research and Innovation (R&I) department. These difficulties render studies of Prevent in the NHS slower to develop. To date, literature on the Prevent Duty in health care can be divided into two streams: debates in forensic psychiatry about the scientific reliability of extremism risk scoring tools and social scientific research into the NHS as a counter-radicalisation actor. This literature review focuses only on the latter.

In the field of Psychiatry, David Goldberg, Jadhav, and Younis (2017) have recently problematised the use of the term “pre-criminal space” in NHS England Prevent Training and Competencies documentation. To foster acceptance in the health care sector, the term situates the positioning of Prevent as a safeguarding and protection measure. Intervening to protect people in the “pre-criminal” space emphasises the separation of Prevent safeguarding from judicial measures. As Goldberg et al. rightly point out, the obscure term “pre-criminal space” does not appear in Home Office Prevent policies nor in any other NHS safeguarding policy: in policy terms, it is unique to NHS England’s Prevent Guidance. They explore the etymology and usage of “pre-criminal space”, arguing that it operates as both metaphor and analogy – smoothing and bridging the discourses of the health and criminal justice sectors, and persuading NHS professionals to comply with the duty (Goldberg, Jadhav, and Younis 2017).

Other academic research into the Prevent Duty focuses on the mass responsabilisation of health care workers for counterterrorism detection and prevention. Heath-Kelly (2017a, 2017b) has explored how the Prevent Duty expands the application of preventative counterterrorism to the entire population, rather than deploying it upon smaller suspect communities. The training of the 1.3 million NHS workers to report radicalisation demonstrates a transition of security apparatus away from security professionals (such as counterterrorism officers) who possess formal training, towards a far looser type of counterterrorism “expertise”. In the NHS, a 1- or 2-hour training session in front of the “WRAP” DVD qualifies a staff member to detect and report radicalisation. The minimal training for such a sensitive task shows that central government have prioritised large-scale reporting of radicalisation suspicions across the population, rather than targeted and precise counterterrorism measures (Heath-Kelly 2017a, 2017b). Indeed, upon the release of the 2013 Prevent Guidance document “Building Partnerships, Staying Safe”, Director of Nursing Hilary Garratt wrote to all CCG commissioning leads and emphasised that the size of the NHS (which makes 1 million patient contacts every 36 hours), rather than any specific expertise, qualified it as a key partner within the Prevent Strategy (Garratt 2013). Size matters, it seems, in the new Prevent Duty.

Outside these formal studies, various health care professionals have also taken to the pages of academic and professional journals to voice concern, and occasionally support, for the Prevent Duty in the NHS. Derek Summerfield, a consultant at South London and Maudsley NHS Trust, wrote in *BJPsych Bulletin* that compelling medical staff to attend Prevent training is as follows: “a corrosion of the ethics of the doctor-patient relationship, and is to prime us for an activity which is a duplicitous deviation from the medical assessment, advice and treatment that has brought the patient to us. (Summerfield 2016)”

Dr Rosemary Rizq has similar concerns about the conflation of health care and protection with the reporting of terrorist deviance. She argues that surveillance and control insidiously invade the consulting room through the Prevent Duty,

turning the patient requiring health care into an already-securitised risk, and forbidding the free play of speech so essential for therapy (Rizq 2017).

Prevent as safeguarding?

This perceived clash between medical ethics and reporting radicalisation suspicions is complicated by the positioning of the Prevent Duty as a safeguarding measure. Central government policy has explicitly presented the Prevent Duty as an additional patient safeguarding measure which entails no extra responsibilities on behalf of clinical and non-clinical staff (Department of Health 2011: 3). Accordingly, NHS England places responsibility for Prevent training and the processing of Prevent referrals with Trust and CCG safeguarding teams. These safeguarding experts provide WRAP training to staff with the Home Office DVD and script, process Prevent queries (filtering out inappropriate referrals), and determine which queries are referred to Local Authorities and the police. Safeguarding discursively and operationally situates Prevent in the NHS.

While safeguarding is more loosely defined as a “protective intervention” in the educational and social care sectors, safeguarding processes in the NHS are tightly defined. Health care safeguarding is designed *to protect those with care and support needs* (like learning disabilities, severe mental health conditions, dementia, drug and alcohol addiction) from abuse, where they cannot protect themselves. They are a necessary societal protection for those with reduced individual capacity or agency. The Care Act was passed in 2014 to legally enforce the safeguarding of vulnerable people, and it states that local authorities must intervene to support adults in cases: “where a local authority has reasonable cause to suspect that an adult in its area (whether or not ordinarily resident there) – (a) *has needs for care and support* (whether or not the authority is meeting any of those needs), (b) *is experiencing, or is at risk of, abuse or neglect, and* (c) as a result of those needs is unable to protect himself or herself against the abuse or neglect or the risk of it. (2) The local authority must make (or cause to be made) whatever enquiries it thinks necessary to enable it to decide whether any action should be taken in the adult’s case. (Care Act 2014, c.23, section 42, emphasis added)”

If an adult has care and support needs, faces the risk of abuse *and* cannot protect themselves, then the individual’s agency ceases to be a paramount principle. Rightly, the Local Authority becomes duty bound to intervene in these situations.

In the NHS, safeguarding teams take reports about vulnerable patients who are at risk of abuse (physical, sexual, financial) and liaise with the Local Authority, and that patient, to put a care package in place. But under the Prevent Duty, safeguarding protocols are activated in cases where no care and support need exists. In Prevent protocols, the explicit provision regarding “care and support needs” in the Care Act is watered down to a suggestion of “vulnerabilities” – creating concerns that the presumption of adult agency has been side-lined.

Home Office and NHS England policy guidance presents radicalisation as a process of abusive exploitation performed upon “vulnerable” persons. But vulnerability, under the Prevent Duty guidance protocols, is no longer a formal state of reduced capacity (like care and support needs); rather, “vulnerability” is extended to potentially cover the entire population. Anyone, with or without care needs, can be the subject of a Prevent safeguarding inquiry. How is this interference in a person’s agency justified, before the criminal threshold is reached? One’s vulnerability (and the need for safeguarding intervention) is constituted through a circular argument: simply by being associated with a radicalisation referral, a person *must already have been vulnerable* to extremist influence. The assumption plays out that no person with full capacity, or in control of their life, would support political extremism or terrorism – thus any presumed sympathy denotes reduced capacity or “vulnerability”.

While any person can be subject to a Prevent safeguarding referral, regardless of their formal capacity level, the Department of Health does provide some guidance on “factors which put people at risk of exploitation by radicalisers”. Worryingly, these racialise “vulnerability” to extremism. The factors emphasise the migration status of an individual as a point of vulnerability to extremism, their “traditional” family life (in a context where “traditional” acts as a synonym for people of colour), and their “religious/cultural heritage”. For example, the first factor highlighted by the Department of Health as indicating radicalisation vulnerability is “identity crisis”, but this is characterised as follows: “Adolescents/vulnerable adults who are exploring issues of identity can feel both distant from their parents/family and cultural and religious heritage, and uncomfortable with their place in society around them. (Department of Health 2011: 10)”

Identity crisis seems to be associated here with second- or third-generation immigrants, positioned between cultures. Apparently “identity crisis” is not a potential experience that anyone could experience, only specific and racialized groups.

The second factor in the Department of Health’s list of radicalisation vulnerability factors is “personal crisis” (characterised as the “isolation of the vulnerable individual from the *traditional* certainties of family life” [emphasis added]). Following on from the first racialised indicator, this invocation of “traditional family life” reads like a synonym for racialised groups in society. The third factor in vulnerability relates to an individual’s “personal circumstances”. We all have “personal circumstances”, but these are characterised by the Department of Health in terms of cultural, religious and raced identities leading towards radicalisation vulnerability: “Personal Circumstances: The experience of migration, local tensions or events affecting families in countries of origin may contribute to alienation from UK values and a decision to cause harm to symbols of the community or state. (Department of Health 2011: 10)”

Finally, unemployment/underemployment and criminality are listed (without racialised undertones) as factors which may make a person vulnerable to radicalisation (Department of Health 2011: 10).

Without a clinical evidence base or NICE guidance, these factors replace the formal care and support needs which are central to other forms of NHS safeguarding. These “factors” fudge the centrality of care and support needs to safeguarding (Care Act 2014, c.23, section 42) by repeatedly invoking the “vulnerability” of a person experiencing disenfranchisement or ennui, but provide no other basis for the interruption of their agency by a safeguarding action.

Without care and support needs, an adult should be entitled to live uninterrupted by the state unless they request support and assistance. Indeed, NHS safeguarding policy enshrines the principle of agency, in all cases apart from where “coercion and undue influence” might apply: “Adults have a legal right to make their own decisions, even if they are unwise, as long as they have capacity to make that decision and are free from coercion or undue influence. (NHS England 2015: 16)”

Given the usual presumption of agency for adults without care and support needs, Prevent in the NHS stretches normal safeguarding customs and protocols to their limit. The “coercion and undue influence” usually understood to constitute impaired agency are severe situational constraints. For example, people experiencing domestic violence or human trafficking can receive safeguarding assistance despite not necessarily possessing “care and support needs” – because they are experiencing significant coercion and abuse from which they cannot reasonably be expected to protect themselves.

But is it legitimate for Prevent to equate the coercion experienced by human trafficking and domestic violence victims, trapped within appalling situations and experiencing dramatic constraints upon their agency, to those engaging with extreme political opinions and those who voice them? Given the potentially dramatic contrast, it would be far more appropriate to presume that individuals retain agency and can engage with political ideas freely. While the intention of safeguarding practitioners is to keep people safe from travelling to war zones or becoming involved in terrorism, the Prevent Duty involves a significant departure from the presumption of adult agency in cases where there is often no cognitive or coercive impediment.

In the next section, we highlight the testimonies of safeguarding leads within NHS trusts and CCG’s on the imperfect fit between Prevent and Safeguarding. These safeguarding experts experienced significant dissonance between their desire to protect potential victims of radicalisers, and their knowledge that safeguarding interventions explicitly require the recipient to have “care and support needs” to justify the intervention upon agency.

NHS safeguarding experts on the prevent strategy

Our interviews with safeguarding experts shed light on some of the key features of Prevent’s uneasy situation within existing safeguarding infrastructure. Most of the safeguarding experts we interviewed held conflicting views and beliefs with regards to the place, function and broader implications of Prevent referrals made by NHS staff, even if they had come to accept, endorse or re-appropriate the Prevent Duty. These dissonances in how safeguarding experts see their role reveal important tensions and concerns that arise when a counterterrorism reporting structure is embedded within an otherwise evidence-based medical culture.

Normal safeguarding referrals utilise a transparent process which is subject to audit and clinical governance. They follow an approach of person-centred care that presupposes the person’s consent and in line with general professional

guidelines in the NHS, foregrounds patient choice. However, the tension between Prevent and the medical duty to provide care was immediately noted by some of our expert interviewees. One General Practitioner (GP) we spoke to noted that with Prevent the very object and objective of protection changes: “When you do safeguarding, the person sat in front of you is your main concern because you’re trying to protect that person. Whereas with this, you’re protecting the state from that person” (Consultant Psychiatrist B and GP 2, 2017). This underlying shift makes Prevent a controversial subject within the NHS, but also demonstrates an imperfect fit with existing safeguarding structures which necessitates a constant negotiation of the Prevent Duty by health care professionals.

Upon the introduction of Prevent to the NHS, a CCG Prevent Lead (responsible for giving the Prevent training) recalled that the policy “didn’t originally sit very well with [them] or a lot of [their] team” (CCG Prevent Lead B, 2017). These concerns reflect the problematic situation of Prevent within NHS safeguarding. Prevent aims to orchestrate a new way of “seeing” and performing safeguarding by cultivating an “awareness” for vulnerable people being at risk of radicalisation. Prevent sits in tension with the approaches, principles and definitions of safeguarding under the Care Act. These tensions become apparent when one attempts to understand the type of “abuse” upon which Prevent intervenes. Normal safeguarding processes exist to protect vulnerable people from financial, physical and sexual abuse, where they cannot protect themselves. For Prevent interventions, the closest fit would be protection from psychological abuse, *qua* domestic violence safeguarding. But even this fit is imperfect. One expert practitioner of Prevent safeguarding understood radicalisation as a “type of grooming” evident when “people are being harassed, they’re being groomed, they may not have any control over what they’re being drawn into [...]. Particularly if they’re very vulnerable and they don’t recognise it” (Safeguarding Expert P, 2017).

Yet a different Prevent trainer pointed out to us that the notion of “vulnerability” is used and talked about very differently between the safeguarding and Prevent contexts. Instead of a focus on “care and support needs”, what is emphasised is a “complex set of grievances” related to ideology, exclusion and identity. For example, “Prevent, to me, is about finding people who are at the cusp in their lives of not having anything else other than somebody saying, “why don’t you do this?” [...] And for a young Muslim child growing up, I suppose, who has a strong family bond and then suddenly is an isolated teenager, racially abused perhaps, can’t find work, you’re going to start connecting with things that perhaps, you know, you see and hear and read, and to deal with your own feelings of anger: “oh, why haven’t I got a job? Why am I in this position?” And that’s who Prevent is meant to protect, but the fact that it sits under Safeguarding, I don’t think it sits comfortably with Safeguarding. (CCG Safeguarding Expert C, 2017)”

Here, the type of abuse that NHS staff are duty-bound to protect against seems to be exclusion, rather than the existing typologies of abuse within safeguarding regimes.

The introduction of the Prevent Duty as a form of safeguarding protection has led to professional dissonance. During our interviews with safeguarding experts, it was common for them to first make the case that Prevent fits well within safeguarding – on the basis that the professional intuition already developed within safeguarding practice is an appropriate tool for detecting radicalisation. In this regard, the Prevent Duty requirements made sense to staff. Safeguarding professionals were described as having a particular nose for detecting the unfamiliar, understood as a “gut instinct that there’s something, but I don’t know what” (Safeguarding Experts F and J, 2017). But interviewees would then draw out some differences in how this intuition is utilised within Prevent. The safeguarding remit, they acknowledged, is now extended beyond people with care and support needs. Furthermore, in normal safeguarding, the emphasis is on “making the person immediately safe,” which is not the case in Prevent (Ibid).

However, the ways in which Prevent stretches beyond the scope of safeguarding was (despite these inconsistencies) often seen in a positive light. The point was made that in actual practice, normal safeguarding *also* extends beyond the strict definitions of the Care Act. Safeguarding experts F and J framed this work as a banal type of intervention upon society: “like any one of us [...] have been a victim of something, but haven’t got care and support needs, but still need some signposting” (Ibid). In this sense, they argue that “although it’s different, I suppose, [Prevent] is not that different, because some of what we do sits in and out of safeguarding as it sits under the Care Act” (Ibid). Here, Prevent was framed as “early help,” before something “reaches a critical point”. These safeguarding experts saw the Prevent Duty as complementary to the Care Act as “we’re not always working completely in line with the Care Act, because there’s more to it, and we will try and prevent things before they get to that point” (Ibid).

Other safeguarding experts also made similar rhetorical moves which positioned Prevent within the safeguarding regime and existing practice. It is “almost parental care” for an individual rather than being ‘explicit and saying, actually, this is an act ... this is dangerous, this is potentially dangerous (CCG Safeguarding Expert C, 2017). This is interesting,

because it shows how the provisions of the Care Act and the Prevent Duty have been appropriated and renegotiated by health care professionals. Prevent's vagueness on "vulnerability" has been re-appropriated to redirect attention to the needs of, and rectifying the exclusion of, the person. One interviewee used it as a "pathway" – something like a personal care-centred corrective to the Care Act – in order to secure resources for clients who would otherwise have fallen through the safety net of social care (Ibid).

Yet, this negotiation of ambiguities is also practised by Central Government, who have manufactured an overlap between NHS safeguarding and the anticipatory surveillance of potential radicals. Unlike normal safeguarding, Prevent referrals from the NHS are fed directly to the police as a matter of routine. In regular clinical practice, collaboration with the police follows established procedures: in cases where clear threats to personal safety are voiced, the police are called first and concerns about health come second. But Prevent operates before this threshold of explicit threat and involves the police as a matter of course. If a health care professional makes a Prevent referral, it is first screened by the safeguarding team before those cases deemed Prevent-worthy progress to the stage of police disambiguation (Home Office 2017: 5–6). The health care professional as well as the safeguarding team screen for signs of "radicalisation" that stop short of threats to personal safety, before involving the police. But what kind of expertise informs this professional judgement?

Trainers and safeguarding teams are not experts in counterterrorism: they receive the same WRAP training as those they train, while also receiving occasional briefings from the Regional Prevent Coordinator. Interviewees confirmed that there is an "inclination" within the NHS to share information with the police and make a referral in order to avoid risks. However, they also acknowledged that Prevent is an essentially "grey area" in that "what we now get involved with is 'if there's potential' – and this is where it's really grey with Prevent" (CCG Prevent Lead B, 2017). This is particularly worrying as doubt is actively discouraged in the process: as a CCG safeguarding expert noted, what is looked for under Prevent is "a little bit of concern" about someone's behaviour, which will be triaged by the safeguarding team – so the one who makes the referral doesn't have to "own" it (CCG Safeguarding Expert C, 2017). As another CCG Prevent Lead admitted, "I'm not sure that [a referral] will help some people. I think it runs contrary to safeguarding under the Care Act in terms of how that works" (CCG Prevent Lead B, 2017).

Concerns about the potential inaccuracy and stigmatisation involved in this haphazard reporting structure are assuaged through policy discussion of the "pre-criminal space". Prevent documentation, as well as interviewee statements, repeatedly emphasised that referees could come to little harm from the referral process – given that they would not obtain a criminal record or penalty. We also discovered that people referred to Prevent are often unaware that such a referral has been made. Their consent only needs to be obtained if the process reaches the stage where the Local Authority consider involving Channel. While policy documents encourage social care sectors to obtain consent when making Prevent referrals, they are not obliged to do so (NHS England 2017: 15–16). And, given the controversial and sensitive nature of a Prevent-referral conversation, our interviewees consistently left us with the impression that consent is usually sidelined (unlike in normal safeguarding procedures) or is fudged as a vague reference to "concerns" and obtaining unspecified "support" for the patient (CCG Safeguarding Expert C, 2017).

One particular Prevent trainer was particularly explicit about the contradiction they saw between the Prevent brief and normal safeguarding procedures of obtaining consent: "You're supposed to ask their permission [...] I don't know whether anybody does. But you're supposed to ask for their consent. 'I think you're being radicalised, I think you want to blow us up, would you mind if I referred you?' " (Safeguarding Expert A, 2017).

But, regardless of not receiving a criminal record or even not knowing one has been referred, being put through a referral process could be highly stigmatising for individuals and breaks the trust established between health care and local communities. Several expert practitioners noted that "I think it's very difficult to come back from a Prevent referral" (Safeguarding Expert A, 2017), and "that person's life can be blighted [by a Prevent referral] in all sorts of ways. Professionally, personally, if you're a child at school and nowadays, everyone knows you've been referred [...] That label will stay with you, well after the investigation and possible trial" (Consultant Psychiatrist B and GP 2, 2017). The referral process was also thought to have broader negative effects upon the relationship between health care professionals and their local communities: "If that leaks out that you did an inappropriate Prevent referral, you break down your relationship with that community, your patients, that patient's family. They'll talk to other patients. She did the referral to Prevent. She thought I was a terrorist or whatever. It would be a total disaster, where you've worked so hard to create a safe space for these people to come and talk about some really sensitive issues. You have to think before you do that. (Consultant Psychiatrist B and GP 2, 2017)"

In essence, safeguarding experts are aware of the imperfect fit between the Prevent Duty and safeguarding protocols. However, they mitigated those discrepancies by emphasising how their everyday (non-Prevent) safeguarding practice also sometimes exceeds the bounds of the Care Act, and by renegotiating aspects of the Duty. During our interviews, it became clear that some safeguarding experts assuaged their concerns about being implicated in predictive detection, by reframing the Prevent Duty as a way to reallocate resources to those deprived by the economic context of austerity. We now turn away from expert testimony to explore the everyday experiences of NHS staff with Prevent – specifically the training provided to NHS staff on Prevent and their interpretations of it.

Description of the content of WRAP training

One of the many tasks of NHS safeguarding teams is to deliver WRAP training to Trust/CCG staff. The “WRAP” training lasts 1–2 hours and involves the screening of clips from the Home Office provided DVD. Since 2016, WRAP trainers need not attend a “train the trainer” workshop; they are qualified by simply having previously attended a WRAP session and by achieving their line manager’s approval for taking on the role. In an NHS England National Prevent Update, cascaded to all safeguarding teams and prevent leads in the NHS in August 2016, staff were informed that 10.1080/17539153.2018.1494123-UF0001

(NHS England 2016: 2–3)

No specific expertise is required to deliver Prevent training, because the role involves reading from the Home Office approve script for the session and interspersing the monologue with clips from the DVD. But in the course of our interviews with Prevent leads across the Midlands, it became clear that no one found it possible or effective to stick to the script. Some trainers reported that they use jokes about the training to lighten the atmosphere, whereas others integrated discussion of current events into the session.

The “Facilitators Workbook” provided by the Home Office suggests that trainers tailor their session to the level required to “achieve buy-in” from the audience. For management audiences, the Home Office recommend that this might only involve playing the “what is Prevent” clip alongside one of the case studies contained on the DVD. However, the workbook then states that there is a minimum content threshold for the session to be considered a WRAP. The relationship between full WRAP, and the recommended session for management audiences, remains unclear: 10.1080/17539153.2018.1494123-UF0002

(Home Office undated: 2)

After the introduction of Prevent, the Workbook then instructs the trainer to proceed by choosing one of the case studies included on the DVD: either “Al Qaeda”-related radicalisation, or “Far Right”. Emphasis is placed on choosing the clip which “best suits your audience”, and ensuring that the second clip used later reflects a different ideological standpoint. Interestingly, the Facilitator’s Workbook then explicitly scripts the trainer in a fake “trust-building admission”, designed to win over their audience. The trainer is advised to reveal that they once found it hard to accept Prevent as a form of safeguarding, and how they overcame that perspective by “recognising that their conception of terrorism was too narrow”. This, the Workbook advises, will build trust that can later be exploited by “educating the audience” with the iceberg metaphor of terrorism and enable you to “assert your authority for the rest of the session”: 10.1080/17539153.2018.1494123-UF0003

(Home Office undated: 4).

The Facilitator’s Workbook clearly shows that the training package aims to deflect criticism that Prevent does not fit within NHS safeguarding protocols. The aim of the training is not to engage open discussion but to embed the duty to report radicalisation concerns to one’s line manager or safeguarding team.

Similarly, the internal narrative of the Facilitator’s Workbook instructs trainers to control the discussion of case studies from the DVD. Rather than allowing flippant suggestions of vulnerability indicators, or “shouting out”, the trainer is repeatedly instructed to focus the discussion on emotional states that might lead to radicalisation: 10.1080/17539153.2018.1494123-UF0004

(Home Office undated: 6)

Through the policing of discussion possibilities, and the threat of being put on the spot by the trainer, the audience are drilled to accept vague emotional and social states (family upheaval; low self-esteem; social exclusion) as precipitating factors in radicalisation. NHS staff are never trained in specific behavioural signs that indicate radicalisation, but rather instructed to adopt an attitude of suspicion towards emotional states.

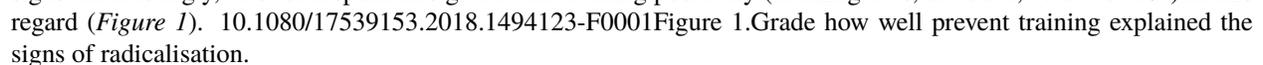

Given the multiple contexts in which family upheaval, low self-esteem and social exclusion are manifest, the indicators of radicalisation are presented in very broad terms within WRAP. So what scenarios do NHS professionals think they are supposed to report? The second stage of our study involved testing NHS staff attitudes towards the Prevent Training through a questionnaire, and asking what scenarios they consider to be reportable as a Prevent query.

Everyday NHS staff attitudes to the prevent duty and WRAP training

Our questionnaire was developed to capture data around each participant's pay grade, the NHS Trust/CCG for whom they work, their confidence in the WRAP training, the behaviours which they would consider reporting as a Prevent query and their perceptions of the social functions of the Prevent Duty (safeguarding or surveillance). The questionnaire was hosted on a University of Warwick server, gained ethical clearance from the University's Biomedical Sciences Research Ethics Committee, and was distributed to the workforces of each trust and CCG participating in the study by their Head of Safeguarding. In total, 329 NHS staff completed the questionnaire.

The uptake between participating Trusts and CCGs was imbalanced: 76% of responses were drawn from a mental health trust in a non-priority Prevent area of the Midlands; 15% came from an Acute Trust in a non-priority area; 3% came from CCG staff in a non-priority area and the remaining respondents either did not specify their employer or were employed in various other trusts across the UK. These "others" discovered the survey through publicisation by the MEND network (Muslim Engagement and Development). We did attempt to obtain research access to Trusts and CCGs in Prevent priority areas but we were not successful.

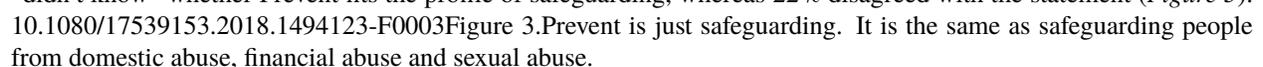

After obtaining contextual details about the participant's pay grade (to establish the degree of seniority they possess) and previous safeguarding training received, we asked respondents to grade how well WRAP (or other forms of Prevent training) explained the signs of radicalisation. We were interested to know how NHS staff felt about the training, given that our content analysis of WRAP demonstrated significant vagueness around the communication of radicalisation signs. Interestingly, 71% of respondents graded the training positively (marking it as, or above, "7 out of 10") in this regard (*Figure 1*). 10.1080/17539153.2018.1494123-F0001

We interpret this positive reaction to the training's communication of radicalisation indicators as also being an endorsement of radicalisation as the interruptible process which leads to terrorism. If a respondent was unconvinced by the radicalisation narrative put forth by government and media, then we argue that they would have marked the training as "bad" or "extremely bad" on this scale. Similarly, positive results were obtained when we asked participants to reflect on their comfort or discomfort with the material presented during their Prevent training. About 72% of respondents graded themselves as "comfortable" or "extremely comfortable" with the training materials (*Figure 2*). 10.1080/17539153.2018.1494123-F0002

At first glance, these findings tend to support the conclusions of a study which explores the roll-out of Prevent in education – specifically, that the majority of public sector respondents accept the core government narrative that Prevent should be understood as part of their safeguarding duties (Busher et al. 2017). However, when we directly asked health care professionals whether they understood the Prevent Duty to be a form of safeguarding, our results became far more ambiguous. Only 47% reported agreement with the statement that "Prevent is just safeguarding. It is the same as safeguarding people from domestic abuse, financial abuse and sexual abuse". Slightly over 30% of people "didn't know" whether Prevent fits the profile of safeguarding, whereas 22% disagreed with the statement (*Figure 3*). 10.1080/17539153.2018.1494123-F0003

This move towards ambiguity when directly questioned about Prevent's status as safeguarding is very interesting. When compared to similar research in the education sector (Busher et al. 2017), it suggests that the context of safeguarding in health affects respondents' attitudes towards the Duty. In health care, unlike education, safeguarding is associated with

protective intervention upon adults with “care and support needs”. Our results show that the majority of health care professionals (in our study) are accepting the Prevent Duty’s place in health and are comfortable with its requirements; however, this acceptance does not signify a similar acceptance that Prevent is safeguarding. Results for that question were significantly split, with less than 50% of respondents agreeing with the Department of Health’s framing of Prevent as safeguarding.

Our survey continued by exploring health care professionals’ attitudes towards various scenarios and whether they would constitute grounds for making a Prevent query. We developed these questions to probe deeper into the pedagogical effects of WRAP training. WRAP is quite vague on specific indicators of radicalisation and instead emphasises the wide-ranging emotional states which “make a person vulnerable” to extremism, like family upheaval, low self-esteem and social exclusion (Home Office undated: 6).

One of the most significant findings was that health care professionals’ confidence in their ability to spot radicalisation fell away when we introduced mildly complex scenarios. For example, we asked respondents to grade their confidence in distinguishing radicalisation from someone’s interest in Middle Eastern politics and wars. Only one in three respondents reported having any degree of confidence that they could make the distinction; 56% of participants stated that they “didn’t know” if they could distinguish interest in Middle Eastern politics and wars from radicalisation and 11% were explicitly unconfident to tell the difference (*Figure 4*). 10.1080/17539153.2018.1494123-F0004Figure 4. Grade how confident you feel to tell the difference between someone experiencing radicalisation and someone with an interest in middle eastern politics and wars.

This represents significant ambiguity about the character of radicalisation and its relationship to someone’s general interest in current and/or political affairs. This finding was also apparent when we asked health care professionals’ to consider whether someone’s possession of radical philosophy necessitated making a Prevent Duty query. We deliberately did not qualify what we meant by “radical Islamic/anarchist philosophy” in the survey, to see if respondents queried the definition. It is notoriously difficult to classify philosophy as radical or non-radical. However, health care professionals felt extremely confident to understand the difference, without specific training on the matter. Only one respondent (from a sample of 329) left comments on the survey about potential difficulties in distinguishing radical from non-radical philosophy.

Leaving aside the unspecified nature of radical philosophy, 70% of respondents were “somewhat likely” or “very likely” to make a Prevent referral about someone on the basis of radical philosophy possession. Only 22% were “unlikely” or “extremely unlikely” to make such a referral. 8% said that they “didn’t know” if they would make such a referral (*Figure 5*). 10.1080/17539153.2018.1494123-F0005Figure 5. If a patient or staff member possessed books about radical Islamic philosophers or radical anarchism, how likely is it that you would make a safeguarding query?.

We conclude from this that health care professionals feel inappropriately confident to judge whether philosophical books are radical, and that they are worryingly inclined to suspect radicalisation solely from the possession of radical philosophy. Academic research suggests that the philosophically and religiously literate are actually less susceptible to radicalisation (Coolsaet 2015; Roy 2011), and WRAP training makes no mention of philosophy books as an indicator of concern, so we believe that respondents are drawing their attitudes from popular culture rather than official training or academic research.

Our suspicion that respondents are drawing their understanding of radicalisation from popular culture is further confirmed by their association of beheading videos with signs of concern. Beheading videos are not mentioned in Prevent training, so the association of viewing such videos with radicalisation comes from popular media. When asked if they would make a Prevent query about someone who watched beheading videos, 74% of respondents said “yes” (without any reference to the “care and support needs” generally needed for a concern to become relevant to safeguarding procedures); 21% “didn’t know”; and only 5% said they wouldn’t make a Prevent referral on this basis (*Figure 6*). 10.1080/17539153.2018.1494123-F0006Figure 6. If you saw a patient or staff member watching video clips of beheadings, would you make a safeguarding query?.

Other criteria which health care staff strongly associated with radicalisation included hate speech about ethnicities, sexualities and other minority groups. An enormous 82% of respondents reported that they would be “very” or “somewhat” likely to make a Prevent query upon hearing such hate speech. Only 15% were “not likely” or “very unlikely” to make such a referral (*Figure 7*). While it is important to challenge hate speech in the workplace, the Prevent training does not specify that such illiberal opinion indicates radicalisation. However, upon the launch of the Prevent Duty, Ed-

education Secretary Nicky Morgan did identify vocal homophobia as a potential sign of radicalisation (BBC News 2015). [5]_10.1080/17539153.2018.1494123-F0007Figure 7.If a patient or staff member made hateful statements against an ethnicity, sexuality, or another minority group, how likely is it that you would make a safeguarding query?

However, interests in political events, possessing unpleasant opinions, or reading religious philosophy are not necessarily indications of radicalisation. NHS England has itself emphasised this in the most recent policy guidance for implementing the Prevent Duty: “Professionals should also have due regard to the Public Sector Equality Duty and be sensitive in their considerations. Outward expressions of faith or an interest in global or political events, or opinions that may seem unpleasant, in the absence of any other indicator of vulnerability or risk are not reason to make a referral to Channel. (NHS England 2017: 14)”

And yet, our study indicates that NHS health care professionals in the Midlands are inclined to draw such conclusions and to potentially make Prevent referrals on these grounds.

Conclusion

In the era of “after, after 9/11” in the UK, terrorism prevention has come to be framed as the extension of safeguarding. This framing of peer-to-peer counterterrorism surveillance as a banal measure of care has ensured the successful rollout of the Prevent Duty throughout the public sector. However, upon examination, there is an imperfect fit between Prevent and safeguarding in the health care sector (where Prevent is applied to people with formal care and support needs). We have raised concerns that the Prevent Duty deemphasises the formal care and support needs which legitimate protective intervention in an adult’s life, replacing them with vague (and circular) notions of vulnerability to extremist rhetoric. We also showed the various strategies health care professionals deploy to negotiate the tensions of Prevent in the NHS, including the highlighting of “grey areas” in normal safeguarding practice and the reframing of Prevent pathways as a way to redistribute care resources to those excluded by society.

Outside the realm of formal definitions and their interpretation by safeguarding experts, we also discussed the everyday experience of NHS staff with Prevent. After describing the content and pedagogy of the WRAP training product, we analysed the attitudes of 329 NHS staff to the Prevent Duty and their conceptions of radicalisation. Here, we found that the majority of those surveyed approved of the Duty, but were somewhat unconvinced of its status as genuine safeguarding. More concerning were the prominent trends within survey data which showed how staff associate radicalisation with philosophy possession and with hate speech. Illiberal attitudes and beliefs are being associated with radicalisation. Finally, we expressed grave concerns that only one in three respondents considered themselves confident to tell the difference between radicalisation and an interest in Middle Eastern wars and politics. Our survey results raise concerns that WRAP training generates a significant number of inappropriate referrals, some of which are removed from the system by the local safeguarding team, whereas others are deemed “misguided” by the Police Prevent Lead or Local Authority.

No figures exist for referrals which are deemed irrelevant or misguided by safeguarding teams or police. These fail to reach the Prevent Case Management system. But the figures for those referrals which do reach the Prevent Case Management system demonstrate a remarkably high attrition rate. Only 5% of formal Prevent referrals in 2016 and 2017 were allocated a deradicalisation mentor (Home Office 2017, 2018). Instead, the figures for 2017 show that 36% of formal referrals were abandoned,⁶ and 45% were given support from housing, education or health services. The remaining 19% were discussed at Channel Panel, of which a minority (5% of all formal referrals) received mentoring (Home Office 2018).

6

No figures exist for informal referrals which are removed from the pipeline by safeguarding teams or the initial police check. The real attribution rate for Prevent referrals is thus much higher.

Before the statutory duty was introduced in 2015, this figure for mentoring (and thus the formal accuracy of Prevent referrals) was much higher. About 20% of referrals went on to receive mentoring support from Channel. But since the introduction of the Prevent Duty, the total number of referrals has jumped from 500–1000 per year to 7631 in 2015/16 (Home Office 2017). As Thomas Martin argues, this enormous increase in referral numbers – and the drop to 5% receiving Channel mentoring – reflects the responsabilisation of the public sector for counter-radicalisation and the prospect of censure for non-compliance (Martin 2018). Legal obligation has increased the numbers of referrals but not their quality.

This remarkably high failure rate of the Prevent Duty to identify subjects who require deradicalisation mentoring also speaks to the impact of the safeguarding framing and economic austerity. The provision of normal safeguarding support (housing, mental health care, education) to 45% of Prevent referrals distracts attention from the small number of people deemed to actually require deradicalisation intervention. But why could not these outcomes be obtained through normal social service provision, rather than a counterterrorism pathway? The context of economic austerity in the United Kingdom has diminished the capacities of the public sector to respond to social needs, and we find that the Prevent Strategy is gradually filling the gap – while simultaneously enabling surveillance (Heath-Kelly 2017a).

Supplementary Material

Supplemental Material

Charlotte Heath-Kelly is an Associate Professor of Politics and International Studies at the University of Warwick. She has published one monograph on war-on-terror memorialisation, ‘Death and Security: Memory and Mortality at the Bombsite’ (Manchester University Press, 2016), and one monograph on ex-militant testimony and the post-conflict politics of memory in Southern Europe, ‘Politics of Violence: Militancy, International Politics, Killing in the Name’ (Routledge, 2013). Her research interests include counter-radicalisation policies, memorialisation and critical studies on terrorism.

Erzsebet Strausz is an Assistant Professor of Politics and International Studies at the University of Warwick. Her monograph, ‘Writing the Self and Transforming Knowledge in International Relations: Towards a Politics of Liminality’, was recently published by Routledge (2018). Her research interests include continental philosophy, aesthetics and critical pedagogy.

Abstract

Aims and method

Admissions of patients to secure forensic hospitals are often lengthy. Previous research has examined factors associated with prolonged admission, but studies analysing admission data at a single medium secure unit (MSU) over a prolonged time period are lacking. We compared admission data for all patients admitted to a MSU in England during the years 1985, 1995, 2005 and 2012.

Results

The median length of admission increased from 167 days in 1985 to 580 days in 2012, though not in the intervening cohorts. There have been changes in the discharge destination of patients, away from independent accommodation in the community towards further care or supported accommodation.

Clinical implications

The results suggest a change in the delivery of care. Further studies should be performed to assess whether the same trends exist at other sites. If these trends are also found elsewhere, this should trigger a specialty-wide discussion about admission length and its effects on bed availability.

Declaration of interest

None.

- *A retrospective study comparing the length of admission of medium secure unit patients admitted in the three decades since 1985*
 - *Materials and method*
 - *Results*
 - *Discussion*

Forensic hospitals, including high, medium and low secure services, have important roles in the treatment of psychiatric patients with a criminal history. Patients are admitted to these specialised services when it is felt they pose a risk to others, often due to a history of serious violence or other offending behaviours. The care of these patients, now more than ever, involves a multidisciplinary approach.^{1,2}

There is an expanding body of literature analysing the outcomes of admission to medium secure units (MSUs). These studies suggest that patients are at significant risk of readmission and, sadly, at significantly increased risk of death compared with the general population.³⁻⁶ Admissions to MSUs are now often lengthy,⁷⁻⁹ findings that were echoed by a recent study analysing length of stay data in high secure units across Europe.¹⁰ Factors identified as associated with a longer length of stay include a diagnosis of a psychotic disorder, detention under a restriction order – in particular, those under section 37/41 (Section 37 is a court-issued order that means the patient will be sent to hospital rather than prison, and Section 41 is a so-called ‘restriction order’ that is designed to reduce the risk to the general public) of the Mental Health Act 1983 (amended 2007) – poor treatment response and the seriousness of the index offence.⁸ However, data from single sites over a prolonged period of time are lacking.

The objective of our study was to observe trends in the diagnoses, length of stay and discharge of patients admitted to a local MSU in the years 1985, 1995, 2005 and 2012. We also considered what factors or changes in service provision over the study period had affected the length of admission and discharge locations of our medium secure service.

Materials and method

Ethical approval for this study was gained from the local clinical audit department as a service evaluation and did not require approval from the local Research Ethics Committee. Non-anonymised data required by the study were gathered by one author (D.T.), and anonymised data were subsequently analysed by the remaining authors.

All male and female patients admitted to the MSU during the years 1985, 1995, 2005 and 2012 were included in the study. The admission year of 2012 was chosen (rather than a later year) as it provided sufficient time from admission to the date of data collection for treatment courses and possible discharges to be assessed.

One hundred and seventy-nine patient records were included in this study. The date of data collection was 4 April 2016. No patients were excluded from the study. Electronic records were analysed for a variety of criteria, including age on admission, date of admission, date of discharge, diagnosis, source of admission, location of discharge and convictions on admission. In the 2012 cohort, four patients had not yet moved on from the MSU on the date of data collection. Their discharge date was recorded as the date of data collection to give a minimum median length of stay for the 2012 cohort. These patients were excluded from the analysis of discharge destination.

Data compilation and analysis were performed in Microsoft Excel (Microsoft Corporation, Redmond, WA, USA). Statistical analysis comparing length of admission of different cohorts was performed with one-way ANOVA using an internet-based calculator (<http://www.statisticslectures.com/calculators>).

Results

There were 47, 65, 37 and 30 patients admitted to the MSU in 1985, 1995, 2005 and 2012, respectively. The majority of these patients were diagnosed with paranoid schizophrenia. The primary diagnoses of patients included in the different cohorts are shown in *Table 1*. The average age of the patient population varied little over the time period included in our study. *Table 1* Diagnoses of patients admitted to our medium secure unit during 1985, 1995, 2005 and 2012

Diagnosis	1985	1995	2005	2012
Paranoid schizophrenia	32 (67%)	60 (92%)	26 (70%)	24 (80%)
Schizoaffective disorder	1 (2%)	0 (0%)	5 (14%)	3 (10%)
Mood disorder, manic episode	0 (0%)	0 (0%)	0 (0%)	1 (3%)
Bipolar disorder	7 (15%)	2 (3%)	2 (5%)	0 (0%)
Depressive episode	0 (0%)	1 (2%)	1 (3%)	1 (3%)
Recurrent depressive disorder	0 (0%)	0 (0%)	1 (3%)	0 (0%)
Affective mood disorder	0 (0%)	0 (0%)	0 (0%)	1 (3%)
Antisocial personality disorder	2 (4%)	0 (0%)	0 (0%)	0 (0%)
Emotionally unstable personality disorder	0 (0%)	0 (0%)	1 (3%)	0 (0%)
Organic	1 (2%)	1 (2%)	0 (0%)	0 (0%)
Undetermined	5 (10%)	1 (2%)	1 (3%)	0 (0%)

The median length of admission increased dramatically in our final cohort, from 167 days in 1985 to 580 days in 2012 (*Table 2*). According to a one-way ANOVA test, the median durations of the first and last cohorts, but not the intervening cohorts, differed significantly from one another ($P < 0.01$). *Table 2* Median duration of admission of patients in the medium secure unit in each of the years included in the study. The minimum and maximum duration of stay are also included

Year	1985	1995	2005	2012
Median duration of admission, days \pm s.d.	167 \pm 299	114 \pm 425	110 \pm 566	580 \pm 453
Minimum duration, days	11	33	13	33
Maximum duration, days	113	33	133	580

days166219522297Unknown^{a1}

The discharge location also showed changes over the study period (*Table 3*). Fewer patients were discharged directly to their home (54% in the 1985 cohort and 13% in the 2012 cohort), and more patients were discharged to other forms of psychiatric hospital, such as other MSUs (0% in 1985, 3% in 1995 and 2005, 17% in 2012) or to low secure units (10% in the 1985 cohort compared with 33% in the 2012 cohort). *Table 3* Discharge location of patients discharged from our medium secure unit (MSU) in the 1985, 1995, 2005 and 2012 admission cohorts

Discharge location	1985	1995	2005	2012
Police custody	0 (0%)	0 (0%)	0 (0%)	1 (3%)
Prison	5 (10%)	7 (11%)	6 (16%)	3 (10%)
Low secure psychiatric hospital	5 (10%)	4 (6%)	8 (22%)	10 (33%)
Other MSU	0 (0%)	2 (3%)	1 (3%)	5 (17%)
High secure psychiatric hospital	4 (8%)	5 (8%)	1 (3%)	1 (3%)
Remained in our MSU	0 (0%)	0 (0%)	0 (0%)	4 (13%)
Supported accommodation	8 (17%)	28 (43%)	10 (27%)	2 (7%)
Home	26 (54%)	17 (26%)	9 (24%)	4 (13%)
Died	0 (0%)	0 (0%)	2 (5%)	0 (0%)
No information	0 (0%)	2 (3%)	0 (0%)	0 (0%)

Discussion

The main finding of this study is that the duration of admission has increased significantly in the three decades since the initial cohort, with patients now remaining for a median of close to two years in the MSU. This correlates with a reduction in the number of new admissions per year, down from a peak of 65 in 1995 to 30 in 2012. The duration of admission appears to have been relatively stable in the decades prior to the 2012 cohort; only in this cohort did the length of admission increase significantly.

The four patients in the 2012 cohort still in the MSU on 1 April 2016 each had a length of stay of at least three years and three months. Their final length of admission may be significantly longer, and we cannot know by how much the median length of stay is an underestimate.

Recommendations regarding treatment of mentally disordered offenders were made in the Glancy and Butler reports.^{11,12} These reports informed the development of the regional secure units (now known as MSUs) to complement the existing special hospitals (now known as high secure hospitals). An upper limit for length of stay of two years in the regional secure units was suggested, but this is now regularly exceeded, as this study shows. The increasing length of stay in MSU has been criticised, being deemed ‘too long in very expensive and often unsuitable provision’ in a report by the Schizophrenia Commission.¹³

Despite the aforementioned criticism of the increasing length of stay and the undoubted expense of a medium secure bed, these services have the potential to save society a significant financial burden. One report suggests an average saving of over £600 000 per patient transferred from prison to psychiatric units.

Information regarding the length of stay at a single site has been investigated previously.^{14–17} However, no studies have investigated how the length of stay has changed over a prolonged period of time. Therefore, we feel that the data provided by our study add to the literature and provide a primary example of how length of admission has changed across a significant period of time. When comparisons were made with these early studies, the length of admission was comparable with that of the earliest cohort of our study. For example, in one paper published in 1981, the vast majority of patients were discharged in less than one year, which fits with the length of stay of the 1985 cohort in our study.¹⁴ It would be interesting to see modern studies in these other hospitals, to identify whether they have witnessed similar increases in length of stay.

One of the major changes since 1985 is in how patients are treated. In the older cohorts, the principal role of the forensic mental health service was to ensure that the symptoms of the patient’s mental illness had reduced or resolved;

1

The maximum duration is unknown for this cohort owing to ongoing admission.

offending risk related to other factors such as personality, substance misuse, social circumstances or life choices was often not felt to be the domain of mental health services. This underwent a significant change in the following decades. Mental health services now provide far broader care to address these other aspects, as evidenced by the essential roles of the multidisciplinary team^{1,2} and the adoption of recovery principles. These important changes are time and labour intensive, and as such may be a contributing factor to the increased length of stay.

In the analysis of the discharge locations and admission sources of these patient cohorts, certain patterns emerged. Far fewer patients are discharged directly to their home. Our patients are often discharged to long-term MSUs, lower security psychiatric units or supported accommodation. Notably, therefore, despite the increasing length of stay, fewer patients are discharged directly into independent accommodation in the community. Numerous studies have provided detailed analysis of the follow-up of patients discharged from forensic psychiatry units.³⁻⁶ Given the risks inherent in these patients returning to day-to-day life, further care in supported environments may reduce risk to others at a population level. Responses to serious untoward incidents have changed over time^{18,19} and may now be more likely to lead to greater restrictions for patients. This in turn may contribute to the increasing lengths of stay described above.

There are limitations to our study. As our cohort was from a single MSU, the general applicability of our findings may be limited. It is recommended that further research be undertaken to examine whether the trends identified here are reproduced in other MSUs.

1.5.98 'Prescribing' psychotropic medication to our rivers and estuaries

Alex T. Ford Helena Herrera

Correspondence

Alex T. Ford (alex.ford@port.ac.uk)

date

2019-8

Abstract

Summary

The influence of pharmaceuticals on the environment is an increasing concern among environmental toxicologists. It is known that their growing use is leading to detectable levels in wastewater, conceivably causing harm to aquatic ecosystems. Psychotropic medication is one such group of substances, particularly affecting high-income countries. While these drugs have a clear place in therapy, there is debate around the risk/benefit ratio in patients with mild mental health problems. Therefore, it is necessary to evaluate the wider implications as risks could extend beyond the individual to non-target organisms, particularly those in rivers and estuaries.

Psychotropic drug use patterns

Adequate psychiatric service provision is central to health and quality of life, and the use of psychotropic medication can be invaluable in the treatment and management of mental health problems. The uses of these drugs have been evident since their introduction, and they have a well-established place in clinical practice. However, within the medical fields, there has been a debate in recent years about the over-reliance on drugs such as antidepressants, anti-anxiety drugs and antipsychotics.¹⁻⁴ Data from a number of countries have indicated rapid rises in prescriptions, with as many as 10% of the population taking such medications, particularly in high-income countries such as the UK.³ Within the field of environmental toxicology, the effects of these drugs have recently started to generate some interest too.

Pharmaceuticals as emergent pollutants

Currently, pharmaceuticals mainly enter the environment through wastewater after their excretion, either in their original form or as metabolites. This has long been known,⁵⁻⁶ with the first reports of these substances entering the environment dating back to the 1960s.⁷ However, sewage treatment plant processes do not adequately remove pharmaceuticals. With the sheer number of different medications being prescribed and the inability of even quite modern sewage treatment processes to fully break them down, it could be argued that our aquatic life is bathing in a soup of multiple drugs.

Toxicity levels of pharmaceuticals in the environment do not necessarily relate to high concentrations, but to their constant low-level discharge, persistence in ecosystems and highly active biological functions. In this way, pharmaceuticals that are found in relatively low concentrations could be extremely potent and very persistent, and able to significantly affect non-target organisms. For example, low concentrations of antidepressants and other psychotropic drugs can cause disruption to the normal functioning of aquatic organisms.⁸

The concept of environmental relevance, therefore, becomes important. For example, selective serotonin reuptake inhibitors, selective serotonin–noradrenaline reuptake inhibitors, serotonin antagonist reuptake inhibitors, tricyclic antidepressants and benzodiazepines have all been detected in urbanised waterways, mostly in the ng/L range, but also in concentrations up to g/L.⁷ What is particularly starting to interest scientists is that these antidepressants can cause disruption to the normal functioning of aquatic life in laboratory experiments at low concentrations. The uptake of these compounds appears to be highly dependent on the organism's mode of feeding.⁹ In terms of presence in the environment, for example, diazepam has been found in all matrices – wastewater, surface, ground and drinking water, soils, bio-solids and tissues¹⁰ – and in concentrations as high as 10 ng/L in rivers and potable water.¹¹

Pharmaceuticals are not present in isolation in the environment, and the widespread high use of a wide variety of drugs leads to multiple substances being found together, in a situation where synergistic or antagonistic effects can occur.⁷ In addition, exposure of some non-target organisms to these substances takes place for the entirety of their life cycle.¹²

Currently, pharmaceuticals and their active metabolites are globally considered to be an important emergent group of pollutants that are intrinsically bioactive, causing adverse drug reactions and previously undocumented effects on non-target organisms.⁷

The effects of psychotropic drugs on the aquatic environment

The notion that drugs prescribed to humans might be affecting wildlife first came to light in the 1990s, when scientists highlighted that natural and synthetic oestrogens from contraceptive pills and hormone replacement therapy in wastewater effluent could feminise fish at very low concentrations.¹³ Growing incidences of reproductive and other abnormalities developed into an interdisciplinary field, linking human and environmental toxicology to the study of endocrine-disrupting chemicals. As improved analytical techniques become available and interest in this field increases, the influence of pharmaceuticals on the environment is increasingly being documented. Identified cases where pharmaceuticals are causing detrimental effects are therefore becoming more common. For example, the veterinary use of the non-steroidal anti-inflammatory drug diclofenac has recently been linked to widespread (over 90%) declines in vulture species in some countries¹⁴ and serves as a reminder that, sometimes, the effects of biologically active drugs can have far-reaching consequences.

While the potential for pharmaceuticals to lead to toxicity in non-target organisms exists across all therapeutic groups, the case of psychotropic medication is particularly concerning. This is because these drugs, which are among the most commonly detected in aquatic environments, affect not only the central nervous system but are also linked with reproduction, growth and immune functions.^{13,15} In this way, psychotropic drugs such as antidepressants modulate neurotransmitters serotonin, dopamine and noradrenaline, having multiple physiological effects in humans such as weight gain, fatigue and sexual dysfunction.

The ability of psychotropic medication to disrupt the normal biological systems of abundant and ecologically important groups of non-target organisms in aquatic environments is extensive. Since reuptake transporters and receptors evolved in invertebrates such as molluscs and Crustacea, release of neurohormones would be expected to have multiple biological effects on these invertebrates, in addition to vertebrates such as fishes. Therefore, any compounds in the environment at a sufficient concentration able to alter neurohormones have the capacity to affect a wide range of biological processes,¹⁶ leading to salient effects on critical life cycle events. Processes affected include reproduction, growth, maturation, metabolism, immunity, feeding, locomotion, colour physiology and behaviour. Examples of adverse effects that have been observed include photo- and geotactic behaviour, abnormal activity patterns, aggressive behaviour, developmental and metabolic abnormalities, and reproductive abnormalities. Interestingly, some of these effects are only exhibited at low concentrations, rather than being dose dependent as may have been expected.¹⁶

For example, Guler and Ford¹⁷ studied the effects of a variety of pharmaceuticals and the hormone serotonin on the preference for light versus dark choice chambers in amphipods. They reported a significant preference for light and response to gravity in terms of position in amphipods exposed to fluoxetine and serotonin. The dose response was linear for serotonin, whereas for fluoxetine the response was not dose dependent and the behaviour was induced only at lower concentrations (10–100 ng/L). Similarly, when crabs were injected with serotonin, photonegative behaviour was reduced and they spent substantially less time hidden.¹⁶ This would have consequences for aquatic life, as preference to light has been demonstrated to increase the likelihood of predation.

Other studies found that while 1 ng/L fluoxetine influenced learning in the cuttlefish, 100 ng/L did not, but did significantly influence the retention of memory. Effects observed include fluoxetine influencing on learning and memory in cuttlefishes at concentrations between 1 and 100 ng/L.¹⁸ Swimming activity has been observed to be altered in amphipod crustaceans at levels as low as 1–100 ng/L,¹⁹ and gonadal aberrations in zebra mussels have been induced in ranges as low as 20 ng/L. Moreover, fluvoxamine was found to induce egg deposition in zebra mussels at ~318 ng/L,²⁰ and exposure to venlafaxine has caused foot detachment (an inability to cling to the side of a tank) at levels as low as 313 pg/L and 31.3 ng/L.^{21,22} Further effects on reproductive output in terms of frequency of broods, offspring production, gamete release and gene expression have been demonstrated in the ng/L concentrations.

Induction of hyperglycaemic responses in a variety of crustaceans has also been observed. The regulation of blood glucose through crustacean hyperglycaemic hormone is under the control of a variety of neurohormones.²³ There have also been reports that dopamine, serotonin, noradrenaline and adrenaline are all effective in inducing hyperglycaemic

responses in a variety of crustaceans.²⁴ The release of crustacean hyperglycaemic hormone has been shown to be promoted by injection with serotonin in a variety of species.²³ Interestingly, studies with crabs have shown that both serotonin and fluoxetine can stimulate crustacean hyperglycaemic hormone and suppress moulting hormones.²⁵ In terms of pigmentation, serotonin has been shown to influence red pigment-dispersing hormone, while dopamine influences red and black pigment-concentrating hormones in shrimp. It has also been found that noradrenaline triggers release of black pigment-dispersing hormone.²³ Therefore, any drugs with the capability to modulate these neurohormones can conceivably interfere with the camouflage abilities of aquatic invertebrates.

Perhaps it is not surprising that fish exposed to antidepressants or antianxiety medication display altered behaviours when one considers how evolutionarily conserved the nervous system is among the vertebrates. Furthermore, because of this conserved ancestry, fish are now more commonly used in drug discovery, with behavioural tests commonly used in rats and mice being translated to fish models.²⁶⁻²⁷ For example, the novel tank test measures the 'normal' reluctance of a fish to venture in the open surroundings of a new tank, which can be altered by antianxiety medication.²⁸⁻²⁹ Other studies within the field of environmental toxicology have observed a wide range of altered behaviours in fish, including aggression towards conspecifics,³⁰⁻³¹ reproduction,³²⁻³³ predator avoidance³⁴ and feeding.³⁵

A body of evidence is therefore building which suggests that antidepressants in particular, at concentrations found in surface, waste and ground waters, can cause a wide variety of effects. Whether these are occurring in the field downstream of wastewater treatment plants (WWTPs) represents an important and challenging question to address, as the ability to measure abnormal behaviour *in situ* remains a logistical and technological challenge. Moreover, while the underlying role of neurotransmitters has been described in vertebrates, there is considerable paucity of data on their role in invertebrates.¹⁶ The non-monotonic dose responses shown by some drugs,¹⁷⁻¹⁸⁻³⁶⁻³⁸ for which pharmacological effects are not dose dependent and a response is triggered by a low concentration, with no response to higher concentrations, poses questions which are difficult to ignore.³⁹ While some studies have been conducted on the toxicology of antidepressants such as fluoxetine,¹⁶ these are few and far between. Given the evidence on the influence of pharmaceuticals, particularly psychotropic drugs, on the environment, it can be argued that greater emphasis should be placed on how they may be affecting aquatic life.

The solutions

The solutions to these problems, as might be expected, are multifactorial and somewhat influenced by historical decisions. For example, some WWTPs may have historically serviced small towns and villages which later grew in population into large towns and cities. If these WWTPs historically discarded their effluent into small (low flow) rivers, then the effluent to river water ratios could change over time. Changes in water usage upstream, for example, water extraction for farming, could further confound the problem. Advanced treatment at wastewater treatment facilities would reduce many of the potentially harmful pharmaceutical waste products and their breakdown metabolites. Where technological improvements of sewage treatment have been implemented, there have been reductions in intersex (feminised) fish caused by steroid oestrogens and their mimics, as well as improvements in river biodiversity.⁴⁰⁻⁴¹ These improvements, however, are costly. Owen and Jobling (2012)⁴² estimated that upgrading all the WWTPs in England and Wales to comply with EU regulation to bring synthetic oestrogens below an average of 0.035 pg/L ethinylestradiol per annum would cost an estimated £26 billion.

Another solution to this complex problem is to change behaviours whereby people would traditionally flush their unwanted medications down the toilet or dispose of them in the bin. 'Take back' programmes vary in their popularity across Europe, but serve as one means to prevent unwanted medication entering aquatic systems directly following wastewater treatment or indirectly through underground seepage from landfills. The question of green pharmacy has also been raised, whereby the pharmaceutical industry considers the cradle-to-grave approach of their products and designs drugs which readily break down. However, this is extremely difficult to achieve for most drugs, owing to the need to produce pharmacologically active pharmaceuticals in suitable formulations.⁴³

Reflections for policy and practice

Mental healthcare services are provided through complex systems, which are generally based around the use of medication, with training in psychiatry covering vast areas to enable the provision of quality care to patients. However, there is no inclusion of aspects of pollution and the effects of psychotropic medication, and how this could affect aquatic environments. Could educating the medical profession help improve the utility of take back programmes and patient behaviour with regard to drug waste? These substances are not currently covered by existing regulations with regards to sewage management, and analytical methods for detection are just now becoming available. Adequate resources for the diagnosis and management of mental health conditions could help reduce the need for medication and the documented toxic effects of the use of these drugs on non-target organisms. ‘Prescribing’ psychotropic medication for our rivers and estuaries poses a potential risk to aquatic life. Further knowledge and education on adequate therapeutic choices, and improved resources for diagnosis, could support prescribers and practitioners to make environmentally sensible choices, based on evidence of efficacy and safety.⁴⁴

1.5.99 Reforming care without bureaucracy

: Commentary on... Care Programme Approach

Peter Tyrer

Correspondence

Peter Tyrer (p.tyrer@imperial.ac.uk)¹

date

2019-6

Abstract

The Care Programme Approach was a valiant attempt to improve the aftercare of people with severe mental illness after discharge from hospital. It was introduced as a response to a scandal, not an advance in knowledge, and has always suffered by being a reaction to events rather than a trailblazer for the future. It may have dragged the worst of care upwards, but at the expense of creating a bureaucratic monstrosity that has hindered good practice by excessive attention to risk, and vastly

The article by David Kingdon,¹ who is over-modest about his own role in creating the Care Programme Approach (CPA) for mental health services, is a welcome suggestion to a system that needs changing. To understand the CPA it is necessary to understand the full history behind it. As David Kingdon indicates, it came about not following new research evidence but – like most reforms in the National Health Service (NHS) – through scandal, and all should be sceptical about its benefits under these circumstances until independent evidence becomes available.

So picture the situation in 1988, when the Spokes Inquiry² made recommendations following the murder of a social worker by an ex-patient in her offices in Bexley. The patient, Sharon Campbell, had apparently been discharged without adequate supervision and the report sent a shudder through the corridors of the NHS hierarchy and the Royal College of Psychiatrists. How many other potentially dangerous patients were similarly being treated, or even untreated, as a consequence of the decision to close hospitals and move towards community care?

The Spokes Inquiry

The Spokes Inquiry² made appropriate and reasonable recommendations that could be summarised as ‘when psychiatric patients, particularly those with severe mental illness, are discharged from hospital there needs to be an after-care plan in place for both health and social services’. The implementation of these plans was not specified exactly and the Royal College of Psychiatrists was asked to create such an aftercare policy. There already was a system called case management, which had devotees, but most of the evidence was imported unwisely from the USA where the notion of universal care was anathema to the land of the free market.

So the CPA was introduced as a diluted form of case management appropriate for the NHS. Note the wording. It was not a mandatory requirement for practitioners to do this or that, but a gentle nudge to ensure a coordinated system of care, an approach rather than a directive. It certainly worked to a point; consultants could no longer discharge patients to follow-up by the general practitioner without some sort of care plan in place. The CPA was introduced so gently that its implementation was almost imperceptible, allowing a randomised trial to take place using the old system of care as the comparator. The results showed that many fewer patients were lost to follow-up, but readmissions were much more common once good follow-up was in place.³

Early years of the CPA

The notion of care plans – and the need for a single person, the care coordinator, to synthesise care with the parties involved – is a sensible one and many health professionals felt they were doing it already. It was held together successfully at first through the efficiency and cooperation of community psychiatric teams, whose contribution and value, including a reduction in deaths,⁴ has been somewhat underestimated as these teams have never had the glamour of assertive outreach and crisis resolution teams. Where it began to fail was not a fault of the approach but a lack of resources to implement it properly, so it was never applied universally. It is very odd that no organisation within the healthcare system made any attempt to cost the full implementation of the CPA. What may also not have been anticipated was the rapid growth of managers once cost pressures increased,⁵ and whose attempts to improve integration of care were often resented by practitioners as undue interference.⁶

Thus, 15 years after its introduction, Simpson *et al*⁷ concluded after a careful review in 2003: “‘The CPA was a flawed policy introduced insensitively into an inhospitable environment. It was destined to fail and after more than a decade remains ineffectively implemented. Changes introduced recently may have contradictory influences on the ability of services to provide effective case management but remain to be evaluated.’”⁷

Standard and Enhanced CPA

In 2008 the Enhanced CPA was subsequently introduced for people ‘who need: multi-agency support; active engagement; intense intervention; support with dual diagnoses; and who are at higher risk’.⁸ It was also emphasised that acceptance for enhanced care ‘should *not* be used as a “gateway” to social services or as a “badge” of entitlement’⁸ to other services. But of course it was used that way, as it was bound to be; thus it merely added another layer of bureaucracy to an over-burdened system.

The consequence has been an increasing transfer of face-to-face clinical care to a paper-based cynical affair that does no credit to anybody, least of all the patients, who all too frequently see a technocrat facing a desk instead of a sympathetic carer across the room. The tick box has now become the kick box, an exercise to get a patient off one team’s case load and on to another, promoting discontinuity and disruption of care.

What is the solution?

There are many lessons to be learned about the CPA. First, it has to be accepted by all health professionals, politicians and society at large that suicides and violent deaths in the community perpetrated by psychiatric patients can never be prevented altogether. Putting this another way: extreme statistical outliers should not determine policy. Second, and probably most importantly, good psychiatric and social care is flexible and collaborative and can never be prescribed by statute. I recently discharged myself from hospital prematurely against medical advice. But I insisted the record was not recorded as ‘against advice’ by writing in detail in the hospital notes why it was better for me to leave hospital as my aftercare was well arranged and would lead to cost savings. (They accepted this and were probably pleased to see me go.)

Third, allow practitioners and patients, working together, to do what is best and not to be too risk averse. Kingdon recommends that we should develop ‘more individualised and sophisticated pathway-based systems’.¹ This is in itself a telling criticism of the CPA. Once we have such individualised systems, we leave the directives behind; we use a combination of skills and resources to produce a plan that is, more often than not, unique and cannot be classified. Such plans can never be truly evidence based.

So, in summary, the CPA needs reform by becoming simpler rather than more complicated. It is there to prevent poor care, not to interfere with care that is already competent or good. Its wording should be chosen with care to allow good clinicians to be reinforced and praised in their tasks, for nervous ones to be encouraged and for those who are under par to receive a gentle rap on the knuckles to improve their game. It can also be a great deal shorter.

Peter Tyrer is Emeritus Professor of Psychiatry at Imperial College, London, UK.

1.6 2017

1.6.1 The access and waiting-time standard for first-episode psychosis: an opportunity for identification and treatment of psychosis risk states?

Richard Whale Andrew Thompson Rick Fraser

Correspondence

Richard Whale

(richard.whale@brighton.ac.uk)¹

date

2017-2

Abstract

Expansion of early intervention services to identify and clinically manage at-risk mental state for psychosis has been recently commissioned by NHS England. Although this is a welcome development for preventive psychiatry, further clarity is required on thresholds for definition of such risk states and their ability to predict subsequent outcomes. Intervention studies for these risk states have demonstrated that a variety of interventions, including those with fewer adverse effects than antipsychotic medication, may potentially be effective but they should be interpreted with caution.

in vulnerable individuals, as originally developed in 1994 by the Personal Assistance and Crisis Evaluation clinic in Melbourne.² There is an expectation that early intervention in psychosis services will now also offer interventions for at-risk mental state for psychosis (ARMS), based on our evolving understanding of best practice in this area.

This move is exciting for a number of reasons. It represents a commitment from the Government to support mental health service development and reform, especially preventive approaches, at a time when many services are experiencing cuts. Cost-effectiveness of ARMS services has been demonstrated.³ Second, as a treatment paradigm the preventive strategy represents a possibility that we can alter the trajectory of a potentially serious condition and improve outcomes in all domains, including symptoms and functioning. Third, we may be able to use, at an earlier stage of illness, more benign treatments that are potentially less costly, less stigmatising and better tolerated.² This preventive model also represents an opportunity to broaden treatment paradigms within mental health, not just for psychosis but for other disorders, fitting perfectly with another current health development strategy – low-stigma, accessible and responsive youth mental health services. Debate continues as to whether such services are appropriately placed within established early intervention for psychosis or whether new, dedicated teams with a more public health emphasis should be created. However, existing services have expertise in both defining first-episode psychosis thresholds and offering relevant clinical support packages for both ARMS and first-episode psychosis.⁴

The criteria commonly used in the UK for ARMS depend on the presenting clinical features, relative functional impairment and help-seeking.² Consistent quantification of distress relating to these features is currently lacking. It also remains unclear how these clinical risk features differ from more widespread psychotic phenomena in the general population. Psychotic experiences in non-help-seeking populations appear relatively common, affecting about 5%,⁵ and higher in child and adolescent samples;⁶ there is apparent sharing of aetiological risk factors with schizophrenia. Clinical outcomes of this non-help-seeking group are unknown. Psychosis transition threshold is commonly defined by three Positive and Negative Syndrome Scale items (delusions, hallucinations or conceptual disorganisation) achieving adequate severity for at least 7 days,⁷ but such psychosis thresholds are not without controversy.⁸ The large majority of those identified as ARMS do not cross this severity threshold within 3 years of follow-up, although many remain functionally impaired or develop other disorders.² Whether other transition criteria, or modifications of existing criteria, are better able to predict longer-term outcome remains to be established. The reliability of identifying such thresholds in clinical practice is also less than in research settings,⁹ despite using widely available tools.² This is further complicated by concurrent substance misuse, common in such clinical populations. However, the definition and adoption of such thresholds is clearly necessary to educate clinicians, decide when to appropriately intervene and support research. The complexity of the psychosis sub-syndrome groups (including individuals with a family history of psychotic illness, those with schizotypal disorder or the attenuated psychosis syndrome, those with brief limited intermittent notable severity psychotic episodes and those help-seeking or not) and their undetermined probable outcomes may lead to services primarily adopting a more discrete threshold for inception, such as the DSM-5 research-appendix-defined attenuated psychosis syndrome, which has marked clinical overlap with ARMS-defined populations.⁹

Without clear diagnostic robustness of a condition, and with a wide variation in clinical outcome, interpretation of intervention studies is problematic. Initially, randomised studies of diverse interventions for operationally defined ARMS (termed ultra high risk for psychosis) seemed to show similar beneficial effects *v.* control. Reviews pooling outcomes of these studies clearly advocated intervention.^{7,10} More recent randomised studies have demonstrated less clear benefits over control than earlier studies, as is often seen in health research (arguably ‘active’ controls were used in many of these studies). Primary intervention recommendations of supportive counselling/case management for this clinical group have emerged, as previously used as a control intervention. Several factors will need to be considered, with future investigations including previous low sample size due to recruitment problems, use of robust and consistent thresholds for group inclusion, and transition to psychosis to reduce heterogeneity of outcome, consistent inclusion of functional outcomes, translation of findings to usual clinical care (away from research clinics), ensuring timely publication of results and the importance of replication of existing findings.

While considerable progress has been made in this area, we remain at the early stages of defining a risk syndrome for psychosis. The currently adopted clinical threshold for ARMS seems to be a valid construct to identify clinical need but the heterogeneity of subsequent clinical outcomes is wide. Specific interventions for ARMS are unclear, aside from those for commonly identified comorbidities (such as anxiety, depression and substance misuse). Intervention studies to date highlight the importance of methodological rigour and consistency of diagnostic thresholds used, to which end the DSM-5 attenuated psychosis syndrome may be a positive step.⁹ Biological models for psychosis risk need replication, clinical validation and combining with clinical markers in larger, longitudinal studies to enhance risk

determination.^{2,11,12}

Despite these caveats, this field of study represents an important advance in the development of preventive psychiatry. The current move to incorporate earlier psychosis states in more widespread clinical services, with appropriate threshold definition and outcome monitoring, may also have important societal impact.

1.6.2 Plans, hopes and ideas for mental health

John R. Ashton Correspondence c/o BJPsych Bulletin (pb@repsych.ac.uk)

date

2017-2

Abstract

Mental health and the failings of the mental health services are in the spotlight as never before. Nowhere is this more apparent than in the often dire situation with regard to child and adolescent mental health. At the same time, there is a renewed interest in the scope for prevention of mental illness and distress, and in population approaches to mental well-being. It may come as a surprise to some that others have given such serious consideration to strategic approaches to public mental health as long ago as the 1950s. It appears that such consideration was squeezed out by the dominant concerns of serious and enduring mental illness and a prevailing biological view of psychiatry. The time is right to engage with this agenda in recognition of the importance of public mental health, not only for the individual and for families, but also for society as a whole and for the economy. The publication of a review of the subject by the Faculty of Public Health and the Mental Health Foundation is to be commended. Let us make sure it leads to action.

Contents

- *Plans, hopes and ideas for mental health*

The recent announcement by UK Prime Minister David Cameron of a new initiative for mental health, with a particular emphasis on parenting classes,¹ is most welcome. It comes at the end of a year in which there has been an increasing concern for the state of the nation's mental health, with a flurry of documents and reports, a campaign led by *The Times* newspaper² and an increasing demand for parity of resourcing between mental and physical health. Interestingly, some of the pressure to do something specifically about child and adolescent mental health is coming from the independent schools sector. The schools have been expressing increasing concern about the mental well-being of the young people in their care, faced by an apparently steady increase in the incidence of distress manifested by levels of general anxiety and depression, and specifically the levels of eating disorder, self-harm and other behavioural manifestations. Not for the first time in public health, something that has long been a problem for the most disadvantaged in society is being taken seriously once it becomes an issue for the privileged. Nor should we ignore the opportunity presented for progress by the mobilisation of enlightened self-interest by those in positions of power and influence. After all, in Victorian times, the fact that cholera knew no social boundaries led to sanitary reform which was of benefit to rich and poor alike. More recently, once it became apparent that HIV/AIDS was not only a disease of stigmatised minorities, the research dollars rolled in.

As a public health physician who began his career as a psychiatrist and family doctor and is finishing as President of the UK's Faculty of Public Health, I find particular poignancy in returning to the theme of public mental health for my swansong year, a theme which I have chosen for the Faculty to focus on in 2015–2016. I appreciate and welcome this opportunity to share some thoughts with clinical colleagues in psychiatry based on 40 years of trying to make sense of some of the questions raised within a public health paradigm.

My journey from psychiatric registrar in Newcastle in the 1970s offers some perspective. As a student I was one of those medics whose interests spanned the humanities as well as the sciences. History and politics were always as interesting to me as biology, and when I came across the prospectus for the public health masters course at the London School of Hygiene & Tropical Medicine sometime in third year, it was clear to me that sooner or later I would be signing up. For the next 10 years I would religiously send for the latest edition. Fortunately, my interest was nurtured and kept alive by the remarkable social orientation of the Newcastle course, not just in family and community medicine but also in such mainstream clinical areas as paediatrics, psychiatry and obstetrics. The school was imbued with the spirit not just of the pioneering, community-oriented paediatrician Sir James Spence, but also that of Aberdonian obstetrician Dugald Baird through his Newcastle disciples. The strong social and community base was reinforced by a series of Deans of Medicine, who, while hard-nosed neurologists and endocrinologists themselves, supported the work of those such as Donald Irvine, who was centrally involved in establishing the country's first general practice training programme and later oversaw the General Medical Council. When I signed up for the psychiatric training rotation under the formidable Sir Martin Roth, amazingly comprehensive and intellectually stimulating as it turned out to be with placements in all aspects of mental health services, I found myself frustrated at the failure of those services to focus upstream to prevention and the promotion of mental health.

While as a registrar in the heady years of the challenges posed to orthodox practice by the likes of R.D. Laing and Thomas Szasz, I was exposed to the whole spectrum of ideas, from Freud and Jung to Kraepelin, Sargent and Eliot Slater. Although we had opportunities to cut our teeth on individual, group and marital therapy, the broader public health agenda remained elusive. I came to the conclusion that what was on offer was all too little and too late, and as soon as I had finished my training I moved into general practice in the hope of finding more fertile soil for prevention.

My next move took me to Southampton, where the pioneering dean of the new medical school, Donald Acheson, had created an exciting opportunity which seemed tailor-made for somebody like myself. In a university-run health centre in the local community, based on lines recommended by the celebrated Birmingham professor of public health Thomas McKeown, there were to be specialoid general practitioners – GP paediatricians, GP mediatrians (caring for grown-ups), GP geriatrians and a GP psychiatrist (me). Part of the time we would teach medical students, and the remainder was spent providing a combination of general practice, including out-of-hours services, and specialist expertise to the practice patients as well as supporting each other. As far as possible, we would look after the population of the Aldermoor estate (a public health notion), and consume our own smoke.

It was a stimulating time, but there were problems reconciling the competing claims of medical school and service as well as staffing issues. Southampton was within spitting distance of the London School of Hygiene & Tropical Medicine, so it was time to make the logical step into public health, and it was quite clear that I had made the right move. Validation came from, among others, John Wing and Julian Leff from the Maudsley, who also taught social psychiatry at the school, from visiting teachers from the London School of Economics (LSE), such as Bryan Abel Smith, who confirmed what students suspected, namely that 'public health is the political wing of medicine' and that 'Parliament is the dispensary of public health', and others that placed population health at the centre. It was one of those group learning experiences which stays with you down the ensuing years as a highlight and a transformational experience. Yet there was something missing.

In those days students on the public health masters courses at the School had the enormous privilege of a 2-year course, 1 year spent in the classroom and 1 year on a dissertation. The dissertation was a kind of blank cheque that enabled you to pursue something of special interest that would hopefully be built on in future years. And this is where my problem reasserted itself. What would be a suitable dissertation that majored on prevention and mental public health? I was already a member of the social psychiatry section of the Royal College of Psychiatrists and I took advice from as many people as I could find, including Sir Martin Roth. I drew a blank. The nearest anybody could get was early diagnosis and treatment in the community, what I now knew to be secondary prevention in public health, tertiary prevention being rehabilitation. Primary prevention was nowhere to be found.

And so in the end I hit on planned parenthood, something much better understood in a holistic sense in global health

circles, and I carried out a series of studies into family planning and abortion at the population level of Wessex. In my subsequent career as a public health academic, as a regional and county director of public health, as an adviser to the World Health Organization on the Healthy Cities project, and most recently, as President of The UK's Faculty of Public Health, I have reconciled my angst that as a generalist with a population and environmental focus, all my work has ultimately to be judged by its impact on mental health and well-being. So what have I learned and what observations can I make faced with the promise that finally mental health is to be taken seriously?

One of the problems with mental health, as with physical health, is that the dominant approach is to work backwards, from a focus on treatment towards an interest in prevention. The exception is when there is an emergency, a disaster or a war, when needs must apply a public health population-based triage model if harm is to be minimised.

In the 1980s I attended a short course at the School for would-be volunteers to work in refugee camps in the Horn of Africa. One message stays with me almost 40 years later. If a small group of volunteers (doctors, nurses, engineers and so on) is deployed into a camp of 12 000 women and children in dire circumstances (the men are likely to be either already dead or off fighting somewhere), the first thing to do is not to start treating sick patients. Rather, it is to carry out a quick census of who is there and what skills they have, and to set about mobilising the expertise and supporting it.

This is not our traditional medical model, based as it is on putting up your plate outside a consulting room and offering services to those who can afford to pay, with no concern for the denominator of those with unmet need. Take the example of child and adolescent psychiatry. The large community surveys such as those on the Isle of Wight and in South London found that around 10% of children and adolescents suffer from such a level of emotional or conduct disorder as to require specialist help.³ In a borough of 500 000 population (about 70 000 children and adolescents), this will equate to about 7000 potential patients. In a fortunate district perhaps, optimistically, 1000 of those could be adequately managed by a typical child and adolescent mental health service (CAMHS). No district will ever have that kind of establishment. At the risk of being written off as a loony baby boomer, I would quote Mao Zedong: who is said to have claimed that 'If the practice doesn't work, the theory is wrong'. We are starting at the wrong end of the telescope or focusing on the wrong part of the pyramid of needs. So what would public health say and what is to be done?

In 1961 Gerald Caplan published a book titled *An Approach to Community Mental Health*. Caplan was educated at Manchester medical school and worked at the Tavistock Institute in London and the Hadassah Centre in Jerusalem before moving to the USA, where his work was hugely influential, not least with the programme of community mental health centres under President Kennedy. I came across his book in the 1980s and have carried it round with me ever since.

Reading it again now, it is as relevant and fresh today as it was when it was written, and it is a mystery to me why it has not been a blueprint for how we have approached mental health during the intervening years. Perhaps it is because it includes a (very sensible) chapter on ego psychology, when British psychiatry has for so long been under the shadow of organic theorists and psychopharmacology? In essence, what Caplan proposes is a comprehensive community approach to preventive psychiatry and the provision of services which builds on individual and community assets including those of what he calls 'caretaking agents' and those in special positions in everyday life. He includes in this not just doctors and nurses but clergy, teachers, policemen and so on, and advocates a system built on up-skilling those in a position to play a protective and supportive role in everyday life as a first line.

Caplan describes administrative actions that can protect and support good mental health as well as personal and clinical interactions and redefines the role of those with specialist psychiatric expertise in building and supporting both capacity and capability for mental health and well-being. For me, using the example of child and adolescent mental health, this translates into a life cycle approach that starts with planned parenthood, builds on it with the Prime Minister's parenting classes, and ensures that all those in key interactions with parents and children have adequate skills to promote mental health and respond quickly to signs of distress. This extends to children themselves having the opportunity at school to develop mental resilience and skills for mutual mental health assistance with their peers. The administrative part includes key action on wider determinants of health such as economic and social security, housing and access to good educational and work opportunities. If all this is implemented, the question then arises as to what the formal system should be offering in primary care, building on recent developments in Improving Access to Psychological Therapies (IAPT) and how serious breakdown and risk can be handled for the whole population of patients for whom this becomes necessary.⁴

One of the enemies of adopting this kind of comprehensive approach to mental health is the prevailing narrow and reductionist model of scientific evidence as illustrated by recent controversy over the concept of mental well-being as a researchable paradigm.⁵ For Caplan, ““Our lack of knowledge in regard to the significance of the different factors has to be remedied by a continuation of existing research into aetiology. But, meanwhile preventive psychiatrists have been able to learn a lesson from public health colleagues in regard to handling of the problem of the multifactorial nature of the picture ... The incidence of cases of clinical tuberculosis, for example, in any community is no longer conceived of in public health circles as being merely dependent upon the single factor of the presence or absence of the tubercle bacillus. It is recognised that there are many complicated issues that will determine whether a particular person exposed to the germ will contract the clinical disease: issues involving virulence of the germ, host susceptibility and various environmental factors’.”⁶ In public health we have learned to take a whole-systems approach to whole and sub-populations and to use multiple interventions acting on the health ‘field’.

The list of factors of interest to those concerned with protecting and improving mental health, mental well-being and resilience, in addition to the proximal factors of those aspects of personal security already mentioned and the managed challenges that enable people to grow and thrive, includes a set of constructs such as locus of control, self-esteem and coherence. These can be difficult constructs to operationalise for research purposes, especially when they interact in complex systems, but tools can be developed, for example the Rosenberg Self-Esteem Scale,⁷ and in recent years mixed-methods and compound outcomes such as those used in Social Return on Investment⁸ have paved the way for practical interventions based on pragmatic considerations.

We must be careful to avoid the dangers of scientism. When John Snow took the handle from the Broad Street pump during the 1854 cholera epidemic in Soho, the cause of cholera was still believed to be the miasma. This was 20 years before Pasteur’s ground-breaking research. And still nowadays a whole system of education based on the evidence-free assumption that team sports are character forming underpins the British public schools system.

Caplan’s book concludes with a remarkably contemporary proposal for the development of comprehensive community psychiatry based on 11 concepts and assumptions that could well provide the starting point for a consideration as to how any new government funds might be committed. For myself, I have come to the conclusion that in addition to those things which government can and should do through ‘the pharmacy of public health’, there are three approaches, tried and tested in recent years, that should be regarded as delivery systems.

1. ‘Total place’ and ‘defined population’ as developed through Healthy Cities, Healthy Schools, Healthy Prisons and other settings.⁹
2. Asset-based community development as proposed by John McKnight and colleagues in Chicago.^{10,11,12,13} This approach maps and mobilises the gifts and talents of individuals, families and communities on the basis that:
 - they are half-full, not half-empty
 - it takes a village to raise a child
 - 90% of health and social care is lay care
 - unless professional practice supports self-efficacy it can be part of the problem rather than part of the solution.
3. Community-oriented primary (and secondary) care based on an epidemiological understanding of populations and responsibility for them, as practised by Sidney Kark and his colleagues over many years at the Hadassah Medical School in Jerusalem.¹⁴

In conclusion, I am optimistic that we have an opportunity to re-launch mental health in this country at the same time as developing parity and integration with physical health. The Faculty of Public Health is playing its part by launching a new public mental health report in June to share best practice among public health practitioners.¹⁵

There is a particular opportunity to pursue this approach in England, where NHS England’s *Five Year Forward View*¹⁶ with its integrated ‘new care models’ is driving transformational change. However, the paradigm shift to a public health model with co-production at its heart is a precondition. More of the same just won’t do.

1.6.3 Capacity *in vacuo*: an audit of decision-making capacity assessments in a liaison psychiatry service

2017-2

Abstract

Aims and method We aimed to audit the documentation of decision-making capacity (DMC) assessments by our liaison psychiatry service against the legal criteria set out in the Mental Capacity Act 2005. We audited 3 months split over a 2-year period occurring before, during and after an educational intervention to staff.

Results There were 21 assessments of DMC in month 1 (6.9% of all referrals), 27 (9.7%) in month 16, and 24 (6.6%) in month 21. Only during the intervention (month 16) did any meet our gold-standard ($n = 2$). Severity of consequences of the decision (odds ratio (OR) 24.4) and not agreeing to the intervention (OR = 21.8) were highly likely to result in lacking DMC.

Clinical implications Our audit demonstrated that DMC assessments were infrequent and poorly documented, with no effect of our legally focused educational intervention demonstrated. Our findings of factors associated with the outcome of the assessment of DMC confirm the anecdotal beliefs in this area. Clinicians and service leads need to carefully consider how to make the legal model of DMC more meaningful to clinicians when striving to improve documentation of DMC assessments.

- *Capacity in vacuo: an audit of decision-making capacity assessments in a liaison psychiatry service*
 - *Method*
 - *Results*
 - *Discussion*

All doctors are often required to make assessments of their patients' decision-making capacity (DMC). This role is prominent in liaison psychiatry services, as psychiatrists may be asked to provide a second opinion on DMC for other medical specialties (e.g. regarding consent for a surgical procedure). In the UK, psychiatric second opinion tends to be requested following refusal of treatment by a patient,¹ but also when the assessment is likely to be highly complex or

is driven by an underlying psychiatric disorder.^{1,2} DMC is also routinely assessed in the UK in psychiatric patients in emergency settings such as accident and emergency (A&E) departments. At the time of the audit guidance by the Care Quality Commission³ recommended that assessments regarding DMC to consent to treatment and admission should be made on all patients at the point of admission to a psychiatric hospital to clarify whether it was an admission authorised through the consent of a patient with DMC or under the 'best interests' procedures in a patient who is assenting but lacking DMC.

In England and Wales the legal criteria through which DMC is assessed are provided by the Mental Capacity Act 2005, with further guidance in its Code of Practice.⁴ Under the Act, for a person to lack DMC evidence is required that they suffer from 'an impairment of, or a disturbance in the functioning of, the mind or brain' (Section 2(1)), and that as a consequence of this they are unable to perform at least one of the following tasks: '(a) to understand the information relevant to the decision, (b) to retain that information, (c) to use or weigh that information as part of the process of making the decision, or (d) to communicate [their] decision' (Section 3(1)). DMC is 'decision specific' rather than a 'blanket' or global ability: it is tailored to the specific decision at hand and recognises that different factors may influence different decisions.

There are additional considerations during the assessment of DMC, in that the assessor must also take heed of the principles of the Mental Capacity Act 2005 which include that 'A person must be assumed to have capacity unless it is established that he lacks capacity' and 'A person is not to be treated as unable to make a decision unless all practicable steps to help him to do so have been taken without success' (Section 1). Recently the House of Lords Select Committee on the Mental Capacity Act 2005 heavily criticised the implementation of the Act: 'Our evidence suggests that capacity is not always assumed when it should be. Capacity assessments are not often carried out; when they are, the quality is often poor. [...] The presumption of capacity, in particular, is widely misunderstood by those involved in care'.⁵

We know that patients lacking DMC to consent to treatment are common in both general medical in-patient (around 40%)⁶ and psychiatric in-patient settings (around 60%).⁷ An assessment and decision regarding DMC has significant repercussions for the patient, either respecting autonomy or paving the way to surrogate decision-making under 'best interests'. It is therefore important to document clear justification for a decision reached, under the statutory criteria of the Mental Capacity Act 2005. Previous work in the USA has shown poor documentation of DMC in a retrospective study of in-patient lumbar punctures authorised by a surrogate decision-maker (3 patients had DMC documented out of 25 procedures authorised by a surrogate, although in 21 cases there was enough information to 'infer' lack of DMC).⁸

Our aim was to audit the documentation of DMC assessments provided by our liaison psychiatry service against the Mental Capacity Act 2005 and its Code of Practice, and the guidance issued by contemporary literature.⁹ Subsequently, we employed an educational intervention in our service to see whether this improved documentation of the assessments. We collected detailed information on the factors influencing the assessment of DMC to see whether this had an impact on the quality of DMC assessment or of the intervention.

Method

All new referrals received by the King's College Hospital Liaison Psychiatry Team, South London and Maudsley NHS Foundation Trust (SLaM), during the month of November 2011 were collated. The team is split into the accident and emergency team and the general in-patient team covering all referrals. In working hours there are also specialist child and adolescent mental health services (CAMHS), older adults, neuropsychiatry and perinatal psychiatry teams. All referrals outside of working hours are taken on by the general service. CAMHS referrals were excluded from this audit.

Assessments of DMC performed by members of the team are completed without a formal template or form and were documented in the SLaM electronic medical record (EMR) as free text. All patient contacts by the team need to be recorded in the SLaM EMR.

The EMR was searched for documentation of assessments of DMC by searching for the word 'capacity' and any statement declaring that the patient had or lacked DMC was taken to be an assessment of DMC. The entire duration of the patient episode related to that referral was audited. Statements that suggested the patient may or may not have DMC but that did not make formal declaration were taken by this audit to be an assessment of DMC. The exception to this were statements that suggested the person may lack DMC, but that formal assessment could be delayed.

We set our gold-standard to require documentation of: (1) justification of the timing of the assessment/attempts to maximise DMC in accordance with the principles of the Mental Capacity Act 2005 and; (2) the full statutory criteria of DMC (presence or absence of a disorder of ‘mind or brain’, and performance on the four key abilities). We excluded the need for an explicit statement linking psychopathological features of the disorder of ‘mind or brain’ to any deficit found in the four key abilities given that some patients were found to not have a disorder of ‘mind or brain’.

Further information was gathered, including: basic demographic information, whether the assessment took place in or out of hours, the decision for which DMC is being assessed, the professional background of the assessor, and whether the person agreed or objected to the intervention/option proposed. The severity of potential consequences to the patient regarding refusal of the intervention for which DMC was assessed was also quantified, and classed as mild, medium and severe risk of adverse outcome (by a psychiatrist with experience of DMC assessments and patient management in this clinical environment). An example of a severe risk is a refusal of admission into a psychiatric hospital by a patient with florid psychosis or refusal of life-sustaining medical treatment; an example of mild risk is a refusal to contact relatives for information-sharing regarding the patient’s clinical episode.

Following the audit in November 2011 (month 1), we analysed the initial results. Given that none had met our gold-standard (see below), we designed an educational intervention to improve clinicians’ understanding of the legal framework of the assessment of DMC and how to document this appropriately. The intervention took place during the week psychiatrists in training (senior house officers (SHOs)) change jobs (February 2013, month 16), and continued for the following 4 weeks. It involved the lead auditor (B.S.) meeting with the medical (SHO) and nursing (psychiatric liaison nurses (PLNs)) members of the liaison team and explaining the gold-standard of DMC documentation; presenting this to the on-call SHOs during their induction as they may cover the team out of hours; and emailing the SHO cohort and the senior doctors on call (specialist registrars (SpRs)) on a weekly basis with the guidance. Posters with the guidance were put up in the departmental offices seen by the PLNs and SHOs.

The 4-week period in February 2013 (month 16) during which the intervention was applied was audited, along with the month of July 2013 (month 21), using the methods described above. This audit was reviewed and approved by the trust Psychological Medicine Audit Committee in January 2012.

Results

In month 1, there were 21 (6.9%) assessments of DMC for 306 referrals, in month 16 there were 27 (9.7%) assessments for 278 referrals, and in month 21 there were 24 (6.6%) assessments for 365 referrals (*Table 1*). Overall, DMC was assessed in 72 (7.6%) out of a total of 949 referrals.

Frequency of DMC assessments, demographics, and number meeting audit standards by month *a*

	Month 1	Month 16	Month 21	Total sample
Total referrals, <i>n</i>	306	278	365	949
DMC assessments, <i>n</i> (%)	21 (6.9)	27 (9.7)	24 (6.6)	72 (7.6)
Age, years: mean (s.d.)	45.2 (14.8)	39.3(15.4)	45.6 (15.0)	43.1 (15.2)
Female, <i>n</i> (%)	12 (57.1)	14 (51.9)	14 (58.3)	40 (55.6)
Patients found to have DMC, <i>n</i> (%)	6 (28.6)	16 (59.3)	14 (58.3)	36 (50)
Assessments documenting the statutory criteria, <i>n</i> (%)	2 (9.5)	6 (22.2)	2 (8.3)	10 (13.9)
Assessments meeting the audit gold-standard, <i>n</i> (%)	0	2 (7.4)	0	2 (2.8)

Some patients had more than one DMC assessment. There were no significant differences between months.

None met the gold-standard in months 1 or 21, however, 2 (7.4%) did during the intervention in month 16 (*Table 1*) and both of these assessments were performed by the SHOs who had received the educational intervention. Results were similar when using our lower standard of documentation of the full statutory criteria: $n = 2$ (9.5%) in month 1, $n = 6$ (22.2%) in month 16 and $n = 2$ (8.3%) in month 21. The majority of those failing this standard missed out several elements; only 3 (4.2%) assessments missed reaching the standard through missing only one of the four key abilities, whereas 38 (52.8%) assessments documented none of the four key abilities. We therefore cannot conclude the educational intervention had any impact at all.

Where recorded, we looked at how frequently the key abilities to be tested were lacking in people who lacked DMC. Lacking the ability to 'use or weigh' information was most common ($n = 19$, 73.1% where recorded), followed by 'understanding' ($n = 10$, 43.5% where recorded), 'retaining' ($n = 8$, 57.1% where recorded) and 'communication' ($n = 4$, 33.3% where recorded).

The majority of assessments of DMC were performed by doctors ($n = 51$ (70.8%) *v.* $n = 21$ (29.2%) assessments performed by the PLNs). Of the PLNs' assessments only 3 (14.3%) patients were found to lack DMC, whereas of the doctors' assessments 33 (64.7%) patients lacked DMC (*Table 2*). PLN assessment was significantly more likely to result in a positive DMC than a doctor assessment (OR = 11.0, 95% CI 2.9 to 42.5). The doctors met the gold-standard ($n = 2$, 4%) and full statutory criteria ($n = 9$, 18%) more often than the PLNs ($n = 0$ and $n = 1$, 5% respectively).

Outcome of DMC assessment based on assessing clinician

	DMC present		
Assessing clinician, n (%)			
PLN	3 (14)	18 (86)	21 (29)
Doctor	33 (65)	18 (35)	51 (71)
Total, n	36	36	72

DMC, decision-making capacity; PLN, psychiatric liaison nurse.

We separated the types of decisions to be made by the patient into those that involved 'psychiatric admission or treatment' and 'medical admission or treatment'. For the purposes of the audit, decisions to start a new admission in hospital or discharge oneself from a current admission were seen as interchangeable. Medical and psychiatric decisions were not mutually exclusive and a proportion of patients were assessed for both. There were assessments of DMC that did not focus on these decisions, but they were a minority and focused on decisions not normally tested in this setting, such as DMC to make a decision around ongoing homelessness ($n = 1$) and ongoing abusive relationship/domestic abuse ($n = 2$). These non-treatment-focused assessments of DMC all occurred as part of the psychiatric assessment by a PLN or doctor rather than following a request for second opinion from the medical teams.

We found that the proportion of assessments of DMC for medical admission or treatment formed the majority of assessment at the start of the audit month 1 ($n = 17$, 81%), but this reduced over the course of the audit in month 16 ($n = 12$, 44%) and month 21 ($n = 8$, 33%; Pearson's $\chi^2 = 9.91$, $P = 0.007$) (*Table 3*). Conversely, assessments for psychiatric admission or treatment were the minority at the start of the audit ($n = 5$, 24%) and increased in month 16 ($n = 13$, 48%) and month 21 ($n = 13$, 54%), although the differences were not statistically significant.

Decisions for which DMC was assessed and numbers agreeing with the intervention by month

	Month 1	Month 16	Month 21	Total sample $n = 72$
Decisions to be made, n (%)				
Medical admission or treatment	17 (81) ^a	12 (44) ^a	8 (33) ^a	37 (51)
Psychiatric admission or treatment	5 (24)	13 (48)	13 (54)	31 (43)
Agreement status, n (%)				
Agreeing	5 (24)	15 (56)	12 (50)	32 (44)
Not agreeing (or unable to express a choice/not documented)	16 (76)	12 (44)	12 (50)	40 (56)

DMC, decision-making capacity.

Pearson's $\chi^2 = 9.91$, $P = 0.007$.

We separated the choices of people who were having their DMC assessed into agreeing with the intervention proposed by the assessor/medical team and objecting/unable to express a choice/unknown. Fewer people were assessed who agreed with the intervention in month 1 ($n = 5$, 24%), but in months 16 and 21 they made up half of those assessed (Table 3). Agreement with the intervention was strongly associated with a finding of DMC: 26 (81%) of those agreeing with the intervention were found to have DMC, compared with only 10 (25%) of those who did not agree (either objecting or otherwise) (Table 4). This was highly statistically significant (Pearson's $\chi^2 = 22.50$, $P < 0.001$). Most assessments made by the PLNs were done in patients agreeing to the intervention ($n = 15$, 71%), contrary to doctor assessments ($n = 17$, 33%).

Outcome of DMC assessment based on agreement with the proposed intervention a

	DMC present		
Agreement status, n (%)			
Agreeing	6 (19)	26 (81)	32 (44)
Not-agreeing (or unable to express a choice/not documented)	30 (75)	10 (25)	40 (56)
Total, n	36	36	72

DMC, decision-making capacity.

Pearson's $\chi^2 = 22.50$, $P < 0.001$.

A logistic regression was performed to ascertain the effects of the assessor (PLN or doctor), agreement with the intervention and consequences of the decision. Initial models also included decision to be made and underlying mental disorder, however, these were removed from the final model as they had no effect.

The final regression model was statistically significant (Pearson's $\chi^2 = 45.81$, $P < 0.001$). The model explained 64.7% of the variance (Nagelkerke R^2) and correctly classified 81.2% of the outcome of the assessments of DMC.

Factors associated with the finding of lack of DMC were: more severe consequences of the decision (OR = 24.4, 95% CI 3.47 to 171.8), not agreeing with the intervention (OR = 21.8, 95% CI 4.0 to 118.8), and assessment by doctor rather than PLN (OR = 14.9, 95% CI 2.1 to 104.5).

Discussion

We have shown evidence that documentation of 72 DMC assessments in 3 sampling months in a liaison setting was poor, with only 2 assessments reaching our gold-standard. The impact of a legal education intervention was very limited and was not sustained beyond the month in which it was applied.

There are several possible reasons as to why the proportion of assessments meeting our gold-standard was so low, even after the educational intervention. Clearly, a lack of documentation of all components of the assessment of DMC does not necessarily equate to these components not having been considered by the clinician assessing DMC. However, there is limited documentary justification of the nature of the clinical assessment and the legal model of DMC. Perhaps elements of the education intervention itself (design, style, length etc.) may not have been an effective means of conveying the information, although our audit was not designed to evaluate this. The explicit reference to the principles of the Mental Capacity Act 2005 in our gold-standard might have set the standard too high, but even our more lenient 'full statutory criteria standard' was only achieved in 13.9% of assessments during the course of the audit.

Where lies the difficulty in translation of the legal model to clinical assessments? In situations where evidence is presented to the Court of Protection (the civil court in England and Wales with the jurisdiction for cases in which an individual lacks DMC), the Court requires completion of prescribed forms that demand a level of evidence similar to our gold-standard. In a busy clinical environment it is easy to see how documentation of the presence or absence of DMC could be considered to be sufficient by clinicians. A process that might slow the system down (or be perceived as such) can be expected to be powerfully resisted.

It is interesting that the assessments of DMC by PLNs result more often in the patient being concluded to have decision-making capacity. This finding needs to be approached with caution given that DMC assessments were triggered by several different reasons in our audit, including either: (1) a second opinion assessment of DMC, usually in the context of a patient refusing treatment, in which the assessment would be performed by a doctor; or (2) an assessment of DMC in the context of admission to psychiatric hospital performed by any clinician.

As doctors performed all second opinions of DMC assessment, usually in the context of a patient refusing treatment, and they assess all patients who will need compulsory admission to hospital, there is a referral bias. The majority of DMC assessments performed by the PLNs were in the context of a patient agreeing with the suggested intervention, and hence were used to support the clinical assessment. If there is no dispute around the intervention offered, then DMC assessment has little consequence and it is easier to presume DMC.

The strong association between lack of DMC, high severity of outcome, refusal and lack of assent is striking. To our knowledge this is the first piece of work that has clearly demonstrated this association in real clinical practice. It would seem to suggest that clinicians when assessing DMC in practice use an outcome test of DMC rather than the functional test the law requires. Kim *et al*¹⁰ have shown that assessments of DMC by clinicians using video simulations of consent discussions around involvement in research are risk sensitive. This echoes early work on conceptualising DMC as necessarily risk sensitive.² Owen *et al*¹¹ reported an association between treatment refusal and DMC assessed using the MacArthur Competency Assessment Tool for Treatment. Although the association is striking, we consider it to be largely expected, given the selection bias that assessments of DMC performed as a second opinion by our service are normally prompted by treatment refusal in the context of a possible mental disorder, when refusal is likely to result in significant harm to the patient. It is reassuring that there are a proportion of assessments where people are found to have DMC despite the refusal and high severity of consequences, and we submit that this is evidence of careful clinical consideration of each case on its own merits.

Our audit has shown that there are limitations in the recording of assessments of DMC, and that uptake of an educational intervention was limited. We consider that this is likely due to the perceived disconnect between the legal assessment and clinical assessment. We would recommend that the next step in the audit cycle should include an educational intervention on the assessment of DMC with a formal evaluation, with exploration and focus on clinical factors and their relationship to legal criteria in order to be more acceptable for clinicians.

In conclusion, we have found evidence for the anecdotal belief on the impact of severity of consequences and agreement status of the patient on the outcome on their assessment of DMC. Reassuringly, these factors were not totally deterministic of the outcome but they do suggest that, in practice, the functional test of DMC is yet to fully bed down.

We would like to thank Dr Lisa Conlan for her support and advice during the audit process.

1.6.4 Personality disorder: still the patients psychiatrists dislike?

Abstract

Aims and method In 1988, Lewis and Appleby demonstrated that psychiatrists hold negative attitudes towards patients with personality disorder. We assessed the attitudes of psychiatry trainees towards patients with borderline personality disorder and depression, expecting an improvement. 166 trainees were block randomised to receive one of four case vignettes that varied by diagnosis and ethnic group. We used Lewis and Appleby's original questionnaire and the Attitudes to Personality Disorder Questionnaire (APDQ).

Results We received 76 responses. Lewis and Appleby's questionnaire showed more negative attitudes towards personality disorder than depression, with no significant patient ethnic group effects, and the APDQ also showed a (weak) trend towards more negative attitudes to personality disorder. In subgroup analysis, only in the White British patient group were there significantly more negative attitudes to personality disorder. Factor analysis showed significantly less sense of purpose when working with personality disorder.

Clinical implications The perceived greater lack of purpose in working with personality disorder should be the target of clinical training and intervention. Targeted interventions that include training in managing personality disorder, supervision and practice in non-specialist, general psychiatry settings are important.

* *Limitations*

* *Recommendations*

Personality disorder is characterised by an enduring dysfunctional and distressing pattern of inner experiences, behaviours and interpersonal interactions.¹ Almost a quarter (24%) of people seen in primary care² and 50% of people in secondary mental health services meet the criteria for a diagnosis of personality disorder.³ Patients with personality disorder have high rates of comorbidity⁴ and service utilisation.⁵ A meta-analysis, which identified 391 relevant publications and finally included 14, showed significant differences in prevalence between Black and White groups (although no differences between Asian or Hispanic groups compared with White groups), raising the question of whether there is a neglect of diagnosis in some ethnic groups.⁶

Although there is good evidence that borderline personality disorder (BPD) is a helpful diagnostic construct,⁷ some studies contest the validity (but not the clinical utility) of the diagnosis.⁸ Potter¹ stresses that the psychological and interpersonal dynamics that patients with BPD bring to the clinical setting cause frustration and consternation among clinicians, such that BPD is now a diagnosis that can carry pejorative connotations and compound the stigma that such patients already face. Many patients with BPD feel rejected and disbelieved by clinicians.⁹ Improving clinicians' attitudes toward patients with BPD could bring them clinical benefit.¹⁰

Against this background, there have been systematic efforts to study clinicians' attitudes to personality disorder. A systematic review of the literature shows that healthcare professionals in general have negative attitudes towards such patients.^{11,12} A large study⁷ demonstrated that the clinician's occupational subgroup was significantly related to the attitude they adopted towards patients with BPD: staff nurses had the poorest self-ratings on overall caring attitudes, whereas social workers had the most caring attitudes. Social workers and psychiatrists self-rated highly on treatment optimism, whereas staff nurses rated poorly on empathy and treatment optimism. Overall, the authors suggested that education about the nature and treatment of BPD can lead to more positive attitudes, but also that clinicians with greater levels of experience in terms of both number of BPD patients and years of practice were more likely to express positive attitudes towards such patients. Bodner *et al*¹³ demonstrated that psychologists were less likely than psychiatrists and nurses to express antagonistic judgements towards patients with BPD and suicidal tendencies, whereas nurses were less likely to show empathy than psychiatrists and psychologists. They identified a number of factors influencing attitudes, including motivation to improve diagnostic skills, seniority, training and supervision, gender and familiarity with treatment modalities.

In 1997, Bowers *et al*¹⁴ developed a new instrument called the Attitude to Personality Disorder Questionnaire (APDQ). The APDQ is a reliable and valid measure of attitude to personality disorder, and is useful for outcome studies. It was tested among nurses and prison officers.¹⁵⁻¹⁷ One of these studies¹⁶ revealed that psychiatric nurses' attitudes were more negative than those of prison officers. Prison officers more often liked and showed an interest in prisoners with personality disorder, and they showed less fear and helplessness, less anger, more optimism about treatment and less frustration. The other studies found that nurses considered people with personality disorder difficult to treat; they were pessimistic about the efficacy and outcome of treatment and felt they were poorly trained to care for such patients.

Over 20 years ago Lewis & Appleby¹⁸ demonstrated that psychiatrists hold negative attitudes towards patients with a diagnosis of personality disorder, and that the diagnostic label was more influential on their attitudes than the patient's gender or class. Patients given a previous diagnosis of personality disorder were seen as more difficult and less deserving of care than controls. The authors concluded that a diagnosis of personality disorder carries enduring negative sentiments and is not used to guide effective treatment. For example, people with this diagnosis may experience difficulties when seeking help for psychiatric symptoms such as depression. The authors proposed that the concept of personality disorder be abandoned.

In 2002 the National Personality Disorder Development Programme was introduced in the UK, accompanied by the publication of *No Longer a Diagnosis of Exclusion*¹⁹ and *Breaking the Cycle of Rejection*,²⁰ policy attempts that aimed to improve the evidence base of effective interventions for patients with personality disorder in specialist personality disorder services and, it was hoped, would also mitigate stigma.

Given the above, it seemed timely to see whether the attitudes of psychiatrists towards BPD showed any change. We selected psychiatric trainees, despite the difference in seniority/experience compared with Lewis & Appleby's original study (mean 16.5 years of psychiatric practice), as they are on the front line of service provision and are the next

generation of consultant psychiatrists. Considering the findings of McGilloway *et al*⁶ and the multi-ethnic patient population in east and north-east London our sample was drawn from, we also examined the impact of ethnicity on attitudes.

Objectives

The objectives of the study were: to assess the attitudes of psychiatry trainees towards patients with BPD compared with depression to assess the impact of patient ethnicity on the attitudes of trainees to BPD.

Method

The study population consisted of the cohort of doctors training in psychiatry on the north-east London rotations (East London NHS Foundation Trust and North East London NHS Foundation Trust) between February and July 2013: core trainees 1–3, specialist trainees 4–6, general practice vocational trainees and foundation year 2 doctors. Overall, 166 doctors in training were block randomised in blocks of 8 to receive one of four different case vignettes (*Box 1*) that varied by previous diagnosis (BPD or depression) and ethnic group (White British or Bangladeshi). The case vignettes were modified versions of those used by Lewis & Appleby.¹⁸

Box 1 Case vignettes used in the study

Case 1

A 25-year-old White British woman is seen in out-patients. She complains of feeling depressed and crying all the time. She is worried she may be having a ‘breakdown’ and is requesting admission. She says she has thought of killing herself by taking an overdose of tablets at home. She has a history of an overdose 2 years ago after a relationship break-up, following which she saw a psychiatrist who diagnosed her with depressive episode. She recently lost her job and is worried about how she will pay the bills. She is finding it difficult to sleep and her GP prescribed nitrazepam, which she says has been helpful and which she would like to continue.

Case 2

Same as case 1, but the patient is Bangladeshi.

Case 3

Same as case 1, but the previous diagnosis is borderline personality disorder.

Case 4

Same as case 3, but the patient is Bangladeshi.

We used the following tools to measure attitudes:

Lewis & Appleby’s 22 semantic differentials on a 6-point scale. Using the original scoring conventions, the semantic differentials were scored so that a higher score represented responses that were more rejecting or that indicated lack of active treatment.

APDQ: a questionnaire that consists of 37 affective statements about patients with personality disorder (e.g. ‘I like personality disorder people’, ‘I feel drained by personality disorder people’, ‘I feel patient when caring for personality disorder people’). Respondents rate the frequency of their experiences of these feelings on a 6-point Likert scale: never, seldom, occasionally, often, very often and always. The responses can be summed to give a total score; the higher the score, the more positive the attitude towards patients with a personality disorder. Five subfactors can be scored: factor 1, enjoyment: warmth, liking for and interest in contact with patients with personality disorder factor 2, security: the lack of fears, anxieties and helplessness in relation to patients with personality disorder factor 3, acceptance: the absence of anger towards patients with personality disorder and a sense of being different from them factor 4, purpose: feelings of meaning and purpose in working with patients with personality disorder factor 5, enthusiasm: energy and absence of tiredness.

For the purposes of this study we modified the affective statements to ‘I like these patients’, ‘I feel drained by these patients’ etc. to correspond to the case vignette of either personality disorder or depression.

Analysis

As regards Lewis & Appleby’s 22-item semantic differentials, we compared mean and s.d. scores on items. We assessed the structure of the items by running a principal components analysis. We summed scores of the most dominant factors that explained most of the variance and compared them by diagnosis and by ethnic group.

The APDQ scores (mean, s.d.) were compared for trainees across the four case vignettes. These were compared as groups that differed by diagnosis or by ethnic group in logistic regression analyses, to assess the role of diagnosis and ethnic group. We used the original APDQ factors as an additional variable to assess differences by patient ethnic group and diagnosis.

The study was granted ethical approval by the South West London REC 3 (ref. 10/H0803/159). We obtained the names and positions of all trainees in the rotation from the core training scheme manager for the north-east London rotations. We contacted all trainees via email asking them to complete questionnaires online (on the SurveyMonkey platform, www.surveymonkey.co.uk). All respondents gave informed consent and all responses were anonymous.

Results

We received 76 responses (response rate 46%). However, a small number of respondents failed to answer a number of questions. We thus analysed data from 73 responses to Lewis & Appleby’s questionnaire ($n = 19$ for case 1, case 3 and case 4, and $n = 16$ for case 2) and 68 responses to the APDQ (17 for case 1, 15 for case 2, 20 for case 3, and 16 for case 4). Respondent characteristics are given in *Table 1*.

Respondent characteristics

GP, general practice vocational trainee; FY, foundation year; CT, core trainee; ST, specialist trainee.

Lewis & Appleby's 22-item semantic differentials

The scale was subject to principal components factor analysis followed by an orthogonal rotation to identify 16 of the 22 items loaded (loading of greater than 0.5) on the first factor (eigenvalue 10.42, explaining 71% of the variance), with two further candidate factors (eigenvalue 1.68, explaining 11.5% and eigenvalue 1.00, explaining 6.1%, respectively) (*Table 2*). Only items from the first factor were summed to compare attitudes, as the second and third factors were accounted for by 3 items each and did not show a clear conceptual distinction between each other. The mean and s.d. score of factor 1 was compared by diagnosis and by ethnic group (case 1: mean 42.42, s.d. = 8.54; case 2: mean 48, s.d. = 8.71; case 3: mean 53.68, s.d. = 11.99; case 4: mean 51.53, s.d. = 10.51). The scores did not vary by ethnic groups. The rank sums showed significant differences by diagnosis, with higher scores (more stigma) towards personality disorder than depression (overall Kruskal–Wallis $\chi^2 = 11.38$, d.f. = 3, $P = 0.01$) (*Table 3*).

Principal components analysis

	Mean (s.d.)	Loading					
F actor 1 (eigen value 1 0.42)							
Poses difficult management problem	3.25 (1.18)	4.20 (1.30)	0	0	0	0	0

Likely to annoy	3.11 (1.28)	3.64 (1.48)	0	0	0	0	0

BPD, borderline personality disorder; BZ, benzodiazepine; NHS, National Health Service.

Means: higher values indicate greater agreement with statement; there was a 6-point scale between the two statements of the semantic differential.

Attitudes to BPD based on the four test vignettes (factor 1: Kruskal–Wallis equality-of-populations rank test)

Case vignette	Respondents, <i>n</i>	Rank sum
1	19	460.50
2	16	564.50
3	19	860.50
4	19	815.50

$\chi^2 = 11.38$, d.f. = 3, $P = 0.01$

APDQ

Multiple regression analysis of overall scores showed a weak trend towards lower scores in assessment of attitudes towards patients with a previous diagnosis of BPD compared with patients with a previous diagnosis of depression (lower scores indicate more negative attitudes in the APDQ and this is consistent with findings from the Appleby measure); however, this difference fell just short of statistical significance ($z = 1.75$, $P = 0.08$). There was no significant ethnic difference in attitudes towards patients. In subgroup analysis, only among White British patients with a previous diagnosis of BPD was there a lower overall score compared with White British patients with a previous diagnosis of depression ($z = 1.98$, $P = 0.047$).

This outcome had already been subjected to factor analysis by the original inventors of the measure. When we assessed scores on the basis of the five factors (using Kruskal–Wallis equality-of-populations rank) there was no statistically significant difference in scores for factors 1 (enjoyment), 2 (security), 3 (acceptance) and 5 (enthusiasm). However, there was a statistically significant ($P = 0.03$) difference found for factor 4 (purpose), with higher scores in attitudes (more positive) towards patients with depression (mean 4.60) compared with patients with a previous diagnosis of BPD (mean 4.15).

Discussion

Since the original study of Lewis and Appleby nearly 30 years ago, a number of studies spanning from 1993 to 2012, as summarised in the introduction, have consistently shown that clinicians hold negative attitudes towards personality disorder. Our finding of more negative attitudes towards personality disorder compared with depression among psychiatric trainees, using the same instrument as Lewis and Appleby, is in line with previous research. However, it is difficult to show and theorise a sense of longitudinal change. This is mainly because different studies have looked at different professional groups, including nurses, prison officers, social workers, psychologists and psychiatrists, with varying training and levels of experience, and in different countries and/or care settings. In addition, our study examined the attitudes of a less experienced sample of psychiatrists than the Lewis and Appleby study, and this has to be taken into consideration when comparing current attitudes with previous ones. However, the ongoing finding of more stigma towards patients with personality disorder, almost 14 years after the introduction of the National Personality Disorder Development Programme, is disheartening.

More encouraging is the lack of evidence of differences in attitudes to patients with personality disorder of different ethnicity. The greater negative attitudes to personality disorder than depression in White British but not in Bangladeshi

patients raises questions of differences in how clinicians may view the disorder in different ethnic groups, especially given that culture influences significantly what is considered to be a person and personality. Culture influences a number of factors relevant to the construct of personality disorder, such as learning inside and outside the family, the threshold when personality vulnerability cannot be compensated for by the person, and the social threshold when such decompensations are labelled pathological.^{21–23} If one accepts personality pathology as universal,²⁴ perhaps this finding can also raise further questions regarding under-diagnosis of personality problems in certain ethnic groups, although supporting such a link is beyond the scope of this paper and further research is needed looking into both the universality of personality disorder and issues of under-diagnosis or misdiagnosis.

The question of why psychiatrists stigmatise personality disorder is complex and not simple to answer. In addition to the issues discussed above in relation to caring for these often emotionally draining patients, it is of relevance that specific features of BPD can cause negative attitudes. It is known that a wide range of impulsive and potentially self-damaging behaviours are observed, especially early in the course of the disorder.^{25,26} These include gambling, irresponsible money handling, reckless driving and unsafe sexual practices,²⁷ as well as problematic substance use, self-harm, suicidal behaviour and disordered eating.^{28–31} Most of these behaviours carry strong moral connotations, sometimes challenging social norms, and can thus provoke negative reactions, triggering clinicians' implicit beliefs and possibly prejudices towards such behaviours.

While mounting anti-stigma campaigns may be required, the finding of a greater lack of purpose in clinicians in working with personality disorder allows for more modest and targeted intervention. Lack of purpose and therapeutic pessimism raise the importance of designing targeted interventions which may include training in personality disorder. As personality disorder is prevalent in all psychiatric settings, this is an important part of training for all psychiatrists.

Limitations

Limitations of the present study include the small sample numbers, which, despite a reasonable response rate for a questionnaire study, makes it difficult to rely on comparisons between the groups, and thus compromises the power of the study. Our study population is taken from only two mental health trusts in the UK. However, the trusts cover both inner and outer London areas, and the training programmes are similar to those of others in the UK, as there is a specific framework for postgraduate training in psychiatry.

Recommendations

Increased training in evidence-based practice for generalist mental health professionals in borderline personality disorder may address the issue of clinicians' lack of sense of purpose. The emphasis is thus on increasing the skills of clinicians in managing personality disorder in general psychiatric settings, which usually lack the structure, training and resources to deal with these complex patients. The difficulties faced by general psychiatry clinicians have been acknowledged in the literature, and in that respect 'structured clinical management' has been discussed as an effective way of working with BPD patients in non-specialist settings, as long as certain principles are followed and interventions implemented.³²

It has been shown that people with personality disorder present specific challenges to the therapeutic alliance.^{33–35} Training and supervision^{36–39} as well as participation in a Balint group⁴⁰ can improve negative attitudes.

Patients with personality disorder can provoke strong countertransference reactions, there is thus an ongoing need for clinicians to monitor their countertransference when working with such patients. This highlights the ongoing need for psychotherapy training. Evidence-based psychotherapy treatments have a documented applicability as a useful model for general psychiatrists.⁴¹ Supervision and further training is also necessary for consultants, as they often supervise trainee doctors and inevitably influence them through their own attitudes to these patients.

Recent research on stigma reduction has identified certain key ingredients that anti-stigma initiatives should take into consideration: a recovery emphasis and having multiple forms of social contact are especially important for maximising outcomes.⁴² These key ingredients can be taken up to introduce specific initiatives to reduce stigma against personality disorder. For example, Knaak *et al*⁴³ found that a 3-hour workshop on BPD and dialectical behavioural therapy (DBT)

was successful at improving attitudes and behavioural intentions towards persons with BPD. This is in line with those studies that show that training and education programmes tend to improve attitudes.

1.6.5 Pokorny's complaint: the insoluble problem of the overwhelming number of false positives generated by suicide risk assessment

Abstract

Alex Pokorny's 1983 prospective study of suicide found that 96.3% of high-risk predictions were false positives, and that more than half of the suicides occurred in the low-risk group and were hence false negatives. All subsequent prospective studies, including the recent US Army Study To Assess Risk and Resilience in Servicemembers (STARRS), have reported similar results. We argue that since risk assessment cannot be a practical basis for interventions aimed at reducing suicide, the alternative is for mental health services to carefully consider what amounts to an adequate standard of care, and to adopt the universal precaution of attempting to provide that to all of our patients.

Pokorny's pioneering study

It is over 30 years since the publication of Alex Pokorny's landmark prospective study of suicide among consecutive first admissions to the Houston Veterans Administration Medical Center.^{1,2} Pokorny examined a cohort of 4800 men using a comprehensive array of relevant and reliable rating scales and assessed 803 (17%) to be at high risk of suicide because of the presence of a combination of risk factors. In the next 5 years, 30 (3.7%) high-risk patients and 37 (0.9%) of the 3997 lower-risk patients died by suicide, an odds of suicide that was 4 times greater in the high-risk group.

The 37 suicides among lower-risk patients were in effect false negatives. Pokorny considered false negatives to be inevitable because patients sometimes conceal their suicidal plans and their circumstances change over time. What concerned him more was the overwhelming proportion of false positives, because 96.3% of the patients categorised as high-risk did not commit suicide. He concluded: "We might tolerate 50% false negatives; if we could apply a screening test that would correctly identify only half of the future suicides without false positives that would be very helpful. However, with currently known tests to identify the actual suicides, we will also have to make a great many false-positive identifications, labeling up to a quarter of the total group as future suicides when only 1% to 5% actually are. From a cost-benefit standpoint, the application of such a test is simply not feasible."¹

Other prospective studies of suicide

There have been relatively few prospective studies of the factors associated with subsequent suicide, probably because of the methodological and logistical difficulties involved. Not long after Pokorny, Goldstein *et al*³ followed up a cohort of 1906 patients diagnosed with affective disorders and found that none of the 46 suicides occurred among the group, albeit smaller than in Pokorny's study, defined as being at high risk. More recently, two prospective studies examined the proportion of suicide deaths among those considered to be at high risk.⁴⁻⁶ Madsen *et al*^{4,5} reported a suicide rate of 0.14% among those defined as high risk in a national study of the suicide of psychiatric in-patients in Denmark, and Steeg reported the suicide of 0.5% of patients identified as being at high risk among a large cohort of people who presented to emergency departments in three English counties after self-harm.⁶

Faced with growing concern about suicides among veterans and current serving members of the U.S. Armed Forces, the U.S. Department of Veterans Affairs and the U.S. Department of Defense included the use of risk stratification in clinical practice guidelines.⁷ As part of the Study to Assess Risk and Resilience in Servicemembers (STARRS), Kessler and associates then examined factors associated with suicide among 53 769 American soldiers in the 12 months after discharge from military psychiatric hospitals,⁸ with the benefit of the very detailed longitudinal US Army personnel database and highly sophisticated statistical techniques derived from artificial intelligence research. They identified a high-risk group comprising 2689 admissions, or 5% of the sample, from which there were 36 suicides, corresponding to a 22 times increased risk of suicide in that group. However, in other respects the results were eerily familiar, as nearly half of the suicides occurred among the 51 080 low-risk patients, and only 1.3% of the high-risk group died by suicide, leaving an overwhelming number of false positive cases.

The problem remains of the disturbingly high suicide rates among psychiatric patients as a whole. For example, in the Madsen study, the rate of suicide of psychiatric in-patients was 72 times that of the general community, at 860 per 100 000 patient years, and in the Steeg study the suicide rate among all patients presenting to hospital after self-harm was 622 per 100 000 patient years. Hence, although we know that all of the patients under our care are at greatly increased risk of suicide compared with the wider community,⁵ our ability to distinguish between groups of patients with respect to the probability of subsequent suicide risk is, at best, quite modest.

Implications for mental health services

This observation has important implications for mental health services, given the unrealistic expectations for risk assessment to prevent serious adverse events, and the way risk assessment has changed professional practice.⁹ If risk stratification is to be a part of how mental health services approach suicide prevention, we need to carefully consider the interventions offered to patients believed to be at high risk but denied to those assessed to be at lower risk. Because the vast majority of high-risk patients will not die by suicide, any intervention has to be shown to be somewhat effective, but also benign enough so as not to infringe on the rights of the many with false positive assessments. However, if we do have an effective and benign intervention, it is then hard to justify denying this to low-risk patients, who, after all, are still many times more likely to die by suicide than the general community.

If there is no effective and yet benign intervention to justify offering different treatments to groups of patients on the basis of risk stratification, how can mental health services respond to the knowledge that our patients are at greatly increased risk of suicide compared with the wider community?

The alternative is the application of universal precautions to all patients, including the design of in-patient facilities that minimise the opportunity to attempt suicide,¹⁰ the provision of community treatment for all patients in the weeks after discharge from hospital,¹¹ and safety planning at the point of contact in emergency departments.¹² Most importantly, every patient should have access to timely, individualised, high-quality treatment for psychiatric disorder. Modifiable factors associated with suicide should be addressed in all patients, not only those considered to be at greatest risk. Moreover, no intervention can be justified on the basis of the assessed risk alone. We go so far as to suggest that the assessed risk of suicide on its own is not a sufficient reason for restrictive interventions such as involuntary detention in hospital or other coercive treatment,^{13,14} which would then need to be justified on additional grounds, including the patient's inability to recognise the potential benefit of treatment and their particular circumstances and treatment needs. In any case, preventive detention in hospital of all patients assessed to be at high risk of suicide would be impossible, because of the huge numbers of patients identified and the long duration of secure detention that would be required to protect such patients.

Addressing the modifiable risk factors in populations of patients involves ensuring the adequate identification, assessment and treatment of patients with a range of mental disorders, addressing substance use and, wherever possible, limiting the availability of potentially lethal means to die by suicide. Treatment should be with the patient's consent, or provided on the basis that the patient lacks the capacity to consent, rather than being based on perceived risk, which we now know we are not able to reliably assess.

A further implication for mental health services of the demonstrated limitation of risk assessment is in responding to lawsuits for failing to predict the suicides of individual patients. While the suicide of any patient might be foreseeable in the legal sense of being not fanciful or far-fetched, mental health services cannot be reasonably expected to be able to identify which patients will die by suicide. Expert evidence in one recent case on the estimated probability of suicide after discharge included absurdly high estimates of between a 5 and 70% chance of suicide within days of discharge.¹⁵ Instead of guessing the probability with the help of hindsight bias,¹⁶ negligence claims after suicides should hinge on the accepted standard for care of people with various psychiatric disorders, regardless of the presence of known risk factors. Services should be concerned about the adverse consequences of failing to provide an adequate standard of care to any patient they assess or treat, not only those considered to be at high risk.

Pokorny's complaint that the overwhelming number of false positives renders suicide risk assessment unfeasible is just as valid in 2016 as it was in 1983. His finding, which has been replicated in all subsequent studies, poses a challenge to military and civilian mental health services that have been developed around a model of identifying and managing risk. In response, we recommend abandoning attempts to design interventions based on risk stratification and instead aim to provide an adequate standard of care to all of our patients.

1.6.6 Juvenile delinquency, welfare, justice and therapeutic interventions: a global perspective

Susan Young Ben Greer Richard Church

2017-2

Abstract

This review considers juvenile delinquency and justice from an international perspective. Youth crime is a growing concern. Many young offenders are also victims with complex needs, leading to a public health approach that requires a balance of welfare and justice models. However, around the world there are variable and inadequate legal frameworks and a lack of a specialist workforce. The UK and other high-income countries worldwide have established forensic child and adolescent psychiatry, a multifaceted discipline incorporating legal, psychiatric and developmental fields. Its adoption of an evidence-based therapeutic intervention philosophy has been associated with greater reductions in recidivism compared with punitive approaches prevalent in some countries worldwide, and it is therefore a superior approach to dealing with the problem of juvenile delinquency.

Recent years have seen sustained public and academic interest in criminality and mental health, with attention often focused on antisocial behaviour by children and adolescents. The scale of the problem of juvenile delinquency has provoked mixed responses from governments and the media across the world, with calls for improved rehabilitation and support for juvenile offenders competing with voices advocating more punitive approaches.¹ Meanwhile, decades of rigorous academic scrutiny have shed light on the complex and diverse needs of children who come into conflict with the law.²⁻⁵ Much of the growing body of literature on juvenile offenders shows considerable overlap between criminological, social and biomedical research, with a consensus emerging around the significance of a developmental understanding of the emergence of juvenile delinquency.

Importantly, juvenile offenders have consistently been identified as a population that suffers from a markedly elevated prevalence and severity of mental disorder compared with the general juvenile population.^{6,7} Meeting the needs of these young offenders presents practical and ethical challenges concerning treatment and management, including liaison with other agencies.

What is juvenile delinquency?

Who counts as juvenile?

Juvenile delinquency is a term commonly used in academic literature for referring to a young person who has committed a criminal offence, although its precise definition can vary according to the local jurisdiction. The specific reasons underlying these differences are unclear, but they may arise from the lack of an agreed international standard.⁸

A ‘juvenile’ in this context refers to an individual who is legally able to commit a criminal offence owing to being over the minimum age of criminal responsibility, but who is under the age of criminal majority, when a person is legally considered an adult. The minimum age of criminal responsibility varies internationally between 6 and 18 years, but the age of criminal majority is usually 18 years.

In some cases individuals older than 18 years may be heard in a juvenile court, and therefore will still be considered juveniles; indeed, the United Nations (UN) defines ‘youth’ as between 15 and 24 years of age. The term ‘child delinquents’ has been used in reference to children below the age of 13 who have committed a delinquent act,⁹ although elsewhere ‘children’ are often defined as being under 18 years of age. The term ‘young offenders’ is broad, and can refer to offenders aged under 18 years or include young adults up to their mid-20s.

What is a crime?

A ‘delinquent’ is an individual who has committed a criminal offence. Delinquency therefore encompasses an enormous range of behaviours which are subject to legislation differing from one jurisdiction to another, and are subject to changes in law over time. Whereas acts of theft and serious interpersonal violence are commonly considered to constitute criminal offences, other acts including alcohol consumption and sexual behaviour in young people are tolerated to very differing degrees across the world. Sometimes these differences arise as a consequence of historical or cultural factors, and they may be underpinned by traditional religious laws, such as in some Middle Eastern countries. Some offences may be shared between jurisdictions but be enforced to differing standards – for instance, ‘unlawful assembly’, often used to prevent riots, is applied in Singapore to young people meeting in public in groups of five or more as part of police efforts to tackle youth gangs. Furthermore, ‘status offences’ – acts that would be permissible in adults but criminalised in children, such as consumption of alcohol or truancy – not only vary between jurisdictions, but contribute to discontinuity when comparing juvenile delinquency with adult populations in the same jurisdiction.

Lack of clarity can also arise in jurisdictions where a young offender is processed via a welfare system rather than a youth justice process. Countries with a high minimum age of criminal responsibility may not technically criminalise young people for behaviour that would normally be prosecuted and therefore classed as ‘delinquent’ elsewhere.

Not all incarcerated juveniles are ‘delinquent’, since some may be detained pre-trial and may not be convicted of an offence. Even if convicted, it would be wrong to assume that every ‘juvenile delinquent’ meets criteria for a diagnosis of conduct disorder; offences vary considerably and may not be associated with a broad repertoire of offending behaviour. Also, most ‘juvenile delinquents’ do not pose an immediate risk of violence to others, and the vast majority of convicted juveniles serve their sentences in the community.

To meet the diagnostic criteria of conduct disorder requires evidence of a persistent pattern of dissocial or aggressive conduct, such that it defies age-appropriate social expectations. Behaviours may include cruelty to people or animals, truancy, frequent and severe temper tantrums, excessive fighting or bullying and fire-setting; diagnosis of conduct disorder can be made in the marked presence of one of these behaviours.¹⁰

Overall, the term ‘juvenile delinquent’ is used extensively in academic literature, but requires some care. It can be a potentially problematic term, and in some contexts can strike a pejorative tone with misleading negative assumptions. For several years the UN has used the phrase ‘children in conflict with the law’ to describe the breadth of the heterogeneous group of individuals under the age of 18 who have broken the law or are at risk of doing so.

General principles of juvenile justice

Welfare v. justice models

The sentencing of an individual convicted of a criminal offence is largely driven by three key considerations: retribution (punishment), deterrence and rehabilitation. In the case of juvenile offenders the principle of rehabilitation is often assigned the greatest weight.¹¹

Special consideration for juveniles within the criminal justice system is not a new concept. In Roman law, the principle of *doli incapax* protected young children from prosecution owing to the presumption of a lack of capacity and understanding required to be guilty of a criminal offence. Most countries have some provision for special treatment of children who come into conflict with the law, however, the degree to which this is provided varies across the world.^{1,12} In some countries a ‘welfare’ model prevails, which focuses on the needs of the child, diagnosis, treatment and more informal procedures, whereas other countries favour a ‘justice’ model, which emphasises accountability, punishment and procedural formality.

Belgium is frequently cited as an example of a country with a strong welfare process, supported by a high minimum age of criminal responsibility of 18 years. Similarly, France built a strong welfare reputation by placing education and rehabilitation at the centre of youth justice reforms in the 1940s. New Zealand in 1989 established the widely praised system of Family Group Conferencing as an integral part of youth justice, with a focus on restoration of relationships and reduction of incarceration that would be considered part of a welfare approach. In contrast, the UK and the USA

have traditionally been associated with a justice model and low age of criminal responsibility – 10 years in England and Wales, and as low as 6 years in several US states.

Within welfare or justice models, a young person may at some point be ‘deprived of liberty’ – defined as any form of detention under official authorities in a public or private location which the child is not permitted to leave. Locations in which children may be deprived of liberty include police stations, detention centres, juvenile or adult prisons, secure remand homes, work or boot camps, penitentiary colonies, locked specialised schools, educational or rehabilitation establishments, military camps and prisons, immigration detention centres, secure youth hostels and hospitals.¹³

Between the less and more punitive systems

The UN supports the development of specialised systems for managing children in conflict with the law. When the first children’s courts were set up in the USA in the 1930s, they were widely praised as a progressive system for serving the best interests of the child. Although informality was championed as a particular benefit, in the 1960s substantial concerns arose about due process and the protection of the legal rights of minors. The subsequent development of formal juvenile courts occurred in the context of a continuing ethos of rehabilitation of young people, with a move away from incarceration of juveniles in the 1970s, especially in Massachusetts and California. However, following a marked peak in juvenile offending statistics during the 1980s and 1990s, public and political opinion swung firmly in a more punitive direction. This was accompanied by legal reforms that increased the severity of penalties available to juvenile courts and lowered the age threshold for juveniles to be tried in adult criminal courts.

When the UN Convention on the Rights of the Child entered into force in 1990, the USA was not a signatory owing to 22 states permitting capital punishment of individuals who had committed their crimes as juveniles. It is reported that 19 juvenile offenders were executed in the USA between 1990 and 2005. Although this number may represent a small percentage of the total who faced the death penalty in the USA during that period, the practice was widely criticised by international bodies and organisations.¹⁴ A landmark ruling in the US Supreme Court¹⁵ outlawed the execution of juvenile offenders in the USA, but to date a small number of countries worldwide still implement this practice, sometimes as a result of religious laws.

However, it would be wrong to assume that welfare systems are automatically preferable to a juvenile justice approach, since welfare arrangements can be equally coercive in terms of deprivation of liberty of juveniles. They may lack due process, safeguards for obtaining reliable evidence from young people, processes for testing evidence, and procedures for scrutiny or appeal following disposal.

Trends in youth crime

The USA witnessed a dramatic increase in arrest rates of young people for homicide and other violent crimes in the 1980s and 1990s, sometimes referred to as the ‘violence epidemic’.¹⁶ The ensuing moral panic led to harsh and punitive policy changes in juvenile justice and, although official statistics document a subsequent fall of 20% in court case-loads between 1997 and 2009, victimisation surveys have indicated a degree of continuity in high levels of offending, consistent with a reported increase in juvenile offending between 2000 and 2006.¹⁷

In common with the USA and several other high-income countries, the UK also experienced a rise in juvenile offending in the 1980s and 1990s, but figures from the Youth Justice Board for England and Wales appear to indicate a general improvement in recent years. Between 2009/2010 and 2014/2015 a 67% reduction has been observed in the number of young people entering the juvenile justice system for the first time, a 65% reduction in the number of young people receiving a caution or court disposal and a 57% reduction in the number of young people in custody.¹⁸ These figures support an overall decrease in juvenile offending noted since the early 1990s.¹⁹

Youth crime figures from Australia have documented a 4% reduction in the overall number of young offenders in 2013/2014,²⁰ although the number of violent offences committed by young people in the urbanised and densely populated region of Victoria has increased by 75% between 2000 and 2010.²¹

The Nordic countries have witnessed an increase in the number of law-abiding youths from 1994 and 2008.²² In Sweden, both objective levels of juvenile crime²³ and self-reported involvement in juvenile crime²⁴ have fallen between 1995

and 2005. Similarly in Finland, where, despite fluctuating trends in juvenile drug use, juvenile property and violent crime is reported to have decreased between 1992 and 2013.²⁵

To summarise, whereas regional and annual trends in juvenile offending are observed and expected, a global trend characterised by decreased juvenile offending appears to have emerged in recent years. Indeed, UN data from a sample of 40 countries lend support to this conclusion, indicating a decrease in the proportion of juveniles suspected (10.9% to 9.2%) and convicted (7.5% to 6%) of crime between 2004 and 2012, respectively.²⁶

Juvenile gang membership

Influence on crime involvement

One of the features of urbanisation across the world has been the rise of youth gangs, groups of young people often defined by geographical area, ethnic identity or ideology; recent reports indicate a rise in groups with extremist views. Explanatory models for the rise in youth gangs include factors such as economic migration, loss of extended family networks, reduced supervision of children, globalisation and exposure to inaccessible lifestyle 'ideals' portrayed in modern media.

Authorities in Japan attributed a surge in serious youth crime in the 1990s primarily to juvenile bike gangs known as 'bosozoku', who were deemed responsible for over 80% of serious offences perpetrated by juveniles, putatively bolstered by a crackdown on yakuza organised crime syndicates.²⁷ Although difficult to quantify, gang involvement appears to feature in a large proportion of juvenile offences, and there is evidence that gang membership has a facilitating effect on perpetration of the most serious violence including homicide.²⁸

Mental health

Compared with general and juvenile offender populations, juvenile gang members exhibit significantly higher rates of mental health problems such as conduct disorder/antisocial personality disorder, post-traumatic stress disorder (PTSD), anxiety disorders and attention-deficit hyperactivity disorder (ADHD).²⁹ Gang members, compared with non-violent men who do not belong to a gang, are far more likely to utilise mental health services and display significantly higher levels of psychiatric morbidity, most notably antisocial personality disorder, psychosis and anxiety disorders.³⁰ Gang membership has also been positively correlated with an increased incidence of depressed mood and suicidal ideation among younger gang members.³¹ Prevalence of ADHD is significantly greater in incarcerated youth populations (30.1%) than in general youth population estimates (3–7%),³² therefore it may be reasonable to expect a similarly increased prevalence in juvenile gang members. ADHD has also been associated with a significantly increased risk of comorbid mood/affective disorder.³³

Forensic child and adolescent psychiatric services

Increased awareness of constitutional and environmental factors that contribute to juvenile offending has strengthened a public health perspective towards the problem, and in the UK entry into the youth justice system has been adopted as an indicator of general public health.³⁴

Dictionaries frequently define 'forensic' as meaning 'legal', implying a relationship with any court of law. Indeed, many forensic psychiatrists, particularly in child and adolescent services, undertake roles that encompass multiple legal domains relevant to mental health, including criminal law, family and child custody proceedings, special educational tribunals, and immigration or extradition matters.

Specialist forensic psychiatric services vary considerably between countries,³⁵ but usually forensic psychiatrists assess and treat individuals in secure psychiatric hospitals, prisons, law courts, police stations and in the community under various levels of security, supervision and support. In some countries there has been a trend towards forensic psychiatrists working almost exclusively with courts of law, providing independent specialist opinion to assist the court.

In the UK, forensic child and adolescent psychiatry has emerged as a clinical subspecialty. Some services are based in specialist secure hospitals for young people and cater for the relatively small number of high-risk young offenders with the most severe mental disorders. In the absence of such specialist resources, young people may be managed in suboptimal environments such as juvenile prisons, secure residential placements or secure mental health wards for adults, or even fail to receive treatment at all.

In light of growing evidence-based interventions for juvenile offenders within a public health framework,³⁶ the role of child and family mental health services may increase over time. Aside from direct clinical roles, practitioners in forensic child and adolescent psychiatry are also well placed to work with a wide range of partner agencies on the planning and delivery of broader interventions for the primary and secondary prevention of juvenile delinquency.

Treatment

Prevalence of mental health problems among juvenile offenders

Rates of mental health problems among juvenile offenders are significantly higher than in their non-offender peers, with two-thirds of male juvenile offenders in the USA suggested as meeting criteria for at least one psychiatric disorder.³⁷ One in five juvenile offenders is estimated to suffer severe functional impairment as a result of their mental health problems.³⁸ Paradoxically, these needs are often unmet,^{39,40} despite evidence of increased contact with mental health services, particularly among first-time juvenile offenders.^{41,42} Of additional concern are the reported associations between mental health problems and mortality in incarcerated juveniles,⁴³ including an elevated suicide rate for males.⁴⁴ Mental health problems must be a target in interventions for juvenile offenders; however, treatments which focus solely on clinical problems are unlikely to result in benefit for criminogenic outcomes.⁴⁵ There is therefore a clear need for effective interventions which address both the clinical and criminogenic needs of these individuals.

Evidence-based treatments for mental health problems

Treatment of PTSD

Estimates regarding the prevalence of PTSD among juvenile offenders suggest that 20 to 23% meet the clinical criteria,^{46,47} with prevalence rates significantly higher among females than males (40% v. 17%).⁴⁶ Moreover, with 62% experiencing trauma within the first 5 years of life⁴⁷ and up to 93% experiencing at least one traumatic event during childhood or adolescence,⁴⁸ this should be a target for intervention.

Cognitive-behavioural therapy (CBT) is regarded as the most effective intervention for adults with PTSD⁴⁹ and also has demonstrated efficacy for juvenile non-offenders.^{50,51} There is limited evidence suggesting a significant reduction in self-reported symptoms of PTSD following group-based CBT in male juvenile offenders,⁵² and of an adapted version of CBT, cognitive processing therapy,⁵³ also resulting in a significant reduction in self-reported symptoms of PTSD and depression compared with waitlist controls.⁵⁴

A trauma-focused emotion regulation intervention (TARGET) has received preliminary empirical support for use in this population. TARGET resulted in nearly twice as much reduction in PTSD symptom severity as treatment as usual (TAU),⁵⁵ in addition to significant reductions in depression, behavioural disturbances and increased optimism.⁵⁶

Mood/anxiety disorders and self-harm

Juvenile offenders in the UK present with a high prevalence of mood and anxiety disorders (67% of females, 41% of males), self-harm (11% of females, 7% of males) and history of suicide attempts (33% of females, 20% of males).⁵⁷ Similarly high prevalence has also been observed cross-culturally, namely in the USA,^{37,58} Switzerland⁵⁹ and Finland.⁶⁰

Despite such high prevalence, there appears to be a paucity of high-quality evaluations regarding the effectiveness of interventions for juvenile offenders with mood and/or anxiety disorders, or problems with self-harm. However, the limited evidence that is available suggests that group-based CBT may aid symptom reduction.⁶¹ Recovery rates for major depressive disorder following group-based CBT are over double those for a life skills tutoring intervention (39% v. 19%, respectively), although no significant difference was noted at 6- or 12-month follow-up. CBT also resulted in significantly greater improvements in self- and observer-reported symptoms of depression and social functioning.⁶²

However, group-based CBT is not reported to be significantly different from TAU in reduction of self-harm,⁶³ whereas individual CBT is not significantly different from TAU in outcomes for depression, anxiety, conduct disorder or PTSD.⁶⁴ Yet recruitment to and retention in intervention seems good, suggesting that CBT is feasible to implement in juvenile offender populations.⁶⁴

Evaluations of alternative interventions have posited muscle relaxation as effective in improving juvenile offenders' tolerance of frustration.⁶⁵ Dialectical behaviour therapy (DBT) has also been reported to significantly reduce incidences of physical aggression in a juvenile offender population⁶⁶ and among juvenile non-offenders expressing suicidal ideation.⁶⁷ It significantly reduced serious behavioural problems and staff punitive actions among juvenile offenders within a mental health unit, although no similar significant reductions were observed for those without mental health problems.⁶⁸

Evidence-based treatments for conduct disorder: family approaches

Relationships with family and peers are recognised as key factors in the criminogenic profile of juvenile offenders.⁶⁹ Multisystemic therapy (MST) is a family-focused intervention targeting characteristics related to antisocial behaviour, including family relationships and peer associations,⁷⁰ with evidence from US and UK studies suggesting MST is a beneficial intervention for juvenile offenders. When compared with conventional services offered by juvenile offending services, MST was associated with a significant reduction in the likelihood of reoffending,⁷¹ maintained 2 and 4 years post-treatment.^{72,73} Offenders engaging in MST are reported to be significantly less likely to become involved in serious and violent offending.^{73,74} Significant improvements have also been observed in both self- and parent-reported delinquency,⁷⁴ family relations and interactions,⁷³ and home, school, community and emotional functioning.⁷¹ A cost offset analysis of MST among UK juvenile offenders suggested that combining MST and conventional services provides greater cost savings than conventional services alone, as a result of its positive effects on recidivism.⁷⁵ Qualitative impressions of MST from juvenile offenders and their parents indicate that key components of a successful delivery of MST include the quality of the therapeutic relationship and ability to re-engage the offender with educational systems.⁷⁶

Some evidence also exists regarding the efficacy of MST when delivered to non-offender antisocial juvenile populations outside the USA and the UK. Compared with TAU, MST resulted in a significantly greater increase in social competence and caregiver satisfaction, and a significant reduction in referrals for out-of-home placements, in Norwegian juveniles exhibiting serious behavioural problems.⁷⁷ However, no significant difference between MST and TAU was reported in outcomes for antisocial behaviour and psychiatric symptoms in Swedish juvenile offenders.⁷⁸ MST was also found to have no significant benefit over TAU in outcomes including recidivism in a sample of Canadian juvenile offenders.⁷⁹ These differing outcomes have been posited as the result of barriers in transferring MST from US and UK populations owing to differing approaches to juvenile justice between countries (i.e. a welfare v. justice approach).⁷⁸ The heterogeneous nature of studies concerning MST in juvenile offender populations prevent a firm conclusion being drawn as to its superiority over alternative interventions, although this does not diminish the positive outcomes which have been observed.⁸⁰

Substance misuse

Motivational interviewing represents a promising approach for juvenile offenders, particularly as a treatment for substance misuse.⁸¹ Group-based motivational interviewing has received positive feedback from participants when implemented with first-time juvenile alcohol or drug offenders,⁸² and compared with TAU, juvenile offenders in receipt of motivational interviewing have greater satisfaction and display lower, though not statistically significant, rates of recidivism at 12-months post-motivational interviewing.⁸³ There is therefore preliminary evidence for the acceptability and feasibility of motivational interviewing for substance-misusing juvenile offenders, but future research regarding long-term outcomes is warranted. To date, motivational interviewing for difficulties faced by juvenile offenders beyond that of substance misuse does not appear to have received much research attention. Juvenile offenders are known for their difficulty to engage in rehabilitative services, therefore further investigation of the effectiveness of motivational interviewing in encouraging engagement is warranted.

Preliminary investigations have also developed a conceptual framework for the delivery of mindfulness-based interventions (MBI) to incarcerated substance-misusing juveniles, with qualitative impressions suggesting this is a potentially feasible and efficacious intervention.⁸⁴ Although literature regarding the effectiveness of MBI in juvenile offenders is scarce, qualitative feedback has indicated positive reception of this style of intervention, with particular improvements in subjective well-being reported by juvenile participants.⁸⁵

Employment and education

Engaging juvenile offenders with education and skills-based training is an important component of successful rehabilitation, with positive engagement in meaningful activities associated with improvements in areas such as self-belief⁸⁶ and protection against future participation in criminal activities.⁸⁷ It is concerning therefore that an evaluation of the use of leisure time over a 1-week period by probationary juvenile offenders in Australia indicated only 10% of this time was spent engaging in productive activities, such as employment or education, with 57% used for passive leisure activities, a level 30% higher than that of their non-offender peers.⁸⁸

Efforts to engage juvenile offenders in vocational and/or occupational activities have shown benefits in a number of areas. A specialised vocational and employment training programme (CRAFT) emphasising practical skills was evaluated against conventional education provision to juvenile offenders in the USA. Over a 30-month follow-up period, those engaged in CRAFT were significantly more likely to be in employment, to have attended an educational diploma programme and to have attended for a significantly longer period of time.⁸⁹ Benefits have also been reported with regard to risk of reoffending, with an after-school programme in the USA incorporating practical community projects, educational sessions and family therapy resulting in a significant reduction in recidivism at 1-year follow-up.⁹⁰

Qualitative investigations of US juvenile offenders suggest there is not a lack of interest in pursuing education among this population, but rather a disconnection with educational systems when education providers are perceived not to care about students' progress.⁹¹ Ensuring education providers are perceived as proactive and caring in this regard may therefore be an important consideration for efforts to engage juvenile offenders with educational systems. Significant barriers to engagement include difficulties in obtaining accurate information regarding the offender's educational history, in addition to identifying community-based education providers willing to accept previously incarcerated juveniles on their release.⁹²

Language and communication

Difficulties with language and communication skills appear to be prevalent among juvenile offenders, with estimates of those falling into the poor or very poor categories ranging from 46 to 67%; overall, up to 90% of juvenile offenders demonstrated language skills below average.⁹³ Specifically, high rates of illiteracy are reported in this population,⁹⁴ with evidence to suggest that an awareness of such problems among juvenile offenders themselves is associated with dissatisfaction and poor self-esteem.⁹⁵ These difficulties may act as barriers to engagement in therapeutic interventions, particularly those delivered in group settings, as well as re-engagement with educational systems. Awareness of the challenges these young people face with regard to confidence and ability to communicate is important, and potential involvement of a speech and language therapist could be considered. Preventing deficits in language and communication through effective schooling and appropriate support in the early years of life may serve as an aid to effective engagement in rehabilitative interventions, and may also mitigate the risk of engagement in criminal activities in the first instance.

Delivery of therapeutic services

Common challenges to a therapeutic youth justice pathway

There are common obstacles to smooth care pathways between different parts of systems, such as in transitions between secure settings and the community, between prisons and secure psychiatric settings, and between child and adult services. In some jurisdictions individuals can only be treated pharmacologically against their will in a hospital setting, a safeguard which limits the extent to which individuals can be treated in prison, but there is still great scope for intervention by prison mental health teams in juvenile prisons.

Factors associated with good outcomes

A meta-analysis has revealed three primary factors associated with effective interventions for juvenile offenders: a 'therapeutic' intervention philosophy, serving high-risk offenders, and quality of implementation.⁹⁶ These findings are consistent with factors posited as correlating with good outcome in residential centres for troubled adolescents and juvenile offenders: good staff-adolescent relations, perception of staff as pro-social role models, positive peer pressure, an individualised therapeutic programme approach, developmentally appropriate programmes and activities, clear expectations and boundaries, and placement locations which allow for continued family contact.^{97,98}

In the community, coercive styles of engagement have been found to be less successful at achieving adherence among juvenile offenders than a client-centred approach.⁹⁹

Factors associated with poor outcomes

'Scared Straight' programmes expose juveniles who have begun to commit offences to inmates of high-security prisons, yet these approaches have been discredited due to evidence that risk of recidivism may in fact increase following such exposure.¹⁰⁰ Similarly poor outcomes have been observed in programmes modelled on military boot camps, in which harsh discipline is considered to be of therapeutic benefit,¹⁰¹ and initiatives such as curfew, probation and hearing juvenile cases in adult court were also shown to be ineffective in reducing recidivism.¹³

Over recent years it has been repeatedly demonstrated that exposure to juvenile court itself appears to have a detrimental effect on juvenile offending.¹⁰²⁻¹⁰⁴ This may be partially explained by effects of labelling, stigma and negative self-image associated with a criminal conviction, but also the practical consequences of sentences, including assortment of delinquent peers in community or prison sentences. Incarceration presents several additional harms, including disturbance of care and pro-social relationships, discontinuity in education, association with delinquent peers, and exposure to violence. Half of detained young offenders in the UK reported victimisation during their current prison term,⁵⁷ while 12% of incarcerated youth in the USA reported sexual victimisation in the previous year.¹⁰⁵ International agreements state that deprivation of liberty (such as juvenile prison) should be used as a last resort and for the shortest time necessary, so should be reserved for the highest-risk offenders. The cost of juvenile antisocial behaviour is known

to be high, and to fall on many agencies.¹⁰⁶ The current climate of austerity in public services demands that any interventions should be not only effective, but also cost-effective, raising a clear challenge – and opportunity – for the implementation of interventions for this population of vulnerable young people. For example, parenting programmes have demonstrated sustained benefits for this population,^{107,108} with economic analysis indicating gross savings of £9288 per child over a 25 year period.¹⁰⁹ Considered together with wider costs of crime, these gross savings exceed the average cost of parenting programmes (£1177) by a factor of approximately 8 to 1.

Conclusions

Many argue that we have a long way to go before arriving at ‘child friendly’ juvenile justice.¹¹⁰ Around the world there are variable and inadequate legal frameworks that are not age-appropriate, there is a lack of age-appropriate services and establishments, and a lack of a specialist workforce, leading to challenges around training and supervision to work with this vulnerable population. In the UK and other high-income countries worldwide, forensic child and adolescent psychiatry is a multifaceted discipline incorporating legal, psychiatric and developmental fields. This approach has navigated clinical and ethical challenges and made an important contribution to welfare and justice needs by its adoption of an evidence-based therapeutic intervention philosophy.

1.6.7 ‘Doc, can I fly to Australia?’ A case report and review of delirium following long-haul flight

Thomas McCabe

Correspondence

Thomas McCabe (thomas.mccabe@nhs.net)¹

2017-2

Abstract

Air travel is now a common feature of most of our elderly population’s lives. There is little by way of warnings, rules or recommendations for our patients with psychiatric diagnoses, in particular dementia, who intend to travel by plane, in contrast to other specialties. In this article I highlight an adverse outcome of long-haul air travel as a result of delirium and resulting accelerated decline in overall cognitive function. I review literature related to the topic and suggest ways to minimise precipitating factors for stressors prior to and during flights. This article suggests that more thought should be given to the title question.

- *Discussion*
- *Recommendations*

Short-haul and long-haul air travel are now commonplace among the elderly population. Evidence suggests such travel is on the increase from the late 1990s, with as many as 1 in 5 people above the age of 65 passing through the main UK international airports in 2014.^{1,2} Little thought is given to short weekend breaks abroad or long-distance holidays with family with mental and physical impairments. In-flight adverse events are difficult to ascertain from information and figures produced by airlines, and apart from the well-recognised morbidity they are not well reported.³ Syncope, respiratory problems and vomiting continue to provide the bulk of in-flight emergencies, with around 1 medical emergency occurring in every 600 flights.⁴ There are no data focusing on the elderly population or people with a diagnosis of mental illness, although one recent source cited ‘anxiety’ as a reason for non-traumatic in-flight complaints.⁵

In this case report I highlight an incident where a delirium has had a significant impact on an elderly patient, resulting in an accelerated decrease in function, long-term impairment and associated symptomatic control with medications that otherwise could have been avoided. I will highlight ways of minimising chances of negative outcomes following air travel in the elderly population.

Case presentation

A 73-year-old man was initially referred to the memory clinic in December 2013 with a history of gradual deterioration of short-term memory and increased dependence on family over an approximate 18-month period. This was with a background of stable multiple sclerosis with no other medical history of note. He was functioning well owing to a supportive family and positive routine activities undertaken mostly with his wife and had a strong academic background which could have contributed to masking of cognitive defects. He was given a diagnosis of a mild cognitive impairment based on impaired short-term memory, as evidenced by clinical evaluation and formal cognitive testing. He scored 80/100 on the Addenbrooke’s Cognitive Examination III; most points were lost in the memory parts (where he scored 10/26) and less so in the fluency part (scoring 10/14) of the test. He was referred to neuropsychology, for brain imaging and was to be seen back in the clinic in 6 months’ time. There were no treatable cardiovascular risk factors at this point; however, the patient was counselled on exercise and diet as well as basic activities to promote cognitive training in keeping with present guidance. The patient and his wife were informed it was difficult to give prognosis and although evidence is varied, a person with amnesic (memory loss) mild cognitive impairment would be at around 1 in 5 risk of being diagnosed with dementia at a later stage. From this presentation and clinical evaluation, it was thought that an Alzheimer’s dementia was the most likely future diagnosis.

The patient then travelled by plane from Scotland to Australia, which involved a short connecting flight to London. On descent from the air to Australia, he experienced an episode of agitation and bizarre, nihilistic delusions about Nazis taking over the plane. After landing, he was admitted to a large, well-known teaching hospital in Australia. He continued to exhibit challenging behaviours such as agitation, wandering and resistance to attempts at basic care from nursing staff. The patient required assistance with feeding and one-to-one nursing care for the majority of the in-patient stay.

The patient’s medical investigations included a positron emission tomography (PET) scan, magnetic resonance imaging (MRI) brain scan, lumbar puncture, electrocardiogram (ECG), chest X-ray, urinalysis, basic blood tests and whole-body computed tomography (CT) over the course of admission without an obvious cause being found for such a dramatic decline and previously unseen behaviours. Of note, any cerebrovascular accident, pneumocephalus, acute kidney injury, external and middle-ear disease and sepsis were ruled out on admission. It was noted that there were no particular risk factors in terms of family history, smoking, hypertension, dyslipidaemia and diabetes which could have increased the risk of most of the proposed diagnoses. Basic observations, including oxygen saturations, were largely unremarkable throughout his admission. He was reviewed by both the neurology and neuropsychiatric teams who came to a joint conclusion that he was experiencing a delirium and previously undiagnosed Alzheimer’s dementia.

He was treated with antipsychotics and given a short trial of intravenous steroid given the history of multiple sclerosis (although not indicated by way of imaging) without any improvement in clinical state.

The patient stabilised enough for repatriation to the UK with a nurse escort after approximately 4 months of in-patient care. At this stage he showed significant deterioration in executive functioning from baseline assessment, limited capacity for new learning, confabulation and required assistance with all personal needs. On descent of the aircraft the patient again deteriorated, with disorientation, agitation and paranoid features once again predominant. Admission to hospital and further investigations gave us no obvious clues to an ongoing acute event. Brain imaging in both Australia and the UK remained unchanged with CT showing generalised atrophy and MRI revealing a minor degree of small vessel disease and smaller than expected hippocampal volume, and suggested Alzheimer's as the only radiological explanation for the presentation.

Outcome

The episode has had a significant effect on the patient's level of functioning and a sizable knock-on effect on his family. He is now a patient in a National Health Service (NHS) long-term care facility requiring assistance with all basic activities of daily living and without much by way of coherent or meaningful conversation. He continues to be managed with antipsychotic medications and benzodiazepines which allow him to be settled on the ward and nursing staff to assist with his needs. It is difficult to ascertain whether there has been any further deterioration in the patient's disease process, however, there has not been any improvement seen. His family continue to harbour feelings of guilt at the original decision to fly to Australia without consultation with medical staff and disappointment at being unable to care for the patient in their home.

My overall aim for writing this case is for the reader to acknowledge the case of a patient with a likely dementia who has had a stark and accelerated decline in function as a result of a change in environment and residual delirium after going on two long-haul flights. Pinpointing the precise mechanism for the delirium continues to be a challenge owing to the number of medical staff involved and the difficulties with communication between continents. Prolonged hypoxia or changes in cabin pressure would seem to be the most obvious causative factors for the delirium given the collateral history, with particular focus on symptoms becoming pronounced on descent. However, this is without any firm scientific basis and is not backed up by anything discovered on clinical examination or investigation.

Discussion

Air travel has become a normal part of everyday life in the UK, with Heathrow, the third-busiest airport in the world, estimated to see approximately 1300 take offs and landings in an average day.⁶ The advent of 'no frills' airlines in the mid 1990s has seen a marked rise in short-haul flights and regional airports have expanded as a result. Combined with the total standardised prevalence of dementia syndrome in the 65+ population, which is thought to be 7.1% at most recent estimates,⁷ air travel is now a common component for a sizable amount of the older population.

From a literature search it would appear that air travel in the elderly population is a safe practice, given that there is little evidence to suggest otherwise. However, there have been a number of reports recently of people with dementia getting lost in airports resulting in national press- and social media-aided searches.^{8,9} Roberto Castiglioni, an adviser to the UK Civil Aviation Authority, has described the impact dementia could have on air travel as 'a ticking time bomb that medical research and the travel industry are yet to address'.¹⁰

There is one reported case of an older man in Australia, a seasoned traveller, who in 2009 developed delirium on a long-haul flight and spent a long period of time as an in-patient as a result.¹¹ The authors state that the patient's decline was precipitated by air travel, but they do not expand on this. They propose that a brief cognitive screening tool to be used prior to travel be developed.

A useful review, also from Australia,¹² summarises the physical hazards associated with air travel and states that people with early dementia may be more prone to developing delirium in flight. It sets out practical ways to minimise this risk.

In contrast to the above there are strict criteria for air travel for physical ailments which are well publicised and adhered to by all the major airlines. For example, the Civil Aviation Authority suggest 14 days have passed prior to air travel following a coronary artery bypass grafting (CABG) procedure and most airlines will not allow women with single pregnancies beyond 36 weeks to travel with their companies. Compare this with the less stringent statement that they would have 'concern' (rather than instruction not to travel) with patients who may exhibit or develop 'disorganised and

disruptive behaviours' in flight, as set out in the Civil Aviation Authority's 'fitness to fly' guidance.¹³ This is a likely reflection on the lack of morbidity and mortality figures available on the topic combined with the unpredictable course and variable stages of dementia and degree of severity of delirium.

It should also be noted that not only this case described but the others mentioned in the discussion involved movement to and from Australia. It would seem unlikely that this alone is a causative factor and indeed it is the length of flight or descent from high altitude that increases the likelihood of deterioration, but it is worth bearing in mind if the overall topic expands, as some have predicted.

Recommendations

Table 1 sets out practical ways to help minimise any air travel-related situations which may potentially cause upset to a patient. These can be addressed prior to travel by input from general practitioners (GPs) and optimising control of pre-existing conditions as well as assistance with travel insurance practicalities. Contact with airports and airlines with the aim of reducing transit time through airports and assistance getting on the plane as well as sensible seating choice (i.e. more leg room, access to lavatory) may also aid in reducing potential stressors.

A summary of recommendations

Pre-flight	In-flight
Attend GP	Stay well hydrated
Optimise chronic conditions	Comfortable clothing
Travel insurance	Familiar distractions
Consider group tours	Inform cabin crew
Assistance in airport	Assistance on/off flight
Extra leg room request	Avoidance of alcohol/unfamiliar foods
Minimise time through security checks	Aisle seating request

GP, general practitioner.

I believe GPs and old age psychiatrists should consider more extensive counselling when the title question is asked and indeed any questions around travel could be pre-empted by medical staff. Patients and carers should be made aware of the dangers posed by hypoxia, changes in pressure environments and barotrauma and the potential for adverse outcomes that these can have on mental state, particularly in those with pre-existing respiratory and ear, nose and throat (ENT) conditions. Little research has been carried out into the overall use, benefit or otherwise of anxiolytics in elderly (or indeed anxious) flyers and this should be explored. Informal discussions with colleagues in the community would suggest the use of benzodiazepines is accepted and relatively common.

1.6.8 Mental capacity and borderline personality disorder

Karyn Ayre Gareth S. Owen Paul Moran

Karyn Ayre (karyn.ayre@slam.nhs.uk)¹

date

2017-2

Abstract

The use of the Mental Capacity Act 2005 in assessing decision-making capacity in patients with borderline personality disorder (BPD) is inconsistent. We believe this may stem from persisting confusion regarding the nosological status of personality disorder and also a failure to recognise the fact that emotional dysregulation and characteristic psychodynamic abnormalities may cause substantial difficulties in using and weighing information. Clearer consensus on these issues is required in order to provide consistent patient care and reduce uncertainty for clinicians in what are often emergency and high-stakes clinical scenarios.

- *Mental capacity and borderline personality disorder*
 - *Applicability of the Act in borderline personality disorder*
 - *How does BPD affect capacity?*
 - *How this affects clinical practice*
 - *Conclusions*

Borderline personality disorder (BPD) is a severe mental disorder affecting around 1% of the population.¹ It is associated with significant psychiatric comorbidity,² impairment in social function³ and a high rate of service utilisation.⁴ Personality disorder as a whole is associated with reduced life expectancy.⁵ People with BPD may engage in self-harming behaviour as a way of regulating negative affect, particularly at times of crises.⁶ Assessing decision-making capacity in a patient with BPD who requires medical treatment following an act of self-harm is particularly challenging.⁷ In the overlap between the Mental Health Act 1983 and Mental Capacity Act 2005 (the Act), it is the decisions around physical healthcare treatment without consent, i.e. those that the Mental Health Act cannot be used to enforce unless treatment is recognised as treatment for mental disorder, that in our experience generate considerable anxiety. This is particularly true in a general hospital setting as exemplified in the tragic case of Kerrie Woollorton.⁸

The Mental Capacity Act is the legal framework used in England and Wales for assessing capacity. It also provides protection to a clinician who makes decisions on behalf of an incapacitous patient, providing its terms are satisfied and the clinician is acting in the patient's best interests. Assessment of capacity is time- and decision-specific, however, in our clinical experience there is inconsistency surrounding the use of the Act with BPD patients. This is partly the result of disputes relating to the nosological status of personality disorder as a whole.^{7,9} Such disputes are discordant with

increasing knowledge about the natural history of BPD and its neurobiological abnormalities and treatability. In this article we explore the key reasons for inconsistency on whether BPD has the potential to give rise to the ‘impairment of, or disturbance in the functioning of, the mind or brain’ criterion of the Act, as well as highlighting the need for clearer guidance on the use of the Act with such individuals.

Applicability of the Act in borderline personality disorder

As indicated by Section 2(1) of the Act, patients must demonstrate an ‘impairment of, or disturbance in the functioning of, the mind or brain’ for the Act to apply – sometimes known as the ‘diagnostic threshold’. Applicability to patients with a psychotic illness or a severe affective disorder is rarely questioned, presumably because these conditions are clearly described and widely accepted as constituting mental disorders that have the potential to impair or disturb function.⁷ However, in one of the few discussions of the impact of personality disorder on competence to refuse treatment, Winburn & Mullen¹⁰ point out that personality disorder, although classed as such under the Mental Health Act 1983, ‘has always been considered to be at the margins of what constitutes mental disorder’. Although it is by no means an exhaustive list, paragraph 4.12 of the Mental Capacity Act Code of Practice¹¹ does not include personality disorder among the other conditions it recommends as having the potential to cause impairment or disturbance in the functioning of the mind or brain. Indeed, as recently as the past decade, lingering doubts about the nosological status of personality disorders in general were still being voiced by senior figures in academic psychiatry.⁹

Over the past 10–15 years, the empirical evidence base for personality disorders in general and particularly for BPD has expanded substantially. Robust longitudinal studies have charted the natural history of BPD¹² and shown that while symptomatic improvement is common, enduring impairment in social functioning³ is a defining feature of the condition. Cost of illness studies have shown that the costs of managing people with BPD exceed the costs associated with managing people with depression.⁴ Other studies have shown that the life expectancy of people with personality disorder is markedly reduced and that the loss of lived years is at least equivalent to that seen in schizophrenia.⁵ There is also growing evidence of underlying neurobiological abnormalities associated with BPD.^{13,14} Finally, the increasing number of well-conducted clinical trials which show that effective treatment is possible provides further evidence supporting the validation of the construct of BPD.¹⁵

In summary, as a result of considerable research endeavour, we now know that BPD is, without doubt, a valid category of mental disorder. As such, it must be considered ‘an impairment of, or a disturbance in, the functioning of the mind or brain’. Therefore, not only is the Mental Capacity Act framework applicable to people with BPD, but it is clinically inappropriate not to consider its relevance when assessing people with BPD. There is a need for greater consensus regarding this, to eradicate the assumption that capacity assessments, *tout court*, cannot apply to such patients.^{7,11}

Perhaps another reason why this assumption has been so pervasive relates to Parsons’s notion of the ‘sick role’.¹⁶ This illustrates the link between illness and its social benefits: among these, the absolution of responsibility.¹⁷ The doctor’s role is key, as it is the doctor who confers this role on the patient and provides social sanction for receipt of those benefits.¹⁶ Doctors are often divided as to whether patients with BPD can be thought of as being ill and thus entitled to a sick role.^{9,18} As the Act requires the presence of an ‘impairment’ or ‘disturbance in function’ to be applicable, one might view its application to BPD patients as being synonymous with sanctioning an adoption of the sick role. Such a view may not sit comfortably with a clinician who may view a volitional act of self-harm as being ‘manipulative’.^{9,18}

The issue of volitional control and, by inference, manipulation, therefore seems the crux of the matter. Pickard¹⁹ points out that it is hard to accept that patients with a personality disorder completely lack control over their actions. She qualifies this by pointing out they ‘may not always have full conscious knowledge of why they are behaving as they do’.¹⁹ Similarly, Szmukler has speculated that suicidal impulses may sometimes stem from ‘an inner disturbance the [person] finds difficult to describe’.⁷ The question for clinicians is that, in situations where high-stakes decisions must be made, how does the phenomenology of BPD impair an individual’s ability to understand and reflect on both the risks and benefits of treatment, and also the motivation underlying their behaviour?

How does BPD affect capacity?

Fuchs²⁰ identified that, at the extremes of emotional dysregulation, BPD patients become enveloped in that mental state to the extent that they are unable to view things objectively. Over time, repetition of this cycle leads to the chronic feelings of emptiness that characterise the disorder, meaning that patients ‘miss the experience of agency or authorship of their life’.²⁰ Broadly speaking, this key concept can be illustrated in two general clinical scenarios.

The first is a patient presenting as an emergency at the extreme of an episode of emotional dysregulation. Self-harming behaviours may serve an affect regulation function⁶ and assessment of capacity to accept or refuse treatment following a severe episode of self-harm is a common clinical scenario. The framework for decision-making, per the Act, requires the patient to understand the pros and cons of treatment for their condition. If the self-harm is life threatening, accepting treatment would therefore be life saving, and to refuse, by inference, a decision likely to result in death.

To ‘use or weigh’ relevant information about options in the process of deciding is the element of the capacity test that causes most interpretative difficulty in BPD. As Principle 4 of the Act states: ‘a person is not to be treated as unable to make a decision merely because he makes an unwise decision’. Deciding to refuse life-saving treatment may be unwise, but it is not the decision *per se* that we are assessing, rather how ‘accountable’ the patient is for the decision.^{21,22} Elliot has argued that in depression, even though patients may understand the risks, ultimately the disorder may affect whether they ‘care’ about that risk, thus reducing the ‘authenticity’ of the decision.²² If depression can lead to a pathological lack of ‘care’ about one’s own interests, could the drive to emotionally regulate via self-harm lead to a pathological ‘resistance’ to acting in one’s own best interests that robs BPD patients of decision authenticity?

Research has suggested that key interpersonal schemas in BPD include sadomasochistic behaviour, where patients hurt themselves in an internalised ‘punitive parent’ mode.²³ The relevance to treatment refusal here seems clear. In addition, as Szukler points out, any capacity assessment is essentially a dynamic between the patient and the doctor.⁷ Refusal of the doctor’s recommendation could also be viewed within this sadomasochistic paradigm. This is surely the source of the sense of ‘manipulation’¹⁸ frequently felt by doctors treating these patients.

The great trap in these scenarios is assuming that refusal of life-saving treatment is equivalent to a wish to die and an acceptable ‘unwise’ decision. While this may indeed be the case in some instances, this *de facto* assumption endangers the lives of some BPD patients, as in some cases the decision to refuse *per se* may simply be a manifestation of the disorder, rather than a carefully considered wish to die. The risk to these patients is compounded by an intolerance of ‘manipulation’ felt by the doctor, who in turn may take this as evidence that the patient has full insight into the situation and accept their refusal as an unwise but capacitous decision. In summary, as a direct consequence of the mental disorder itself, BPD patients may unwittingly become caught up in a destructive iatrogenic cycle of harm.

A second clinical example which aptly illustrates the lack of ‘authorship’ of life¹⁹ that may occur for people with BPD while dealing with doctors has been provided by Winburn & Mullen.¹⁰ They describe the case of a BPD patient who was judged incapacitous to refuse a potentially life-saving blood transfusion. Her decision to refuse treatment was viewed as a consistent, chronic behavioural pattern and overall constituted a ‘disturbed form of engagement ... rather than an effort to disengage’. Case law reflects these views, as seen in the case of *B v Croydon Health Authority*,²⁴ where a young woman with BPD was starving herself to the point where enforced nasogastric feeding was considered. Lord Justice Hoffman wrote in his judgment that he found it difficult to conclude that the patient had capacity, despite her seeming to have a good understanding of the risks and options. It was this that made him question whether her choice was truly autonomous, because, while being able to make cogent and articulate statements about her wishes, it was hard for him to deem someone capacitous when she is ‘crying inside for help but unable to break out of the routine of punishing herself’.

How this affects clinical practice

The assessment of mental capacity in BPD patients is complex and may therefore cause clinicians significant anxiety where high-stakes decisions are to be made. It is conceivable that such anxiety may lead to risk-averse practices. In her review of suicide risk management in BPD patients, Goodman²⁵ highlighted the influence of medico-legal concerns on clinicians, by referring to a survey²⁶ that had shown that 85% of clinicians working with BPD patients had, within the past year, practised in a way ‘that would relieve their anxiety over medicolegal risks’. In our example of the BPD patient refusing life-saving treatment following self-harm and where capacity is marginal, risk-averse practice would presumably involve erring on the side least likely to result in death, i.e. a judgement of incapacity, detention and enforced treatment.

However, Pickard¹⁹ points out that it is particularly in the interests of patients with BPD that we attribute decision-making responsibility to them where possible, as this is the basis of some of the most effective psychological treatments for BPD, where self-control and mentalisation development are key. Szmukler suggests that when capacity could be argued from both sides, ‘one might conclude that ... the patient’s account, although not the one preferred by the clinician, is an adequate one, and sufficient to demonstrate that the patient has capacity’.⁷ Law states that ‘with regard to the degree of incapacity the nearer to the borderline the more weight must in principle be attached to [the patient’s] wishes and feelings’.²⁷ In application to BPD this would appear to imply that if the incapacity is only marginal the patient should, in effect, be approached as if with capacity.

So how do we balance over- and under-attributing capacity to BPD patients in clinical practice? Buchanan’s work²⁸ is relevant to this problem. He describes that when capacity is in doubt, we may vary our threshold for deciding what constitutes true incapacity, based on the stakes of the decision. Thus, when the negative consequences of a decision are likely to be severe, the clinician would require a more robust demonstration of capacity.²⁸ In essence, the clinician is balancing possible infringement of autonomy with negative consequences of the outcome of the decision. Ultimately, capacity is judged legally to be either present or absent, but as Lord Donaldson pointed out in the case of *Re T (Adult: Refusal of Treatment)*,²⁹ doctors should consider whether the capacity that is there is ‘commensurate’ with the seriousness of the decision.

One might argue that proportionality merely reflects the clinicians’ increasing anxiety about higher-stakes situations, thus not addressing the underlying problem: that there is little consensus and guidance on whether and how BPD may affect decision-making. Clearer guidance and consensus on how BPD may affect decision-making abilities in different clinical scenarios will reduce anxiety for clinicians and may help the Act become more predictable in its application.

Conclusions

Borderline personality disorder is a mental disorder. The use of the law in treating patients with BPD should be predictable and its application to clinical scenarios reproducible. The current use of the Mental Capacity Act 2005 in assessing decision-making capacity in such patients is lacking in these respects.

While BPD should be viewed as a mental disorder, this only means the Act is applicable; it is not synonymous with the view that people with BPD necessarily lack capacity for decision-making or responsibility for their actions. The psychopathology of BPD and specifically the way this affects the ‘using and weighing’ element of decision-making capacity is extremely complex and not acknowledged widely enough either in clinical practice or within the Mental Capacity Act itself. This leads to inconsistency in patient care. Further research into this field, along with clearer clinical consensus and legal guidance, is urgently required.

1.6.9 Perceptual distortions and deceptions: what computers can teach us

Abstract

The nature of perception has fascinated philosophers for centuries, and has more recently been the focus of research in psychology and neuroscience. Many psychiatric disorders are characterised by perceptual abnormalities, ranging from sensory distortions to illusions and hallucinations. The distinction between normal and abnormal perception is, however, hard to articulate. In this article we argue that the distinction between normal perception and abnormal perception is best seen as a quantitative one, resting on the degree to which the observer's prior expectations influence perceptual inference. We illustrate this point with an example taken from researchers at Google working on computer vision.

 - *Conclusions*

No mental state examination would be complete without a statement relating to abnormalities of perception. According to Fish, perceptual abnormalities may be classified as either sensory distortions (e.g. hyperacusis and dysmegalopsia) or sensory deceptions (e.g. illusions and hallucinations), with both categories deviating from veridical perception.¹ The clean simplicity of this definition underlies part of its clinical utility, but also gives the impression that the characteristics of 'normal' veridical perception are well understood. The nature of perception, however, has troubled philosophers for centuries,^{2,3} and has been the focus of intense investigation by neuroscientists and psychologists in recent decades.⁴⁻⁷ Just how does the brain transform the light hitting the retina into the infinitely complex three-dimensional world that we see when we open our eyes? How much of what we perceive is really present in the sensory data hitting our eyes, and to what extent do our prior expectations shape our perception? Do we perceive the world as it really is, and if not, does that mean that our normal perceptions are distorted or deceptive? If so, in what way does normal perception differ

from abnormal perception? These questions may seem to be only of philosophical relevance, but researchers working in the fields of perceptual neuroscience and computer vision are regularly confronted by them.

In this article we outline some exciting insights into how the brain may construct reality. Intriguingly, these findings have come from the field of machine learning, a branch of computer science and robotics.

The problem of perception

How does your visual system construct a representation of the world? Perhaps most readers would reply that the brain extracts the information about the physical world that is contained within incoming sensory signals. Much of the neuroscience of the past half-century has investigated perceptual processing starting from this assumption.^{4,8} The account of perceptual processing found in most undergraduate textbooks states that the sensory processing pathway (including the sensory epithelia, subcortical nuclei, thalamus, sensory cortices and heteromodal association cortices) extracts information from incoming sensory data in a stepwise manner. If all goes smoothly we perceive the world ‘as it really is’.

There are several problems, however, with the view that perception proceeds by extracting information from the incoming signals alone. Perhaps the most damning consideration was recognised by George Berkeley in the 18th century as the ‘inverse optics’ problem,^{2,4} which states that information collected by the sensory epithelia is insufficient to allow an unambiguous mapping back on to real-world sources. The light hitting the retina, for example, forms a two-dimensional image, which has an infinite number of possible three-dimensional ‘real-world’ sources. The image conflates information about object illumination, reflectance and transmittance.⁴ Computer vision faces similar problems. A car, for example, looks different from different viewing angles and distances, and in different lighting conditions. The problem of inferring the state of the world from sensory data alone is (mathematically) ill-posed.⁹ One powerful illustration of this principle is demonstrated by the famous Necker cube illusion,⁵ where the sensory information alone is insufficient to resolve the question of the orientation of the wire cube and there is no simple mapping between sensory data and perception (*Fig. 1*).

Expectation is necessary for perception

If sensory data alone cannot support perception, how does the brain create accurate perceptual representations of the world? It is now appreciated that ill-posed problems such as vision can be made tractable by using contextual information to impose constraints on the interpretation of ambiguous data. In the case of vision, for example, past experiences of seeing similar visual scenes sets up expectations about the likely current state of the world, and any new sensory data are interpreted in light of these expectations. Consistent with this hypothesis, the sensory processing pathways in the brain do not just support one-way ‘bottom-up’ information flow (from low-level data in the primary sensory cortex to more complex representations in heteromodal association cortices), but also support ‘top-down’ information flow, whereby information about the current expected state of the world cascades down from high cortical areas to influence information processing in low sensory areas.^{9,10} Some have argued that the ‘heavy lifting’ of perceptual processing is performed by these top-down pathways, which make predictions about the state of the world that are tested against sensory data.¹⁰

The ability of the brain to make sense of sensory information has inspired computer scientists working on computer vision and similar problems to take a similar approach. Recently, researchers at Google created an impressive visual recognition system using a processing architecture inspired by the human brain, called an ‘artificial neural network’ (ANN).¹¹ ANNs consist of artificial ‘neurons’ that are organised into layers, reminiscent of the brain’s hierarchical organisation. These networks are particularly good at detecting features and patterns in new data, and using these features to perform classification tasks. This is similar to what the brain does when engaged in perceptual inference, which may be thought of as the detection of objects and meaningful patterns in sensory data. New data enter the ANN at the lowest ‘input’ layer (analogous to light hitting light-sensitive neurons in the retina) and is processed sequentially by progressively higher layers of the network. At each layer the network attempts to extract patterns and features from these data, with higher layers of the network extracting increasingly more abstract features. At the highest layer a ‘decision’ is made about what the data represent.

Importantly, a new ANN must be adequately ‘trained’ before it can perform successful pattern detection and classification tasks. During training the network is exposed to many different data-sets (e.g. images) and attempts to classify the data appropriately. The network is able to self-calibrate, guided by its successes and errors, in a process analogous to synaptic plasticity. After exposure to thousands of images of, say, cats, the network learns to recognise cats in images to which it has never before been exposed.

The well-trained ANN is primed to recognise salient features and patterns in new data in much the same way that the brain is primed to recognise the patterns in sensory data that are most important for detecting behaviourally relevant objects. Prior to training, the ANN is essentially blind to meaningful patterns in new data. In both the well-trained ANN and the mature human visual system the final decision about what a new image represents is the product of a delicate balance between the information contained within the image itself and the readiness of the network to detect certain features within new data.^{9,10}

Tipping the balance

Perception is therefore the product of two sources of information: the sensory data and prior expectations about the sort of information that the sensory data contain. What happens, however, when prior expectations are given too much weight?

The Google researchers provide an intuitive example of the problems that inappropriately strong prior expectations can cause in their ANN.¹¹ As mentioned previously, the highest layers of the ANN contain latent representations of objects that the network has been trained to see. The Google researchers asked a network trained to see bananas to detect and enhance ‘banana-like’ features in an image that contained only meaningless noise. This manipulation inappropriately weighted prior expectation relative to sensory data. The result was that the network was able to ‘perceive’ objects where none existed in the image itself (akin to a ‘guided hallucination’) (see the Google Research Blog article for examples¹¹). Although the mechanisms employed by this simple network manipulation are not intended to be biologically plausible, the simple experiment demonstrates the power that inappropriately held prior expectations might have on resulting perception.

To what extent can inappropriately held prior expectations influence human perception? This question has relevance to descriptive psychopathology and psychiatry. Karl Jaspers, the father of descriptive psychopathology, postulated that ‘illusions due to affect’ and ‘illusions due to inattentiveness’ may arise when a person has a strong prior expectation about the state of the world and is confronted with noisy and ambiguous sensory data.¹² This exaggerated prior expectation may be informed by the semantic context of a situation (in what have come to be termed ‘completion illusions’), the observer’s current emotional state¹³ (in ‘affect illusions’), or active imaginative processes acting on inherently ambiguous sensory data (in ‘pareidolic illusions’).^{1,12,14,15} It may be argued that in these situations the observer comes to impose their prior expectations on the ambiguous sensory data.

Contemporary accounts of hallucinations

We have argued that perceptual inference always relies on both incoming sensory data and a prior expectation about what these data are likely to represent. Additionally, we have outlined the hypothesis that illusions and hallucinations may be the result of an imbalance between these two sources of information. This simple account is consistent with contemporary theories of illusions and hallucinations, which also implicate a miscalibration between these two sources of evidence.

One of the most influential contemporary accounts of perceptual inference is that of hierarchical predictive coding.^{9,16,17} At the heart of the predictive coding account is the notion that the brain maintains a dynamic representation of the world, which is the brain’s best prediction about the state that the world is likely to be in. Incoming sensory data are compared against this representation. If there is a good match between the prior prediction and the sensory data the current representation of the state of the world is reinforced. If there is a mismatch, a ‘prediction error’ signal drives an updating of the brain’s current representation of the world, which is subsequently re-tested against the real-world data. The iterative process of matching the brain’s predictions to sensory signals underlies perceptual inference.^{10,16,17} This process can become disrupted when the balance between prior predictions and incoming sensory data is changed. The brain’s internal representation of the world will be resistant to change, and thus dominate perceptual inference, if the

prior prediction is given a greater weight than the incoming sensory data, as may happen when the incoming sensory data are noisy.^{9,16,17} It has been proposed that in some pathological states the brain may mistake its own prior predictions for new incoming sensory data, resulting in perceptual and cognitive abnormalities that share some similarity to acute psychosis.¹⁸

Another influential account of complex visual hallucinations is the perception and attention deficit (PAD) model, which was developed after studying clinical populations who experience recurrent complex visual hallucinations.¹⁹ It was found that people in these populations had combined deficits in low-level sensory processing and attention. The PAD model proposes that in order to perceive an object, the perceptual object must first be selected from a pool of candidate ‘proto-objects’, in a process guided by sensory data, prior expectations and attentional processes. In people who have a combined deficit in sensory processing and attention it is conceivable that proto-objects from a misrepresentative pool become inappropriately bound to the visual scene, resulting in a hallucination.¹⁹

Both the predictive coding and PAD accounts of illusions and hallucinations propose that an overweighting of prior expectation relative to sensory data may underlie certain perceptual abnormalities. This overweighting may be a direct result of inappropriately held prior expectations (as can occur in states of high emotional arousal), or may be secondary to a decrease in the quality (or precision) of incoming sensory data (as may occur in states of low attention, fatigue or sensory impairment).^{19,20}

Limitations

There are several limitations and unanswered questions in this ‘expectation-based’ model of hallucinations and illusions. First, although Google’s ANN provides a nice visual example of the power of overweighted prior expectation, it has key structural and functional differences when compared with the human visual system. Among these are the fact that Google’s network hierarchy has many more layers than our current best estimates in the primate brain.^{11,21} Moreover, Google’s network was trained to ‘see’ objects in a ‘supervised’ way, whereby it was told what the images actually represented during training. This bears little resemblance to the ‘unsupervised’ learning that occurs in the brain.

Perhaps more importantly, expectation-based accounts of illusions and hallucinations fall short of explaining some of the most frequently encountered perceptual abnormalities in clinical practice. The hallucinations recounted by patients with psychosis or organic disorders are often bizarre, and seem entirely unexpected given the environmental context.¹⁹ Furthermore, although the account of hallucinations given above applies to all sensory modalities, it is unclear why perceptual abnormalities often occur preferentially in one sensory modality in clinical populations (e.g. auditory verbal hallucinations in schizophrenia).¹⁵ These questions remain unanswered, and pose an ongoing challenge for computational accounts of perceptual abnormalities in psychiatry.

Conclusions

Although psychiatrists ask patients about perceptual abnormalities on a daily basis, it is not often that we stop to ponder what actually distinguishes normal perceptions from perceptual distortions and deceptions. Current work in psychology, neuroscience and computer science paints a picture of normal perception as being inextricably linked to prior expectations about the state of the world. Perception depends on a delicate balance between the sensory information that we are confronted with, and the prior expectations we have about the world. If the balance is disturbed then perceptual inference becomes disrupted. Without prior expectations, perception is a mathematically ill-posed problem^{4,9} (as illustrated by *Fig. 1*), yet when prior expectation dominates the perceptual process, humans (and ANNs) can come to perceive objects which do not exist in the sensory data. As a result, the division between veridical perception and perceptual distortions or deceptions is more subtle than one of clear qualitative difference.

1.6.10 Adherence to medication in the community: audit cycle of interventions to improve the assessment of adherence

Saeed Farooq Abid Choudry

Correspondence

Abid Choudry (abidchoudry@doctors.org.uk)¹

date

2017-2

Abstract

Aims and method To investigate whether medication adherence is monitored during follow-up in out-patient reviews. A retrospective audit was carried out with a sample of 50 follow-up patients with a diagnosis of schizophrenia or schizoaffective disorder. Following this, interventions were made prior to the re-audit (including text messaging clinicians and prompt sheets in the out-patient department to encourage adherence discussions).

Results There was an improvement on all the standards set for this audit following the interventions. More doctors had discussed medication adherence (62% second cycle v. 50% first cycle) with their patient and there was increased discussion and documentation regarding medication side-effects (60% second cycle v. 30% first cycle). More clinicians discussed the response to medication (60% second cycle v. 46% first cycle).

Clinical implications Treatment adherence is not regularly monitored or recorded in clinical notes in routine psychiatric out-patient appointments. This highlights the need for regular training to improve practice.

The World Health Organization defines adherence as the extent to which a person's behaviour – taking medication, following a diet, and/or executing lifestyle changes – corresponds with agreed recommendations from a healthcare provider.¹ Although often used interchangeably with the term 'compliance', adherence is preferred by many as it

acknowledges the patient's role in the decision-making process.² It has been claimed that increasing the effectiveness of adherence interventions may have a far greater impact on the health of the population than any improvement in specific medical treatments.³

Non-adherence to treatment is a major barrier to effective treatment in psychiatry, particularly in individuals with psychotic disorders. Rates of non-adherence vary between 24 and 40% based on medication refill rates available from pharmacy records.^{4,5} This is understandable in view of the different populations, variety of diagnoses, variable follow-up periods and, most importantly, the different definitions and measurement methods used in research.⁶ It has been reported in the literature that non-adherence rates to medication for bipolar disorder typically range between 20 and 60%, with an average of 40%.⁷⁻⁹ In schizophrenia, a systematic review of 39 studies reported a mean rate of medication non-adherence at 41%.¹⁰ When the analysis was restricted to the five methodologically most rigorous studies, which included defining adherence as taking medication at least 75% of the time, the non-adherence rate increased to 50%.¹⁰ Non-adherence to treatment in schizophrenia is often associated with potentially severe clinical consequences.^{11,12} It is also estimated that up to 40% of the total annual cost of schizophrenia, which amounts to £400 million in the UK, could be due to non-adherence to treatment.¹³

The National Institute for Health and Care Excellence (NICE) guidelines^{14,15} recommend that treatment adherence be regularly monitored in patients with schizophrenia but there is relatively little information about how this is done in clinical practice. In general, doctors uniformly underestimate the degree of non-adherence in their patients.¹⁶

Aims

This audit was aimed at investigating whether medication adherence is monitored during the follow-up of patients diagnosed with schizophrenia or schizoaffective disorder. We also evaluated the ways in which medication adherence is discussed during out-patient reviews and recommend practice improvement.

Method

We conducted a retrospective audit in 50 patients presenting to the out-patient follow-up clinic in two UK community mental health teams providing treatment for patients within the complex care team. The clinics were based in the Black Country Partnership NHS Foundation Trust. Only patients with a diagnosis of schizophrenia or schizoaffective disorder who were currently under out-patient follow-up were included. A random sample of patients was generated by taking every fifth patient from the list provided by the clinic administrator. The last clinic letter was reviewed to collect data via the medical notes and electronic healthcare records.

The standards were identified using the NICE guidelines on medicines adherence and treatment of psychosis and schizophrenia.^{14,15} The guidelines have emphasised what should be reviewed and discussed in out-patient clinics. Specifically, they recognise that the treatment should be regularly and systematically reviewed to monitor treatment adherence. During the titration of treatment the following should be regularly monitored: response to treatment, including changes in symptoms and behaviour side-effects of treatment emergence of movement disorders weight waist circumference pulse and blood pressure adherence overall physical health.

The NICE guideline on treatment adherence explicitly states that when reviewing medication the clinician should enquire about adherence: "If non adherence is identified, clarify possible causes and agree any action with the patient. Any plan should include a date for a follow up review."¹⁵ As a consequence, the standards set out for this audit were that: 100% of patients should have a discussion with the doctor regarding the medication, including response and side-effects 100% of patients should have a discussion with the doctor regarding adherence to medication if medication is stopped, reasons for this should be explored. In light of this we constructed a data collection tool for the audit (*Box 1*).

Box 1 Information gathering tool for the audit

- Was adherence to medication discussed?
- Did the clinician ask the patient about any periods when they had missed taking medication?
- Did the patient mention missing any medication and was this discussed with the patient?

- Had the patient missed any medication over the past month?
- Were side-effects of the medication discussed?
- Did the clinician ask the patient whether these side-effects had impact on their adherence?
- If non-adherence was noted to be a significant problem, were any strategies to improve adherence discussed?
- Was the response to medication discussed?
- If medication was stopped, were reasons for this explored?

Results

Audit cycle 1

Data were collected over a period of 4 weeks. The results showed that adherence was discussed and documented only in 50% of consultations, side-effects were discussed only in 30% of consultations and response to medication was discussed in 46% of cases. Further questioning in terms of assessing adherence appeared to be poorly done, with less than 10% of consultations assessing adherence in greater detail.

The results of this initial audit highlighted either a gap in clinical practice or poor documentation. The results were discussed with colleagues in the weekly audit meeting in the hospital and recommendations were made to improve the practice (*Box 2*)

Box 2 Recommendations following the first audit cycle

1. Provide formal training to doctors regarding assessing adherence during the induction for junior trainees and through a session delivered in the local teaching programme for the rest of the clinicians.
2. Provide a list of questions to be asked regarding adherence in clinics.
3. Provide a text reminder to doctors on clinic days to remind them to assess adherence.
4. Re-audit following implementation of changes.

As a consequence of the initial audit, a change in practice was brought about by introducing information sheets in each clinic room with possible questions concerning adherence to ask when assessing patients in clinic. A brief session on adherence was also added to the junior doctor induction. Then, a text message reminder was sent to colleagues. This included consultants, specialty doctors and trainees (core and foundation year 2) at the start of each clinic for a period of 3 months. The text message was very brief, reminding colleagues to discuss adherence with their patients in clinic. The colleagues' consent was sought prior to this 3-month trial. We initially planned to send the text reminders using [NHS.net](#), which provided such a service, but that stopped in early 2015. As a result, we sent out a group message using the work mobile phone.

Following this period a re-audit was carried out. It again focused on patients with schizophrenia and schizoaffective disorder but only spanned the intervention period of the prior 3 months.

Re-audit

As before, a random sample of 50 patients was selected. A similar procedure was carried out, but only patients reviewed after the initial audit were included. The same data collection tool was used (*Box 1*). The results are illustrated in *Fig. 1*.

Fig. 1: Comparison of key audit results.

The results indicated an improvement in all three key comparisons. More doctors had discussed medication adherence with their patient over the past 3 months (62% v. 50%, $P = 0.22$), and there was increased discussion with patients and

documentation of side-effects (60% v. 30%, $P = 0.0025$). More clinicians discussed the response to medication with their patients in the second audit (60% ($n = 30$) v. 46% ($n = 23$), $P = 0.16$). The results regarding further questions about adherence continued to be poor, with only 4% ($n = 2$) asking about whether the patient had missed any doses of medication. However, it was felt this may be secondary to a lack of documentation rather than being a true reflection of practice.

P -values revealed a significant difference in the two audits for the discussion about side-effects, with an improvement noted following the interventions. However, there was no significant difference on discussions about adherence and response to medication between the two audits.

Discussion

Improving treatment adherence is at the heart of clinical psychiatry. It requires building a therapeutic relationship with patients, understanding their needs and tailoring treatment accordingly. Monitoring treatment adherence is a continuous process during which the need to continue medication in the long term is regularly stressed. We need to identify the barriers and help patients and carers to overcome these. This can only be achieved if the treatment is regularly monitored for its efficacy, side-effect burden and acceptability to patients.

This audit presents a rather disappointing picture of the conversation about treatment adherence, which is not common in clinical encounters. Such discussions took place in just half of the consultations, whereas questions about possible side-effects and response to medication were raised even less frequently. The first variable improved to about 60% after regular reminders and inclusion of this topic in the junior doctor induction, but this result was not statistically significant. However, the results were statistically significant concerning discussions about side-effects, with a significant improvement noted following the interventions. This perhaps highlights the need for regular training to improve the monitoring of treatment adherence.

It has been shown that simple questions about different aspects of medication-taking behaviours can be effective in improving treatment adherence.¹⁷ Most of the information regarding assessment of adherence is based on clinical experience or limited research. Clinicians can start by asking patients 'Have you missed any pills in the past week?' A positive response indicates there may be a problem with adherence. Clinicians should bear in mind that patients tend to overestimate their actual adherence to therapy and that the accuracy of the self-report depends on the patient's cognitive abilities, attitudes and openness towards the therapist.⁶ Some simple questions that can be asked in routine clinical care include: 'How are you taking your medications?', 'Have you ever forgotten to take your medications?', 'Are you experiencing any adverse drug reactions?', 'How are you feeling since you started the medication?'⁶

The results of the audit should be interpreted in the light of some limitations. It is possible that these questions are asked but not regularly documented. Patient medication adherence was not directly measured in the audit. The study had a small sample size that represents a snapshot of clinical encounters, which may not be generalisable. The discussion about treatment adherence may have taken place in different settings such as the in-patient setting or with other members of the multidisciplinary team such as the community psychiatric nurse. We used text message reminders, which has helped the clinicians ask about adherence. Text messages have often been used to remind patients about medication, but they have not been commonly used to alter the clinicians' behaviour, and can prove a simple and effective method for improving adherence with good practice.

1.6.11 Training in quality improvement for the next generation of psychiatrists

Elizabeth Ewins Rob Macpherson Geoff van der Linden Stephen Arnott

Correspondence

Elizabeth Ewins (elizabethewins@nhs.net)¹

¹

Elizabeth Ewins is an ST6 dual trainee in general adult and older adult psychiatry and Trainee Lead for QI, Avon and Wiltshire Mental Health Partnership NHS Trust, **Rob Macpherson** is Head of Severn School of Psychiatry, Health Education South West, Bristol, **Geoff van der Linden** is a consultant psychiatrist and **Stephen Arnott** is Director of Medical Education, Avon and Wiltshire Mental Health Partnership NHS Trust.

date

2017-2

Abstract

Quality improvement (QI) projects have been shown to positively influence patient care. They provide opportunities for trainees to present and publish their work locally and nationally, and to gain valuable leadership and management experience. We describe a pilot project to engage in QI trainees across a National Health Service trust and a school of psychiatry. After the first year of this programme over half of psychiatry trainees in the school (58% of core trainees and 47% of advanced trainees) are participating in 28 individual QI projects and QI project methodology is to become embedded in the core psychiatry training course. Specialty doctors, consultants, foundation doctors, general practitioner trainees, medical students and the wider multidisciplinary team have all become engaged alongside trainees, working with patients and their families to identify problems to tackle and ideas to test.

Foundation doctors and core medical trainees are being trained to undertake quality improvement (QI) projects and are doing so competently and effectively.^{1,2} QI projects have been embedded in the Foundation Programme curriculum,³ with an expectation that trainees plan, implement, complete and present a QI project as part of their training, using the results to improve patient care. QI projects have been widely adopted across medicine and are in many areas superseding traditional audit as a way to develop services. However, the development of this methodology has been slower in the mental health field and QI projects are new to most psychiatrists. Here we outline and summarise in simple steps how to undertake a QI project. We also describe our cross-deanery project led in Avon and Wiltshire Mental Health Partnership NHS Trust and the Severn School of Psychiatry, which aims to train and support psychiatrists of the future to become actively engaged in QI projects.

What is a QI project?

QI projects aim to improve patient safety, treatment effectiveness and efficiency, and the patient experience. They are real-time, dynamic processes involving focused, progressive, small-scale changes through a simple structured framework, which enable visible and effective change over a short period of time. QI projects are becoming increasingly important because of the limited resources available in the National Health Service (NHS). They can support service change and to achieve this may engage all professional groups, including trainees. Increasingly, evidence of QI is becoming a training requirement and is taking the place of audit as a subject to discuss at trainee reviews and job interviews.

Often the relationship between audit and QI projects is not clearly understood. Audit is also generally about quality improvement, beginning with identifying an audit subject, selecting audit standards and measuring the level of performance, then making improvements and re-auditing (*Fig. 1*). The focus is therefore on data collection.⁴ This area of practice has been criticised, as often the audit cycle has been left incomplete and the improvement part of the cycle left neglected.^{5,6} QI projects are advantageously placed as they can be seen as part of the improvement element of the audit cycle, where the focus of the project is explicitly on making a service improvement instead of collecting data.⁷ Although more complex than an audit, QI projects focus on changing complex adaptive systems and can empower doctors to investigate problems, identify solutions and work within a team to raise standards.

Practical steps to carrying out a QI project

The first step in developing a QI project is identifying a specific aspect of clinical practice that could be improved. This may be something that has been highlighted by an audit or identified by the wider team. It may be aligned to the local trust's quality and safety agenda, something that has been identified as a clinical incident or near-miss, or raised by patients or their families as a problem or idea to test. Finally, it may simply be an area recognised by local clinicians as something which is time consuming or frustrating and which could be improved. The project has a small focus initially, so rather than looking at 100 patient notes one might begin with just a single patient, or instead of trying to improve a whole hospital the focus may be on a single ward. Once an improvement has been proven to work on a small scale, it can be then tested on another patient or another ward, gradually being systematically scaled up and spread to become embedded in an entire hospital or trust. Depending on complexity, the projects can be undertaken within a 6-month training post.

The Institute for Healthcare Improvement recommend asking three questions⁹ based on the 'model for improvement' when planning a project: What are you trying to accomplish? This helps to set the aim of the project, which should be SMART (specific, measurable, achievable, realistic and timely). How will you know that a change is an improvement? This helps to think about what can be measured to illustrate the impact of the change. What would be an easy measurement? This needs to be done at baseline and then repeated at regular intervals so that the change can lead to learning and to show that it works. What changes can we make that will result in improvement? Possible ideas of changes to implement to make an improvement can be brainstormed. The current sequence of events already used can be examined and areas for improvement identified, for example by eliminating unnecessary tasks or steps, clarifying roles within the process, or by reducing delays and duplication.

Testing changes: the 'plan, do, study, act' (PDSA) cycle

The 'plan, do, study, act' (PDSA) cycles can be used as a way to develop, test and then implement a change on a small scale and in a real work setting (*Fig. 2*).^{9,10} Multiple PDSA cycles will be required to fully implement a QI project.

Stage 1: plan

The first stage is about planning a test of change. This involves taking a single idea and making a prediction as to what might happen when the change is implemented. A test and way of measuring whether what actually happens meets that prediction needs to be designed so that the impact of the change can be evaluated and learned from. This might be numerical data, such as increasing numbers of reviews of patients, or reducing numbers of critical incidents, and may also include patient and/or staff satisfaction scores or comments. Once you have determined what you are going to measure, make a baseline measurement. Determine what target you are aiming for: is it realistic? Plan the time you have available: for example, do you want to complete the project within the time frame of a training post? The planning stage can take time, but good planning will ensure a more successful project.

A useful tool for the early stages of planning a QI project is a driver diagram (*Fig. 3*), which can help to identify what steps could be taken to make an improvement. This has three columns: outcome (the aim of the project) and primary and secondary drivers. Primary drivers are the overall improvement areas that need to be addressed to achieve the desired outcome. Secondary drivers are the specific areas where changes or interventions can be made, motivated by the primary drivers.

Stage 2: do

Following careful planning, one small area of change can be identified. The second stage of the PDSA cycle is where the change is actually implemented. Measures of the impact of change should be taken from an early point and frequently to monitor the effect of the change. Any problems or unexpected results are noted while the change is carried out.

Stage 3: study

The third stage involves analysing collected data and comparing that with the predictions made. A graphical representation of the measurements taken can be a useful way of plotting results to illustrate the pattern observed as changes are made.¹² A goal line can be shown so one can see at a glance where the work is in relation to achieving the aim. Changes or improvements that are made (in repeated PDSA cycles) can annotate the graph to clearly demonstrate the impact of those changes (*Fig. 4*).

Stage 4: act

In the final stage of a PDSA cycle you can ask whether the change you made achieved your aim. If not, what modifications to the change could be made? Or what other ideas can be put in place? When you are ready to make another change, the next PDSA cycle can be outlined.

Implementing and spreading changes

By going through several PDSA cycles a small change can be tested and refined. Once a successful improvement has been proven on a small scale, it can then be tested on a larger scale. This might be across several wards or across several community teams. Once these pilot changes are proven to be successful, they can be embedded in everyday practice and incorporated into local trust policy.

Training in QI for the next generation of psychiatrists – a pilot programme

This is the first year of a pilot developed in the Severn Deanery to support core and advanced trainees to become involved in QI. The programme is being led by an advanced trainee (E.E.) as part of an Educational Fellowship awarded by the Deanery.

Until 2015 it has been a deanery requirement of trainees to carry out an audit project annually. This was amended so that all trainees are to be involved in either an audit or a QI project each year, and if an audit is undertaken trainees are encouraged to use QI methodology for the implementation of change part of the cycle. The structure of training and supporting trainees to undertake their own QI projects was adapted from the local Foundation School¹ and the Royal College of Physician's 'Learning to make a difference' programme.² A half-day training session was developed to teach trainees about QI and project methodology, including using PDSA cycles in practical examples, so that they could undertake their own projects. This was delivered by E.E. alongside the local trust audit and QI department lead. Trainees were encouraged to come up with their own ideas for projects and to work with other trainees to implement changes, under the supervision of a higher trainee, specialty doctor or consultant. They were supported in including the wider multidisciplinary team in developing and implementing projects, as it was felt that this would be more likely to lead to successful and sustainable changes being made.

Training was initially targeted at trainees, but a growing number of specialist doctors and consultants requested to attend and they were invited to a second training session. A resource handbook was developed and a series of short follow-up sessions put in place to provide further advice about QI methodology and to help support trainees' projects. Trainees were asked to register their projects by completing a short online form on the local trust audit and QI academy webpage so the trust can monitor participation.

Results so far

In the first year of this programme, QI projects (28 in total) are being undertaken by 58% of core trainees (21 of 36) and 47% of advanced trainees (16 of 34). A growing number of specialty doctors (6 of 54; 11% of the Trust's total), consultants (24 of 111; 22%) and colleagues from the wider multidisciplinary team, as well as foundation doctors and medical students, are becoming involved in projects. Examples of current projects being undertaken by trainees in the Deanery are shown in *Box 1*. Some trainees have chosen to undertake educational QI projects, which are being used to improve training and trainee representation in their organisations and are felt to be a way of engaging trainees in the trust.

Evaluation of the programme so far through post-course questionnaires and semi-structured interviews held at the end of projects has shown globally positive feedback from consultants and high engagement and enjoyment from trainees. Trainees report high satisfaction owing to being able to choose their own QI projects rather than being instructed what to do. All trainees report that training sessions and follow-up advice has been helpful, and feel that this should be provided to all staff across the multidisciplinary team. One trainee fed back that 'the quality improvements often end up involving other team members so it would be good to get them on side', whereas another trainee highlighted that 'training is needed for senior staff members who we may need to get on board.' Additionally, trainees reflected that most projects needed senior input to facilitate implementation and sustainability of successful changes, and several projects have needed advice on governance issues, which has been provided by the Trust's Quality Academy, responsible for audit and QI projects.

We have found that owing to the nature of our work in mental health, QI projects sometimes need to be structured in a different way than they would be in an acute hospital setting. Careful consideration is needed to find the most appropriate method of change measurement, as frequently qualitative data may be available and innovative methods of quantitative data have been required. We have also found that QI projects have often had to run over a longer period than they perhaps would in an acute hospital, perhaps owing to the longer in-patient stay in a psychiatric hospital.

During the pilot we found that forming close links with the trust Quality Academy provided invaluable assistance in setting up the scheme. The Academy has a QI project lead, who provides advice and training for trainees; they have been particularly helpful with guidance regarding governance and what permissions might need to be sought. Support

from trust medical management leads, including the medical director and director of medical education, has also been key.

As well as positively influencing patient care, trainees report that projects are providing them with invaluable opportunities for leadership and management experience. One advanced trainee leading a QI project reported they had gained ‘experience of leading a team as well as networking with other teams, management experience through attending meetings and presenting ideas, plus the project has provided opportunities to present at a departmental and regional level, as well as an opportunity for publication. This is in addition to positively influencing the future of mental health services’. Many trainees are beginning to present and publish their work and we encourage trainees to do so even if a project has not been fully successful, as much will have been learned by the trainees, and can be learned by the Trust, from all projects.

Box 1 Quality improvement projects being undertaken by trainees across the Severn Deanery

- Improving handover between trainees
- Ensuring physical health monitoring of patients prescribed antipsychotics
- Improving the quality of letters written to general practitioners
- Ensuring timely access to radiology results
- Promoting awareness of mental health in an acute hospital
- Providing support for new consultants
- Advance care planning in later life
- Improving the quality of ward rounds in forensic services
- Training nursing staff about physical healthcare issues
- Providing patients and their families with information regarding child and adolescent mental health services (CAMHS)
- Improving the local academic programme
- Developing an out-of-hours handbook for trainees on call
- Ensuring physical health assessments for patients in early intervention in psychosis
- Improving access to mental health assessments for women during the antenatal period
- Improving trainee representation across the mental health trust

Box 2 Useful resources

- The Institute for Healthcare Improvement website (www.ihl.org) provides many free resources to guide professionals through a quality improvement (QI) project (e.g. short videos which describe the steps involved).
- BMJ Quality (<http://quality.bmj.com>) has an online guide to implementing a QI project and then writing it up, producing a publishable paper as a result. It can be useful to buy a licence to do this and follow the steps (licences last for 1 year so in the case of longer-term projects it may be prudent to sign up later rather than at the start of a project). Note that demonstration of clear ‘plan, do, study, act’ (PDSA) cycles is required for successful publication. There is a growing database of published QI projects which may prove inspirational for ideas that can be developed in psychiatry.
- Local audit departments may be able to support projects directly and help identify potential QI project areas. Health Education England also publishes innovative ideas which can provide further inspiration (<http://hee.nhs.uk/>). Service user groups can be another source of ideas for QI projects.

Future plans

The training course is to be incorporated into the Deanery core trainees' course and it is expected that all new core trainees who have joined the Deanery in the 2015 summer intake will participate in a QI project each year. Formal evaluation of the impact of training and QI projects is to be undertaken for this cohort. Those trainees who have successfully completed a QI project will be encouraged to become mentors and local QI leads in their area for future projects, providing sustainability for the projects as well as supervision, teaching and leadership experience for trainees.

QI projects undertaken by trainees and their seniors are to be regularly presented at the Trust's Medicines Advisory Group meetings, which will not only spread innovative ideas but further encourage psychiatrists to become involved in projects. Connections are being developed with service user groups and local patient safety programmes to help trainees define problems to tackle and ideas to test. Links have been made with the West of England Academic Health Science Network and the Royal College of Psychiatrists' South West Division E-volution programme (www.rcpsych.ac.uk/workinpsychiatry/divisions/southwest/innovationinthesouthwest.aspx) to promote the wider spread of quality improvement and innovation.

We have compiled a list of useful resources (*Box 2*) and tips for developing a QI project (*Box 3*) drawing on our own experience in the Trust.

Box 3 Top tips for completing a quality improvement (QI) project

- **Take time to plan your project.** You may be keen to start putting in place changes and improvements, but ensuring careful planning will mean that a project is more likely to be successful.
- **Have a SMART aim.** Be clear and focused. Have a clear aim so that everyone knows what you are trying to achieve. Make your aim SMART (specific, measurable, achievable and agreed, relevant and time-bound).
- **Keep it small.** This will help ensure an improvement works. Once it is proven to work on a small scale, it can be rolled out more widely.
- **Think outside the box.** Get a group of interested trainees, consultants and the wider multidisciplinary team to think about the project with you and help brainstorm ideas for improvements. This will engage others and help the project to be a success. Get advice from your audit department.
- **Work in a team.** This is more fun, you will come up with more ideas and will feel more motivated.
- **Involve key stakeholders.** Who needs to know about the project for it to be a success? Do you need any approval to carry out changes? This might be a team consultant and team or ward manager, or it could include your clinical director, medical director or director of medical education or head of school. You could present your idea at a local academic meeting.
- **Sustainability.** Think about how you can make your improvements continue, especially if you are in a training post and will be moving on in 6 months or a year. You will need to involve your multidisciplinary team and local team managers.
- **Organise your time.** Think about how much time you have available to complete the project. Set yourself a time frame and stick to it. If you will be moving from a training post, think about whether you want to continue making changes after you leave or whether you need to do some succession planning.
- **Make the most of the opportunity.** After all that hard work, make sure you get some rewards! Present your work locally, submit a poster to a conference, and write up your work and get it published. QI projects frequently provide leadership and management experience, and often teaching opportunities which you can mention at your annual review of competence progression (ARCP), annual appraisals and at job interviews.

We are grateful to Janet Brandling and Emma Adams (AWP Quality Academy), Bridget Kelly (AWP Medical Education Project Manager) and Katherine Finucane (Consultant and QIP Lead, North Bristol Trust) for guidance and support in developing QI projects across the Severn Deanery.

1.6.12 The most important things I have learnt in my career as a psychiatrist

Julian Leff

2017-2

Abstract

This paper is something of a patchwork, incorporating many issues that have intrigued me during 34 years of research. I have included the importance of maintaining a solid base in clinical work, alongside research activities, and being alert to the possibility of a somatic condition contributing to psychiatric symptoms. I stress the value of careful observation of patients, their response to treatments and reasons for dropping out. In addition, I have included 14 more lessons, learned from my experience of research, which I hope will be of use to those readers who aspire to become researchers.

Contents

- *The most important things I have learnt in my career as a psychiatrist*

I was attracted to psychiatry by my experience as a medical student at University College Hospital. Students on the psychiatry firm were expected to take on a psychotherapy patient, supervised by one of the senior therapists. This was the first time in my medical training that I felt valued as a clinician and treated as a responsible adult. (There is an important lesson here for improving the very low recruitment of medical students to psychiatry.)

Having graduated as a doctor I was keen to begin my study of psychiatry and sought advice from Sir Martin Roth, president of the Royal College of Psychiatrists at that time. He was adamant that I had to obtain the Membership of the Royal College of Physicians before applying for training in psychiatry. This was daunting as the Physicians' exam had a very low pass rate. I spent 3 arduous years as house officer in hospitals in London's East End before passing the exam. However, in a strange way it felt like coming home. This was because my father and his family lived in a house in the East End, at least until it was completely destroyed by a German bomb. By working with East Enders I learned to appreciate the fortitude and strength of people in the lowest stratum of society, and I never forgot that.

Throughout my career I always continued with clinical work alongside my role as director of two research teams, holding weekly out-patient clinics and having consultant responsibility for half an acute admission ward at the Maudsley Hospital and later at Friern Hospital. In addition, I supervised community mental health teams for their work with families. In this paper I will present the important things I have learned from both my clinical and my research activities.

Becoming a Fellow of the Royal College of Physicians (FRCP), I applied to the Maudsley training scheme and was accepted. When I met the other trainees in my intake, I found to my chagrin that only half of them had passed the Physicians' exam. There was one occasion in my psychiatric practice when my medical expertise proved its value. An out-patient in my clinic was complaining of anxiety and breathlessness, specifically when leaving her home and being in crowds. Naturally, I diagnosed a phobic condition and prescribed an anxiolytic. As she was about to leave the clinic, she said, 'By the way, doctor, I have a rash on my legs'. I asked her to show it to me and immediately recognised the raised purplish bumps of erythema nodosum. I referred her to the medical specialists who took over the treatment of her medical condition and cured her of her breathlessness.

Lesson 1: always bear in mind the possibility of an underlying medical condition

There is an expanding literature on comorbidity between psychiatric and medical conditions that partly contributes to the high mortality rate in psychiatric patients.

Lesson 2: make careful observations on patients and their response to treatments

Observant clinicians remain curious about puzzling aspects of everyday psychiatry, and this attitude can stimulate research projects which have the potential to lead to breakthroughs in psychiatric treatments. For example, my concern about the failure of antipsychotic medication to suppress auditory hallucinations in one in four patients led me to develop avatar therapy,¹ a novel and effective treatment for this debilitating condition.

Lesson 3: always listen carefully to the patient's narrative

Do not dismiss the patient's belief about the cause and nature of their illness. It has been shown that the greater the disparity between the patient's and the physician's understanding of the patient's illness, the less likely the patient is to adhere to the prescribed treatment. The same caveat applies to the family carers' beliefs about the patient's illness, even if they depart widely from your own understanding. UK psychologists were the first to adapt Beck's cognitive therapy for depression to treat psychosis (CBTp). My experience of working with family carers of people with schizophrenia taught me that many low expressed emotion family carers had developed effective coping strategies for dealing with the patient's difficult behaviour, for example, distraction, reality testing and time out, which closely resembled CBTp. If professionals had listened to these family carers, and given credence to their narratives, they would have introduced CBTp much earlier, saving considerable suffering. While CBTp alleviates the anxiety of patients with persecutory auditory hallucinations, it has little impact on their frequency or volume, as opposed to avatar therapy.¹

Lesson 4: the value of qualitative studies

Qualitative studies provide information of a different nature to quantitative studies, such as patients' experience of novel therapies, but they are of equal importance. Quantitative and qualitative studies are not in competition, but complement each other and are very informative when employed in tandem. An example is the current large-scale replication study of the value of avatar therapy.² Standard quantitative measures of the participants' assessment of the power and malignancy of their persecutory voices are augmented by the participants' accounts of their experience of standing up to the avatar they have created as a proxy for their persecutor.

Lesson 5: it is all too easy to become fascinated with esoteric research and to allow its demands to divert you away from basic clinical work

Working with patients is the crucible that generates the questions that inspire research projects. I cannot emphasise enough the importance of maintaining contact with everyday psychiatric patients, and not being lured exclusively by the glamour of exotic conditions. When I was granted a chair, I was the only professor in the Institute of Psychiatry (now Institute of Psychiatry, Psychology and Neuroscience (IoPPN), King's College London) who held clinics for local patients. Happily, that situation has now changed.

My research career began in earnest in 1968 when I was offered a position in John Wing's Medical Research Council Social Psychiatry Unit at the Institute of Psychiatry. I spent 34 years as a researcher, focusing mainly, but not exclusively, on psychosis. Many of the important lessons I learned were as a result of my research experiences, and it is these I wish to share with you, in the hope that they will inspire you to undertake your own research projects. There are so many unanswered questions in psychiatry that we need many more researchers to tackle these. Sir Aubrey Lewis, who founded the Institute of Psychiatry, was dedicated to promoting research and insisted that trainees conduct their own research project in order to pass their final exam. Sadly this requirement lapsed after Sir Aubrey retired.

Lesson 6: formulating a question

Junior colleagues would often approach me, eyes shining with excitement, saying that they wanted to do research 'with a capital R'. I would then ask them what they would like to do their research on and would be met by a baffled silence, clearly expecting me to spell out a project for them. If a topic engages your curiosity, you need to do some hard thinking and formulate a question that you want to answer. A well-constructed question can be developed into a series of hypotheses, which will determine the trajectory of your research project. A well-designed research study will always generate new unanswered questions that will then form the basis for the next study. The results of a research project you did not expect are as important as those you anticipated, and should lead you on to a new study. Consider the following sequence.

When Christine Vaughn joined the Social Psychiatry Unit, she decided that she wanted to embark on a PhD to replicate the findings of Brown, Birley and Wing that high expressed emotion in family carers significantly predicted relapse of schizophrenia.³ This pioneering study was surprisingly neglected by the psychiatric community, probably because of

the prevailing adherence to biological explanations for schizophrenia. Christine and I decided that a replication would attract the attention these findings deserved.

We discussed collaborating on this project and I suggested that it would add value to the research if we included a group of patients with depressive disorder to ascertain whether expressed emotion was a specific predictor for schizophrenia or whether it would predict relapse of depression as well. In the event it turned out to be a more potent predictor for relapse of depression than for relapse of schizophrenia, as shown by Jill Hooley in her PhD in the USA.⁴ In addition, our study replicated the protective effects of medication and low contact with the carer against the stress of high expressed emotion that the earlier study had revealed. This stimulated me to consider the possibility of intervening in high expressed emotion families to lower expressed emotion and contact between the patient and the family carers. There were two compelling reasons for this: primarily, to determine the direction of causality (do high expressed emotion attitudes cause relapse of schizophrenia or does the patient's disturbed behaviour provoke high expressed emotion attitudes?); and also to determine whether our family interventions could improve the outcome of schizophrenia.

For this project I assembled a team of therapists with different areas of expertise: a cognitive-behavioural therapist with experience of working with groups, a psychodynamic psychiatrist, a psychiatrist from Germany who was a trained psychoanalyst and myself as an eclectic therapist with no strong adherence to any one theory of family functioning. The therapy used by this heterogeneous team was remarkably effective, succeeding in reducing the patients' relapse rate over 9 months from 50% to less than 10%.⁵ The success of this trial led to two more randomised controlled trials (RCTs), including a cost-benefit study. The accumulation of this evidence plus ten replications in different countries led the National Institute for Health and Clinical Excellence (NICE) to recommend that family carers of a patient with schizophrenia must have professional input. This outcome justified the 15 years it took to complete the sequence of RCTs.

Lesson 7: the danger of linear thinking

Linear thinking results from the idea that causal action flows in one direction only, from cause to effect, from producer to produced, analogous to a series of billiard balls in motion. The issue of linear thinking in the social sciences, including psychiatry, merits some discussion.

Linear thinking forms the basis of almost all biological research in psychiatry. It has a long history, having been first formulated by the Greek philosophers Anaximander and Plato. In the modern era, Von Bertalanffy was the first to challenge linear thinking.⁶ He stated that we must think in terms of systems of elements in mutual interaction. At that time, the development of cybernetics promoted systems thinking. The process of feedback whereby missiles could monitor and correct their trajectory was recognised as analogous to the biological system's capacity to maintain and organise itself in nature. This formulation was seen as very relevant to the process of family therapy. The family theorist Gregory Bateson wrote: 'I think that cybernetics is the biggest bite out of the Tree of Knowledge that mankind has taken in the last 2000 years'.⁷ It is ironic that a technology developed to destroy human beings should contribute to our understanding of family relationships.

Homeostasis is a concept fundamental to systems theory. It is achieved by negative feedback loops, which stabilise the system by reducing deviation between goal and performance (cf. missiles). By contrast, positive feedback loops reinforce or amplify deviations, producing novelty and instability and an increase in the complexity of the system, leading to new properties. Applying this understanding to social relationships, which are of central importance to psychiatry, feedback represents the direct perceptual report of the effect of one's behaviour on others, for example, the perception of a smile in response to one's own smile.

Robert Dubin considers that the difficulty of avoiding linear thinking stems from our propensity to look for isolatable one-way causes.⁸ Feedback processes can easily be overlooked, not only because the linear perspective is the dominant mode, but also because they tend to be unnoticed owing to their very pervasiveness.

Earlier I stated that one compelling reason for working with high expressed emotion families was, I quote myself, 'to determine the direction of causality'. You will now recognise this as a prime example of linear thinking. In actuality I was aware that there were multiplex interactions between patients and their family carers, but this was too complex to investigate at that time.

Now I will give you some practical advice on initiating research and carrying it through to publication.

Lesson 8: searching the literature

Electronic databases have made this much simpler and more efficient. Decide on the criteria for your search, and be overinclusive rather than underinclusive (obviously, irrelevant papers can be deleted without needing to read them). Summarise what has been established. This requires a critical attitude to research by others, however eminent they may be. Weigh up the evidence and come to a conclusion. This may be that the question you formulated has been adequately answered, in which case, back to the drawing board!

Lesson 9: focus on a single topic

Avoid being too ambitious. If your initial project produces useful results, you can always extend it. Seek advice from experienced colleagues. They can warn you about pitfalls in your chosen area of research.

Lesson 10: applying for funding

When applying for funding, choose the funding body carefully, paying close attention to their mission statement. It is often worthwhile beginning with a pilot study which can be mounted with minimal or no costs. For instance, determining whether your catchment area will provide sufficient patients for your study. This will show potential funders that you are a serious contender.

Lesson 11: anticipate the concerns of the ethics and research and development committees

Gaining approval from these committees is now an obligatory hurdle to surmount. There are a number of actions you can take to improve your chances of being approved. Anticipate objections from committee members, and be prepared to be able to counter them. In my recent trial of avatar therapy, I anticipated that there would be anxiety in the committee about patients' response to being faced with their persecutor in the shape of the avatar. Therefore, with the aid of my IT specialist, we constructed a bright red 'stress button' which the patient could press in case of high anxiety or for any other reason. This switched off the avatar image on the monitor, which was replaced by an image of a tropical beach with *The Four Seasons* by Vivaldi playing in the background. In the event, only 2 patients out of 18 pressed the stress button, and both were able to continue with the session after reassurance.

Lesson 12: appreciate the value of user-researchers

Involve service users in your study. They should certainly be asked to read the instructions for potential participants, and to suggest changes to the wording. Users can be recruited to play a more important role in your study. The IoPPN has established a list of user-researchers. These are users who have largely recovered from a psychiatric illness and are willing and able to be trained in research procedures. For example, in my avatar therapy trial, I employed a user-researcher who had heard voices himself 8 years previously and was now completely well. I trained him in the assessment tools and he achieved high interrater reliability with me, enabling him to undertake the role of an independent assessor, for which of course he was paid. The employment of users will be greatly appreciated by the ethical committee. If you do appoint a user-researcher, they must be included as an author.

Lesson 13: team building

If you are ambitious and wish to undertake a major study you will need a team, preferably multidisciplinary in nature. Diversity of professional expertise is an asset, as we experienced in our development of working with families. Consult a statistician early on in designing the study. Statisticians are understandably grumpy if they are asked at the last minute to conduct the data analysis without having given any prior input. Develop a cohesive group and deal with rivalry. The media often depict research as a gentlemanly pursuit of the truth. That is a fallacy. There are glittering prizes to be won through research, and the world of research is as competitive and cut-throat as multinational capitalism.

Be fair to junior members of the team. Encourage and support them and give them experience in presenting and appropriate representation in publications. In mid-career I left the Maudsley to take charge of a dysfunctional research group working in a traditional psychiatric hospital. It had been managed by two absentee directors and was in a state of anarchy, with one member of staff suing the directors. The aggrieved staff member left and I had to dismiss another member of staff. I knew my intervention would be resented so introduced a Friday lunch-time picnic in the extensive grounds of the old psychiatric hospital, followed by a game of croquet on the lawn next to the former medical superintendent's villa. I reasoned that being able to knock my balls around would diffuse aggression, and so it did.

There were two reasons for my leaving the Maudsley to work in Friern, a typical 19th-century asylum. One was to emerge from the shadow cast by John Wing, the director of the Medical Research Council Social Psychiatry Unit. Although John left me to pursue my own research interests, he was nearing retirement and I knew that to stand a chance of taking over the directorship of the Unit, I would have to prove that I was capable of mounting important research independently from him. The other reason was the split in the profession of psychiatry between the academics and psychiatrists working in provincial hospitals; the latter felt overburdened by their workload and disregarded by the academics, whom they saw as existing in a 'cloud 9' environment, protected from the realities of jobbing psychiatry. Given that in that era the great majority of psychiatrists were working in antiquated buildings, with insufficient support from psychologists, occupational therapists and other ancillary staff, I felt that I needed to experience the reality of life in an asylum.

It felt to me like another world. The Italianate Gothic frontage was forbidding, as was the original plaque designating the building as the West Sussex Pauper Lunatic Asylum. The entrance corridor was a third of a mile long. At that time it was the longest hospital corridor in Europe. It had windows throughout its length, but they were so low I could only see through them by stooping uncomfortably. At the end of the corridor was a faint glimmer of light from the world outside. Despite the gloom that descended on me, in time I began to appreciate the good qualities of Friern. It was set in extensive grounds, which included a football field and a 9-hole golf course, on which I never saw anyone playing. There was a chapel and a synagogue, and a factory outlet where low-cost clothes were available. Although the main gate was always open, very few patients ventured out into the street. Patients wandered around the grounds unhindered and sexual liaisons were undoubtedly formed, as one of the long-stay patients in my care regularly developed gonorrhoea. I began to appreciate how easy it would be to become accustomed to the environment of the asylum and to forget the existence of the outside world.

Lesson 14: the staff in an institution are often more institutionalised than the patients

Not long after I moved to Friern Hospital the Regional Health Authority decided to close Friern and Claybury hospitals in accord with the government policy of that time. I realised that this was a unique opportunity to evaluate this policy. I succeeded in obtaining funding from the Regional Health Authority, later supplemented by funding from the Department of Health. This enabled me to form a group of researchers under the title of TAPS: The Team for the Assessment of Psychiatric Services. Friern Hospital had been opened in 1851 with 1000 beds. The number of patients grew exponentially, reaching 2500 in the 1940s. The discharges of many patients between 1940 and the beginning of the TAPS programme had reduced the number of long-stay patients to 800.

The first step in the TAPS project was to conduct a comprehensive assessment of the symptoms and the problem behaviours of all the remaining patients in the two hospitals who did not have dementia. Complete data on all 700 patients were collected by the team, a mammoth undertaking. A 5-year follow-up was conducted on this group of patients, of whom only a tiny number were lost to the study, thanks to the efforts of the excellent administrative assistant who made regular checks on the patients' locations in the community. Meanwhile, an extraneous researcher, not a TAPS

member, carried out a survey of all the nursing staff looking after the remaining patients, asking them to estimate the number of patients who could be resettled in the community. The total percentage estimated by the nursing staff was one-third. If this was accurate, the possibility of closing the two hospitals within the 10-year limit set by the managers was negligible. However, the TAPS team had already begun asking individual patients for their preferences when the hospitals closed: one-third wanted to leave the hospital and live in the community, one-third opted to stay in the hospital and one-third were uncertain. In the event, all the patients considered suitable to live in the sheltered homes in the community by the resettlement teams adapted well to life in the outside world, and when asked where they would prefer to live a year later, 84% wanted to stay where they were.⁹

Friern hospital did close on time 10 years after the decanting began. The Claybury closure was delayed because the consultants there went on strike against the closure decision, but the strike collapsed after 6 months and the closure went ahead. So psychiatrists can be as institutionalised as nursing staff.

Lesson 15: presenting at conferences

Always try out your presentations with a sympathetic audience and take note of their criticisms and comments. The golden rule for slides is ‘never put more on a slide than you can get on a T-shirt’. I am often amazed at seeing experienced researchers cramming a slide with illegible lists of data and *P*-values and then saying to the audience, ‘You probably won’t be able to read this but what it shows is ...’ – if it can’t be read, don’t show it!

Lesson 16: writing up the results

Avoid the pall of conventional scientific writing. Break through the conventional anonymity of the passive voice. Humanise your writing to make it attractive to the reader. Keep the language simple and avoid too many technical terms. Always spell out abbreviations the first time they appear in a paper, including the abstract. Pay special attention to the clarity and layout of tables and figures – ensure that they are essential for the understanding of your results. Editors dislike large numbers of tables and figures since they occupy space that could be used to publish another paper. Avoid duplicating results in the text as well as in tabular form.

Lesson 17: submission to a journal

Choose the journal carefully, surveying past issues for the types of papers published. Always read instructions to authors with great care and observe them, particularly the word limit – if you exceed this, your paper will bounce back rapidly. Find out the proportion of submissions accepted, if possible. Always treat the reviewers’ comments seriously and couch your responses respectfully, even if you think the reviewers are idiots. Don’t give up at the first rejection, but look for alternative journals. There are so many journals being published now that there is considerable overlap in their remit. If you are inexperienced, do not be too ambitious in choosing a journal with a high impact factor. I sent my recent paper on avatar therapy serially to *Nature*, *New Scientist* and *Archives of General Psychiatry*, all of which rejected it without sending it for review. So much for hubris! It was eventually published in the *British Journal of Psychiatry*. I was mollified when following a press conference the paper went global.

Maintaining safety

I am interpolating this issue, not to raise your anxieties, but to convey the important advice I received from a senior colleague early in my clinical career. What he said was ‘never let the patient get between you and the exit door of your clinic’. A colleague and friend of mine at the Maudsley Hospital was unaware of this advice and preceded the patient into his clinic; the patient then stabbed him in the back with a pair of scissors. Fortunately, the wound was superficial.

Finale

Do not be put off by the hard work and inevitable disappointments. They are more than compensated for by the intellectual excitement generated by research and the knowledge that you are improving the lives of your patients.

1.6.13 Dudleigh Oscar (John) Topp FRCPsych, MBBS, MFCM, DPM

: Formerly Principal Medical Officer, HM Prison, Brixton

John Topp

date

2017-2

Contents

- *Dudleigh Oscar (John) Topp FRCPsych, MBBS, MFCM, DPM*
- : *Formerly Principal Medical Officer, HM Prison, Brixton*

John Topp, who died on 23 February 2016, was a Principal Medical Officer who was one of the first to draw attention to the increased rate of suicide among the prison population. In the late 1970s, he showed that suicide was three times as common in prisoners as in the general population, that it was most common in those with sentences longer than 18 months and that the greatest risk was in the first few weeks in custody.¹ He subsequently advised on suicide prevention in prisons.

Topp always felt deeply that the prison medical services were often unfairly maligned. He knew that the antiquated estate and restrictive budget did nothing to enhance the practice of modern medicine; yet, he felt that on the whole prisoners were given good care within these constraints. He found the hospital officers of the Prison Medical Service to be generally excellent but felt that many were denied opportunities to achieve the nursing qualifications they desired. Much criticism, he felt, would have been spared if training had been far better resourced and achievement suitably rewarded. Nevertheless, his view was that although the service was not superficially attractive, for those prepared to put effort and interest into it, there could be considerable work satisfaction – something he enjoyed himself despite much frustration.

Dudleigh Oscar Topp, always known as John, was born on 11 September 1924 in Hove, the son of a bank manager. A practising Roman Catholic, he was educated at the Xaverian College in Brighton and attended King's College London, from where he went to Charing Cross Hospital Medical School, qualifying in 1949. After house posts at Oldchurch Hospital, Romford, he served as a captain in the Royal Army Medical Corps in Northern Ireland. He joined the Prison Medical Service in 1953 at Wakefield prison and later became Senior Medical Officer at Brixton prison, from where he was promoted to Principal Medical Officer to serve regionally and centrally, administering various aspects of the prison medical services.

He retired on medical advice in 1984 but remained actively interested in prison affairs and wrote books on the history of the Prison Medical Service. His particular regret was that the Prison Medical Association, which he founded towards the end of his career with the object of promoting the highest standards of medical care in English prisons, did not survive his retirement. However, he lived to learn of the inception of an Academy of Prison Medicine which naturally had his full approval.

Living latterly in Weymouth, where he had the close companionship of two local retired hospital chief officers, he became the founder president of the Pickering Society, a nationwide group of retired hospital prison staff of all categories. It was named after a respected director of prison medical services under whom most of them had served.

Soon after qualifying, John married his childhood sweetheart Joyce Stoner, a nurse from Brighton. They had four daughters, three of whom trained as nurses at the Westminster Hospital, where two of them met and married doctors. There are now eight grandchildren and five great-grandchildren. Tragically, Joyce died in 1975 of carcinoma of the stomach, following which he married her friend Peggy Lange, then a Principal Nursing Officer in Sunderland.

1.6.14 Anthony Carl (Tony) Kaeser FRCP, FRCPsych

: Consultant in Old Age Psychiatry, Basildon sector, Thameside Community Healthcare NHS Trust

Mike Lowe

date

2017-2

Contents

- *Anthony Carl (Tony) Kaeser FRCP, FRCPsych*
 - : *Consultant in Old Age Psychiatry, Basildon sector, Thameside Community Healthcare NHS Trust*

Tony Kaeser, who recently died aged 84, was one of the pioneer consultant psychiatrists who from the 1960s onwards developed departments of psychological medicine in district general hospitals at the time when long-stay mental asylums were being phased out. In the years following his appointment in 1969 as a general adult psychiatrist to Runwell Hospital, he was involved in innumerable planning meetings with the then North East Thames Regional Health Authority to advance the new purpose-built department of psychological medicine at Basildon District General Hospital. This was eventually opened in 1977. It was Tony's attention to detail which improved the ward day areas for the patients – initially they were going to look out on to industrial sites, but with some reconfiguring of the layout the views were transformed to field and countryside vistas.

In the 1980's Tony was appointed convenor for training approval visits for the East Anglian Division of the Royal College of Psychiatrists. He provided liaison psychiatry services at Basildon District General Hospital and was the consultant psychiatrist for the Regional Plastic Surgery and Burns Unit at St. Andrew's Hospital, Billericay for 11 years. He was Chairman of the Basildon General Hospital District Consultant Staff Committee. For the last 7 years of his career he chose to work full time in psychogeriatrics. Despite his heavy clinical load, his professional services were extended willingly to staff and their families from all areas of the National Health Service (NHS) in South Essex.

He was a Foundation member of the Royal College of Psychiatrists. The College recognised his abilities by inviting him in 1984 to act as convenor leading the first team to visit the large Hong Kong training scheme. Shortly before retiring, Tony became a General Medical Council Examiner for doctors with health problems and for a number of years in retirement was one of two Lord Chancellor's Visitors for England. He was also an Area Visitor for the Royal Medical Benevolent Fund until he reached their retirement age.

Tony was born in London in 1932. He qualified at St. Mary's Hospital in 1957 and after house jobs in general medicine he obtained the MRCP and entered the Maudsley training scheme. After obtaining the DPM he was appointed senior

registrar at the Maudsley and Institute of Psychiatry. From there he was appointed consultant psychiatrist to Runwell Hospital.

A gentle, kindly, impressively ethical doctor, he was considered in his thinking and conversation but precise, soundly analytical and unfailingly wise. His manners to everyone he encountered were impeccable and right to the end he retained his genuine interest in people. When he became ill himself, he wanted to know about the lives of his carers.

His personal life was varied and fulfilling. He inherited his father's stamp collection. He loved a wide range of music and enjoyed playing his pianola. He joined in regular contract Bridge sessions with medical colleagues throughout his career and retirement, and these only came to an end 4 years before his death. Tony had a great sense of fun and participated in the staff Christmas show for patients. His performances in playing the femme fatale were such a success that he resigned himself to being typecast. He took delight in the achievements of the members of his family. His wife Wendy was an NHS health visitor and they had 2 children and 6 grandchildren, one of whom is a dancer with the Royal Ballet.

In the latter years of his retirement he experienced gradually declining health. He had been diagnosed with a rare hereditary form of amyloid heart disease and although his cognitive faculties were largely undiminished, progressive cardiac failure slowly developed and he died on 18 May 2016. In line with his commitment to humanistic principles, Tony donated his body tissues for the benefit of others and his brain for research into amyloid disease.

1.6.15 Klaus Minde MD FRCP(C)

: Formerly Chairman, Division of Child and Adolescent Psychiatry, McGill University, Montreal

Philip Graham

date

2017-2

Contents

- *Klaus Minde MD FRCP(C)*
– : *Formerly Chairman, Division of Child and Adolescent Psychiatry, McGill University, Montreal*

Klaus Minde, who recently died at the age of 82, was an academic child and adolescent psychiatrist renowned for his pioneering work in a variety of fields – especially infant psychiatry – and for the development of child mental health services in low-income countries. His early research was in the field of hyperactivity in children. Working with Gaby Weiss and John Werry, he was one of the first to carry out studies of medication in this condition.

In 1961, shortly after he had started his training in child psychiatry, his first child Thomas was born prematurely; he and his wife Nina, a psychologist, were not allowed to touch him – they could only gaze at him through the window of the nursery until they could take him home when he was 4 weeks old. This distressing experience stimulated Klaus' interest in the development of premature babies and the ways parents could be involved in their care. He carried out a number of observational studies¹ which – allied with the development of ideas on mother-infant bonding promoted

by two paediatricians, Marshall Klaus and John Kennell – helped to change practices in the nursing care of premature babies.

From 1971 he spent 2 years on secondment setting up a child psychiatric clinic at Makerere University, Uganda. As well as establishing a service, he carried out a significant amount of research, conducting comparative studies of disorders in Canada and Uganda.² Idi Amin, the brutal, idiosyncratic president of the country, was in power at the time. Klaus described how Amin, as chancellor of the university, required every professor to be present when he had decided to address them. While everyone was waiting for him, 3 empty limousines would arrive, followed – 3 minutes later – by Amin on a bicycle that he had mounted just before entering the university.

In 1983 he spent a sabbatical year in London, where he met John Bowlby, whose work on attachment had so impressed him. He was able to persuade Bowlby to visit Canada to talk about his ideas. After his official retirement from his chairmanship in 2000, he and his wife spent a year in Johannesburg, South Africa, where they worked with very disadvantaged children and families in the townships of Alexandra and Soweto. Once again he carried out research, this time on the assessment of attachment.³ In addition, Nina and he organised a mutual support group of grandmothers looking after their grandchildren (orphaned by the country-wide epidemic of AIDS), which became a model for similar groups in the area.

Klaus always had a strong interest in the plight of disadvantaged children and their need for psychiatric services. From 1994 to 1999 he worked with native Canadian children, acting as a consultant to the Cree Board of Health in Mistissini, Quebec; from 2009 to 2015 he was a consultant to Dans La Rue, an organisation caring for street children in Montreal.

Klaus was born in Leipzig in 1933 in the same year as Hitler came to power in Germany. His father was technical director of Germany's public radio and strongly opposed the Nazi movement. As one of the few senior people who had refused to join the Nazi party, his father was promoted after the war but was later sacked when a communist state was imposed in Eastern Germany in 1949. Klaus attended a humanist school and also rebelled against the ruling party. He wanted to study medicine but given his family background and outspoken political views, he had no chance of entering an East German medical school. Leaving his family behind – it was many years before his mother could join him – he travelled to West Germany and obtained a place to read medicine in Munich. After qualification he won a Fulbright scholarship which enabled him to go to New York and gain experience in paediatrics at Bellevue Hospital and psychology at Columbia University. He then undertook residency training in psychiatry at McGill University in Montreal, remaining in Canada, except for his sabbatical periods, for the rest of his professional life. He was Director of Research at the Hospital for Sick Children, Toronto, from 1973 to 1986 and after a spell at Queen's University in Kingston, Ontario, he was appointed Chairman of the Division of Child and Adolescent Psychiatry at McGill University from 1989 to 2000.

With his boundless energy and enthusiasm, Klaus could set audiences alight with his rhetoric, promoting the cause of better care not just for newborn babies but for children with physical and mental disabilities and for the socially disadvantaged. His whole body, especially his gesticulating arms and plentiful hair, seemed to be engaged in getting over his messages to his audiences, who loved it!

After retirement he continued to mentor colleagues and see patients until he suffered a major stroke shortly before his death on 6 July 2016. He is survived by Nina, his three sons and four grandchildren.

Contents

- *A Practical Guide to the Mental Capacity Act 2005: Putting the Principles of the Act into Practice*

The Mental Capacity Act 2005 (MCA) – which applies specifically to England and Wales – pervades several aspects of daily clinical care within many clinical as well as non-clinical environments, such as care homes.

The authors of *A Practical Guide to the Mental Capacity Act 2005* – whose backgrounds are social work and advocacy – observe that ‘Seven years on [...] the MCA is still not being adhered to nor fully embraced within practice’. Their aim was to produce a ‘theory-to-practice breakdown of the MCA’ and this was readily achieved with a fluent and erudite style of writing and continued emphasis on the practical aspects of implementing the MCA. There were useful case studies and checklists for practice, as well as practical top tips such as videotaping advance statements. A minor gripe would be that, if anything, such checklists and top tips could have been used more often throughout the book; for example, at the end of each chapter. The most useful chapter was that on best interests – very salient practical advice was afforded on the best interests process and assessments, including how to chair meetings and using documentation. This chapter tried to demystify the abstract concept of best interests by conceptualising such decisions as complex and less complex. Another strong chapter – probably reflecting the authors’ expertise in this area – was on advocacy and empowerment, which examined the various roles of the independent mental capacity advocate within the MCA process.

The undoubted highlight was the evocative account of the 2004 case of *HL v UK* which was the catalyst for the introduction of Deprivation of Liberty Safeguards (DoLS) legislation, to plug the now legally infamous ‘Bournewood gap’. HL was a patient with autism and challenging behaviour who was admitted to hospital on an informal basis. He was regarded as being compliant with care but unable to consent to admission; however, this was found to be a contravention of Article 5 of the European Convention on Human Rights (the right to liberty). The account is written by HL and his carers Mr and Mrs E. Although events regarding HL and his carers began in 1993, the account is a fascinating perspective of one of the most, if not the most, important mental health cases in legal history in terms of its potential impact on tens of thousands of people, carers and clinicians on a daily basis. The authors provide useful views on how and why the DoLS legislation has not been implemented well so far.

Overall, this is an excellent short text which should be required reading for those involved in care touching upon the use of the MCA, and would be ideal for medical and nursing students. But with the Court of Protection seemingly currently engaged in trying to crystallise the core essence of DoLS legislation – and with further recent key judgments emerging in the areas of best interests, end-of-life care and DNACPR (do not attempt cardio-pulmonary resuscitation) – it seems likely that this, as well as other similar guides, will need to be updated again in the near future to keep the readership up to date with key developments.

1.6.18 A Clinician’s Brief Guide to the Mental Capacity Act (2nd edn)

Martin Curtice¹

Contents

- *A Clinician's Brief Guide to the Mental Capacity Act (2nd edn)*

This book aims to provide a comprehensive overview of the Mental Capacity Act 2005 (MCA) – which applies specifically to England and Wales – and its implementation in practice.

The authors are all practising psychiatrists and although the style and content is tailored for a medical readership, the guide is suitable for all grades of doctors and all specialties, not just psychiatry. It is also ideal for medical and nursing students. With a punchy and concise writing style, the book has copious amounts of practical advice for clinicians throughout, and at times uses a common sense question-and-answer format with questions that clinicians are likely to pose, which reflects real-life practice.

Importantly, this work sought to translate lengthy and wordy court judgments into concise and simplified reviews outlining key basic principles for clinicians to use in daily practice. Possibly the most interesting chapter was that regarding the role of the Court of Protection. This busy court – which according to the authors hears approximately 23 000 cases annually, a figure that will surely inevitably rise – is often referred to in the media as the secretive court. However, this excellent chapter goes a long way in debunking various perceptions. It also explains the court process and is infused with sage, detailed and practical advice, from how to handle requests for assessments, writing reports and interviewing patients to giving evidence in court and even finding your way there if you need to! The authors suggest that Court of Protection proceedings tend to be more ‘informal and inquisitorial than formal and adversarial’ but that they can still be stressful, which is why they wish readers ‘good luck’. But despite the suggestion that a degree of luck might be needed, anyone new to such court proceedings will be far more prepared having read this chapter than not.

Needless to say, the thorny issue of implementing Deprivation of Liberty Safeguards (DoLS) was discussed at length in a chapter that provided important context by describing the evolution of this legislation and case law. Notwithstanding, owing to a glut of more recent key DoLS judgments, the book is already a little out of date as DoLS case law and guidance have evolved rapidly. It seems likely that an update will be needed soon to keep readers informed of key developments. Nevertheless, there was a good description of practical issues in using and applying DoLS since the *Cheshire West* case in 2014, a case which triggered an upsurge in the use of this legislation. The authors aptly summed up the state of DoLS understanding from further case law since *Cheshire West* by saying it did ‘little to ease the quandaries of health and social care staff in their decision-making in relation to deprivation of liberty’.

Another notable chapter was the one on the assessment of capacity, which provided comprehensive and practical advice, breaking the process down into its components and getting into its minutiae, thus challenging the reader to re-evaluate their own methods for assessing capacity. Other useful sections included advice on how to resolve conflict emanating from complex best-interests meetings and on seeking consent. Although not concluded at the time of publication, the latter resonates with the 2015 seminal Supreme Court case of *Montgomery v Lanarkshire* which has redefined the rules of seeking consent and has implications for how clinical negligence will hence be assessed.

All in all, this is an excellent guide which would aid those involved in care touching upon the use of the MCA.

1.6.19 Motivational Interviewing: A Guide for Medical Trainees

Ed Day¹

date

2017-2

Contents

- *Motivational Interviewing: A Guide for Medical Trainees*

I first encountered motivational interviewing as a trainee when I read Miller and Rollnick's classic 1991 book *Motivational Interviewing: Preparing People to Change Addictive Behavior* and the key concepts have always resonated with me. Although it seems obvious that a man requiring major surgery due to cardiac disease should stop smoking, it is rarely helpful to insist that he does so. People have ambivalent feelings when it comes to changing entrenched behaviours and it is often better to elicit their own reasons for change. After all, it has been said that people believe what they hear themselves say. Perhaps because of its apparent simplicity, motivational interviewing has become an important technique for most UK addiction therapists and its influence has gradually spread to other areas of practice. Therefore, does the world need another book on motivational interviewing?

This book is written by a group of trainees spanning all specialties of medicine, with the goal of demonstrating how motivational interviewing can fundamentally improve the doctor-patient relationship. Motivational interviewing is a way of being rather than an intervention and the book reminded me of its roots in Carl Rogers' person-centred approach to therapy, based on building empathy, congruence and positive regard. As someone who bemoans the biomedical nature of British psychiatry, I was surprised that it succeeded in reawakening my interest in interviewing skills that not only elicit information but also provide therapeutic insights and direction.

Like the practice of psychiatry, motivational interviewing is straightforward to do but hard to do really well. It is not easy to learn from books and so the editors provide lots of dialogue to illustrate key points, and a series of videos on a linked website. They add personal reflections, as well as illustrations of the integration of motivational interviewing into electronic case records and its use in less familiar settings such as paediatrics. There is also a practical emphasis on how to teach and supervise motivational interviewing in the real world. Their enthusiasm for the subject was infectious and I was left in agreement that learning motivational interviewing should be a priority in medical education.

1.6.20 Waking Up: Searching for Spirituality without Religion

Matthew M Nour¹

date

2017-2

Contents

- *Waking Up: Searching for Spirituality without Religion*

Sam Harris has been waiting to write this book for over a decade. This may surprise some. The subject matter – dealing reverently with human spiritual experience – is at odds with Harris’ (in)famous public persona as a strident critic of religion. Yet, for the past 20 years Harris, who has degrees in philosophy and neuroscience, has been on a personal quest in search of ‘transformative insights about the nature of one’s own consciousness’.

Harris defines spiritual practice as the efforts people make, through meditation, use of psychedelics or other means, to fully bring their minds into the present. This practice leads to the insight that our sense of having a unified self is an illusion and that this illusion causes us much psychological suffering. Harris aims to convince his reader of this using philosophical thought experiments, discoveries of contemporary neuroscience and personal experience. He also encourages his reader to test these hypotheses about human consciousness ‘in the laboratory of your own mind’, through meditation practices inspired by Buddhist Dzogchen and Vipassana teaching. He argues that these spiritual insights can be accepted independently of the metaphysical baggage of traditional religion, and laments that until recently they have been under-investigated by an ‘impoverished’ neuroscience.

The resulting book is an ambitious mosaic: part memoir, part neuropsychology text and part meditation guide. A key strength is Harris’ clear, lively and personal writing style, which instils the prose with an endearing conversational air. Many readers will feel, however, that by focusing almost exclusively on solitary meditation practices and psychedelic drug-induced experiences, Harris has omitted important dimensions of human spiritual experience, such as the self-transcendence which may be arrived at when contemplating art or engaging in communal ceremonial practices. Moreover, the occasional barbed criticism of monotheistic religion will deter some readers, but play well to the Harris faithful.

Waking Up is a book for the general public and is not intended to have a clinical application. Why, then, is it being discussed in the pages of this journal? My answer is twofold. First, as psychiatrists we are interested in all dimensions of human experience. Consequently, the growing scientific interest in the mystical/spiritual experience and its potential therapeutic implications is of great importance for our specialty. Second, psychiatrists are humans and all humans may benefit from being reminded from time to time that our conventional sense of a unified self sitting some 2 inches behind the eyes is likely to be a pernicious illusion.

Contents

- *Deconstructing the OSCE*

This volume contests that it is possible to develop a generic way to approach different Observed Structured Clinical Examination (OSCE) scenarios, regardless of medical specialty. Perhaps surprisingly, it is not filled with possible exam scenarios, but rather looks at the underlying barriers to good performance. In this regard, it provides a behavioural and psychological schema for approaching the OSCE. The book makes no apologies for aiming at those who have already had a previous attempt at passing the OSCE, and given that pass rates for membership exams are generally around 50–60%, it is a resource available to a great number of doctors in training.

The initial chapters look at the common emotional and cognitive responses which typically follow an unsuccessful examination attempt – they do a good job of validating these experiences and feelings. Subsequent chapters aim to improve general exam strategy. These include the perhaps more neglected areas of good exam performance; for example, how to establish rapport with the actor or patient, and how to run a good study group and learning environment. An especially useful chapter is that which explores challenging scenarios such as ‘the angry relative’ or ‘the crying patient’. Although these passages are brief, practical tips are given to aid communication in these often difficult situations.

In addition, there are worksheets that support the doctor in understanding that the way they think about the exam influences their emotions and, ultimately, their exam performance. The psychiatry trainee will be no stranger to this process; however, I wonder whether trainees from other specialties might find the experience alienating.

This work undoubtedly highlights that poor exam performance is often not related to lack of knowledge, but to cognitive and emotional barriers. As a result, it may provide a good starting point for ongoing study where examination performance has proven problematic.

- *Schizophrenics can be good mothers too*

To protect her children the author of this book chose to publish it under a pseudonym, Q. S. Lam. However, it's easy to break her anonymity and she accepts it can only be partial. She is a British Bangladeshi artist who has had several psychotic episodes, including postpartum. She has been diagnosed with schizoaffective disorder but prefers to describe herself as having a different sort of brain.

Her friend Stephen Fry has described the book as 'brilliant' – an endorsement displayed on the book cover – and Alastair Campbell has tweeted the same. Artwork and poetry complement the narrative of the author's personal and family history, which includes episodes of psychosis, and the description of the dissociated parts of herself and how she recovers. She does not take antipsychotic medication.

She makes remarks – not always very complimentary – about each mental health practitioner that she has seen over the years, dating back to the time when she first sought help. Also discussed is the impact of her mental health problems on her husband and children. She moved to Brussels, as her husband works there.

The psychiatrist she has most identified with is Erik Thys, who is also an artist. He did not advise Q.S. not to have a second child; instead, he said it was 'doable'. Q.S. openly questions whether it was fair on her children that she became a mother and dedicates the book to them.

The strength of this book is its honesty. Q.S. has experienced multiple sexual assaults by men and considers whether her mental health issues are a sane response to an insane situation. She reveals her heart and mind, truthfully expressing what she feels and thinks, and I found the directness of the book attractive. As Q.S. notes, doctors generally don't like their authority to be challenged. However, in my opinion there needs to be an open discussion about the stigmatisation of mothers with mental health problems.

1.6.23 Epistemic injustice in psychiatry

Abstract

It has been argued that those who suffer from medical conditions are more vulnerable to epistemic injustice (a harm done to a person in their capacity as an epistemic subject) than healthy people. This editorial claims that people with mental disorders are even more vulnerable to epistemic injustice than those with somatic illnesses. Two kinds of contributory factors are outlined, global and specific. Some suggestions are made to counteract the effects of these factors, for instance, we suggest that physicians should participate in groups where the subjective experience of patients is explored, and learn to become more aware of their own unconscious prejudices towards psychiatric patients.

Epistemic injustice is a harm done to a person in her capacity as an epistemic subject (a knower, a reasoner, a questioner) by undermining her capacity to engage in epistemic practices such as giving knowledge to others (testifying) or making sense of one's experiences (interpreting). It typically arises when a hearer does not take the statements of a speaker as seriously as they deserve to be taken. The prime case of epistemic injustice is testimonial: the hearer deflates the level of credibility she gives the speaker because she is (often unconsciously) prejudiced against the social group to which the speaker belongs. Common examples include sexism and racism. In such cases the testimony of a woman or a person from an ethnic minority background will be given deflated credibility, based on the prejudicial associations between that group and negative stereotypes. The reason we chose this approach is that epistemic injustice provides an account for why, despite the best intentions, physicians often do not believe what psychiatric patients tell them. Clarifying some of the reasons for this common prejudicial stereotype of patient unreliability may make it possible to explore ways of overcoming the epistemic injustice that we suggest patients, and in particular psychiatric patients, are vulnerable to.

It is worth noting here that it is prejudicial or negative stereotypes, not stereotypes *per se*, which often give rise to epistemic injustice. We rely on stereotypes as heuristic aids in making credibility judgements because they are often empirically reliable generalisations. However, negative attitudes towards people with a mental illness may lead to negative stereotypes and to generalisations which are resistant to counter-evidence, owing to what philosopher Miranda Fricker calls an 'ethically bad affective investment'.¹ It is these kinds of stereotypes that may lead to epistemic injustice.

Epistemic injustice and psychiatric patients

Epistemic injustice is important in psychiatry because of the persistent negative stereotypes that affect people with mental disorders in particular and lead to a credibility deficit. The consequence is that patient testimonies and interpretations are not acknowledged as credible, and patients are thus undermined in their capacity as knowers and contributors to the epistemic effort to reach a correct diagnosis and treatment. We suggest that people with mental disorders are even more susceptible to epistemic injustice than those with physical illnesses, for reasons that are detailed below.

We have argued in the past that people with physical illnesses are vulnerable to epistemic injustice.^{2,3} Here we suggest that people with mental disorder may be susceptible to even greater epistemic injustice than people with physical illnesses. This is mainly owing to the high prevalence and great power of negative stereotypes of psychiatric illness. As a consequence, the patient may be telling the truth, but the doctor deflates the level of credibility which she gives to the patient ('credibility deficit') and thereby does the patient a distinctive kind of injustice, namely epistemic injustice, which undermines the patient specifically in her capacity as a giver of knowledge. This has detrimental effects on individual psychiatric patients, but also on the funding of psychiatric services and the public perception of mental disorder. Many people are influenced by negative stereotypes about mental disorders, are ill informed about their true nature, and have little understanding of how to treat them. Some measures to improve the current situation are suggested below.

Measures to counter epistemic injustice

The notion of epistemic injustice has been developed by Fricker.¹ She was interested in how social identity and power affects people's status as knowers. She gives the example of a White police officer who stops a Black car driver and asks him whether the car belongs to him. If the driver truthfully says that the car is his, but the policeman does not believe him because of racial prejudice, then he does the driver an injustice in his capacity as a knower.⁴

The main type of epistemic injustice that Fricker discusses is 'testimonial injustice'; it emerges from the fact that testifying, i.e. giving information to others, depends crucially on one's perceived credibility. If a person is seen as lacking credibility, her testimony will be ignored or treated with suspicion, or it might not be solicited at all. Of course, she may lack credibility for a good reason, for instance if she is a known liar. However, testimonial injustice occurs when a person suffers a 'credibility deficit' owing to some negative stereotype or prejudice associated with her social group (e.g. gender or race). This credibility deficit is unjustified and hence constitutes an epistemic injustice. Fricker analyses how negative racial and sexist prejudices unfairly deflate the credibility of people of Black and minority ethnic background and women, such that what they say is ignored, marginalised or otherwise excluded from epistemic consideration. Since being able to give information to others is essential to social life and agential action, testimonial injustice harms those who experience it.

Carel and Kidd have argued that people with physical illnesses are more vulnerable to epistemic injustice than healthy people.^{2,3} The testimonies of patients are often presumed to be irrelevant, unreliable, confused or otherwise lacking in credibility, owing to negative stereotypes associated with ill persons. Such stereotypes include viewing ill persons as cognitively impaired or emotionally compromised, owing either to their somatic condition or to their psychological reactions to it; or as existentially unstable, gripped by anxieties such that they 'cannot think straight'; or as psychologically dominated by their illness in a way that warps their capacity to accurately describe and report their experiences (e.g. 'the moaner' or 'the drama queen' stereotype). Because illness often evokes strong feelings in those affected, their emotions are often taken by health professionals to have a detrimental effect on patients' thinking, distorting the accounts they give of their illness. This pattern may be more acute in cases where subjective symptoms are driving the clinical encounter, such as unexplained breathlessness (see www.lifeofbreath.org), chronic pain, or other medically unexplained symptoms.⁵

Of course, the credibility of an individual is context dependent: if someone is talking about a subject on which she is an acknowledged expert then she is much more likely to be believed than if she is talking about something she is known to have little knowledge of.

Epistemic injustice – real-life situations

We are sufficiently aware of the existence of people's unconscious desires and beliefs to know that they can be mistaken about their own desires and beliefs, but it is also the case that they have exclusive access to many of their desires and beliefs. In the interests of epistemic justice, physicians should accept what people with mental disorders say about these matters as true unless there is good reason not to. Moreover, psychiatric patients who have experience of psychiatric services become reluctant to disclose psychotic symptoms because they know it might make them more likely to be diagnosed with a psychotic illness, and in some cases detained in hospital and medicated against their will. If they nonetheless disclose such symptoms, then psychiatrists might conclude that the symptoms are more severe in the sense that the patients are unable to inhibit their expression and/or that their executive function is also impaired.

Here we give three examples of epistemic injustice affecting psychiatric patients (Boxes 1, 2 and 3). Their purpose is to show that epistemic injustice can be a real problem in psychiatry, with possibly devastating effects on the individuals who are telling the truth. The personal details of the patients concerned have been altered to preserve their anonymity.

One of the important factors which can predispose to epistemic injustice is a widespread misunderstanding of the relationship between emotion and cognition, and the positive contribution made by emotional input to a broader conception of rationality.⁶ A consequence, in a medical and psychiatric context, is that the 'soft evidence' offered by patients is often met by credibility deflation. In practice this may lead to patient reports being ignored or discounted, especially when time pressure and other constraints are at play. Conversely, if the 'hard evidence' provided by objective investigation (e.g. blood tests) is regarded as more reliable, then the opinions of health professionals who can access and interpret that evidence may enjoy credibility inflation. In some cases it may be better for the doctor to try to treat on the basis of the symptoms reported by the patient rather than on the basis of an abnormal blood test result or an abnormal scan alone. An example of this is the PSA (prostate-specific antigen) test, which is a notoriously unreliable guide for the treatment of prostate cancer.

Box 1 Example of epistemic injustice in psychiatry 1

When one of the authors (P.C.) was a medical student in Munich, Germany, he saw a young man on an acute psychiatric ward who said he was a relative of the then Soviet leader. The responsible consultant took this to be a grandiose delusion, and therefore as evidence of a psychotic illness; it later turned out to be true.

Box 2 Example of epistemic injustice in psychiatry 2

The second example is of a woman in her early 50s, a former nun. The police contacted mental health services because they had been alerted by someone doing work on her house. They found evidence of smoke damage to the house, but not of fire damage. She was admitted to a psychiatric ward and detained under section 2 of the Mental Health Act. She claimed that she had been burning incense in the house for many years to drive away evil spirits. During the week she had spent on the ward there was no evidence of her trying to ward off evil spirits or attempting to start a fire, or of any psychotic symptoms. The mental health tribunal members concluded that her beliefs about incense and evil spirits were compatible with her religious faith, that there was no evidence of a psychotic illness, as had been claimed by the psychiatrist and one of the psychiatric nurses, and that section 2 should therefore be rescinded.

Box 3 Example of epistemic injustice in psychiatry 3

The third example is of a young man who was admitted to psychiatric hospital on section 2 despite the fact that he had agreed all along to be admitted and remain in hospital as a voluntary patient. He had been standing near the edge of a high cliff for about an hour until passers-by called the police. The staff involved in his care on admission did not believe that he could be trusted to remain in hospital on a voluntary basis and argued in the tribunal for the maintenance of the section. His community psychiatric nurse attended the tribunal, stating that he should never have been placed on a section, because he had had suicidal thoughts for many years, had gone to the same cliff many times in the past, had been admitted to hospital on several occasions as a voluntary patient, and had misgivings about the stigma attached to being placed on a section. All this had been documented in the hospital notes. She conceded that there would always be a risk of self-harm, but that it was a matter of managing the risk without compulsory detention and with the help of his friends and family. After hearing this evidence the tribunal members decided to rescind the section.

A psychiatric example is to do with making a diagnosis of epilepsy. Here a patient may have some epileptiform waves on the electroencephalogram (EEG), but unless there is also clinical evidence of altered consciousness and/or involuntary

movements which fit into a recognised pattern, a diagnosis of epilepsy cannot be made. An EEG can confirm but cannot exclude the diagnosis, which is essentially clinical.⁷

In very general terms, there are two types of contributory conditions for epistemic injustice affecting people with mental disorders: global and specific. Global factors are those that can affect any patient at risk of psychiatric disorder or those diagnosed as having psychiatric disorders. The fear of stigma among those at risk can make early intervention difficult and those who have been diagnosed may avoid service use and relapse more frequently.

Global contributory conditions for epistemic injustice

There are three global contributory conditions for epistemic injustice in psychiatric illness: problems associated with, and partly caused by, the mental disorder; the higher value placed by health professionals on ‘hard’ or objective evidence compared with patient reports; the entrenched negative stereotypes associated with mental disorders.

1. Problems related to mental disorder

Psychiatric patients are often disadvantaged – cognitively, socially and economically – and these disadvantages are frequently thought to be the patient’s fault. People with mental disorders are often badly educated because the illness has interrupted their education (‘dropouts’); they are often financially impoverished because the effects of the illness may make them unemployable (‘lazy’, ‘dependence culture’); and they are frequently socially isolated (‘loners’). They may become dependent on substances such as nicotine, alcohol and street drugs (‘lack of willpower’) and frequently experience physical illnesses. Causes of physical illnesses include substance misuse, self-neglect secondary to mental disorder and/or substance misuse, and psychotropic medication, such as atypical antipsychotics causing cardiovascular problems (‘down to lifestyle’).

People with mental disorders are thus often seen to have largely brought these disadvantages on themselves and are stigmatised and held responsible for them,¹ even though some conditions contributing to mental disorders, such as genetic factors and a dysfunctional environment, are outside the person’s control. To the extent that such negative stereotypes are shared by their voters, politicians, who often look to save public money, will not be motivated to redress the imbalance in mental health funding: in 2010/2011 mental health services were allocated only 10.8% of the National Health Service (NHS) budget, although mental disorders constituted nearly 22.8% of the disease burden in the NHS.⁹ Simon Wessely, the president of the Royal College of Psychiatrists, notes that despite rising demand, spending on adult mental health by NHS trusts has fallen by 8% since 2010.⁹ A recent parliamentary report advocates ‘whole person’ care, which includes mental and physical health, and highlights some of the barriers to parity of esteem for mental health.¹⁰

2. Hard v. soft evidence

Health professionals are trained to place higher value on ‘hard’ or objective evidence, namely the results of investigations, than on ‘soft’ or subjective evidence provided by patients. In fact, some such objective evidence (e.g. from X-rays or magnetic resonance imaging (MRI) scans) is heavily dependent on interpretation, for instance by a radiologist. This gives health professionals epistemic power, because only they have access to this evidence and have the training to interpret it. Montgomery¹¹ has argued that medicine is not itself a science but rather an interpretive practice that relies on clinical reasoning. A physician looks at the patient’s history along with the presenting physical signs and symptoms and juxtaposes these with clinical experience and empirical studies to construct a tentative account of the illness with what Montgomery calls ‘clinical judgment’. In psychiatry, there is virtually no hard evidence and diagnoses have to be made mainly on the basis of what patients say and how they behave. However, some psychiatrists regard their patients as objects of their epistemic enquiry rather than participants in an epistemic search for the correct diagnosis and best treatment. Anthropologist Tanya Luhrmann¹² argues that insurance companies exercise a more powerful influence over the content of healthcare than do doctors, in that they promote a biological approach to psychiatry because it yields explicit therapeutic rationales, targeted treatments and quantifiable outcomes that can be audited more easily.

Despite the lack of objective evidence in psychiatry, many psychiatrists are influenced by their general medical training and import this bias into the field. Although many acknowledge the biopsychosocial model of mental disorders, they often retain their biological orientation.¹³ Biological psychiatry has been dominant since the 1950s, when the first antipsychotic drugs were introduced, and there is little evidence that this is changing in any significant way. This is partly because the biological approach has practical benefits (e.g. psychiatrists can save time by focusing on drug treatments). Based on his experience working as a liaison psychiatrist in a large medical hospital, one of the authors (P.C.) believes that psychiatry itself is stigmatised within medicine and that some psychiatrists feel that they will be more respected by their medical colleagues if they approach mental disorders from a biological perspective. P.C. also senses that some patients might prefer this attitude, feeling exonerated if they are told that their mental disorder is caused by a 'chemical imbalance in the brain' which can be ameliorated by a drug.

3. Negative stereotypes

People with mental disorders are socially stigmatised and are frequently described with derogatory terms such as 'mad', 'crazy' or 'weird'. The term 'stigma' comes from the ancient Greek word denoting the mark made on slaves by a pointed instrument. Stigma involves negative associations that attach to a social group. Sociologist Erving Goffman¹⁴ argued that stigmatised people are considered abnormal by society and are not fully socially accepted. As a consequence, they constantly try to adjust their social identities. These additional cognitive and social burdens increase the pressures on stigmatised people, exacerbating their already difficult social and cognitive situation. Thornicroft¹⁵ points out that patients often describe the stigma they encounter as worse than the mental disorder itself. Stigma affects every aspect of their lives, including employment, accommodation, financial resources and sense of citizenship. It is a major problem throughout the world.

One of the negative stereotypes associated with mental illness is that people with a mental illness are responsible for their condition. For example, people diagnosed with depression are often told to 'get a grip' or to 'pull themselves together'. Illness, not only mental illness, is often seen as a mark of moral, social and epistemic failure (e.g. drug/alcohol dependence is sometimes seen as weakness of will). Such failures are shaped by group-specific values and commitments – for instance, certain religious groups regard depression as a punishment by God for their sins.¹⁶

However, in a legal setting, the poor insight of patients into their mental state may be recognised by the court as a factor which reduces the patient's responsibility for their actions. Although this diminishes their epistemic status, it also protects them, so recognition of their diminished responsibility may lead to them being treated in hospital rather than imprisoned.

Thus, those who are influenced by negative stereotypes about psychiatric patients may feel justified in cutting funding for mental health services because they think that many psychiatric patients are to blame for their mental health and other problems. In the case of depression, many people who have no personal experience of the illness tend to think that depressed people only need to think more positively for their depression to disappear.^{17,18} The fact that psychiatric services are more poorly funded than other services in the NHS suggests that negative stereotypes about mental disorders may have a role in funding distribution. These negative stereotypes are also influential in the broader context of widespread ignorance about the true nature of mental disorders and their treatment.

Types of stigma and their effects

General stigma

General stigma has negative effects on the prevention, early intervention and treatment of mental disorders. The formulation of a diagnosis has the advantage of making resources available for treatment, as well as providing the best available treatment. Moreover, there is evidence that early treatment improves the prognosis (e.g. in schizophrenia).⁷ On the other hand, having a diagnosis also leads to stigma and discrimination, which can act as a barrier to recovery, for instance making it more difficult to find employment and accommodation.¹⁵

Self-stigma

People with mental illness often accept and internalise negative stereotypes, and this in turn leads to low self-esteem, shame, demoralisation, confidence loss and giving up goals.

Structural stigma and discrimination

Patients typically report that they feel their views are not sufficiently elicited or considered by those who plan and organise psychiatric services.¹⁹ We have already seen that psychiatric provision for approaches other than the biopsychosocial model is severely under-resourced.

Specific contributory conditions

So far we have discussed global contributory conditions for epistemic injustice. In addition to these global conditions, there are specific problems which can lead to further kinds of epistemic injustice as a consequence of the particular nature of the mental disorder in question. Here are two examples, which illustrate how the symptoms of particular disorders may reduce the credibility of what patients report about their own experiences to an extent that constitutes epistemic injustice.

Dementia

The first example is dementia, an acquired impairment of cognitive function without impairment of consciousness. The central feature of its commonest form, Alzheimer's disease, is memory loss, especially of episodic memory, but there can be a wide range of other cognitive impairments as well. The main negative stereotype associated with dementia is the belief that the impairment of cognitive function is severe and global; that the person has or will rapidly and inevitably become a 'vegetable'. In fact, this is hardly ever the case, except perhaps in the final stage of the illness.²⁰

The personality of the individual and some cognitive functions are often well preserved. Thus, patients with mild to moderate dementia can be much more reliable informants than they are often thought to be. There is a need for careful neuropsychological assessment to establish the severity of the impairment. If a person's memory is badly affected, much can be gained by staying in the present in conversations, thereby minimising the occurrence of behavioural markers of epistemic incapacity that can exacerbate the risk of epistemic injustice.²⁰

Schizophrenia

The second example is schizophrenia. Perhaps the most common stereotype associated with it is that because of their delusional beliefs, people with schizophrenia are unpredictable and violent. This may diminish their status as truth-tellers because it may be concluded from one false (delusional) belief that none of their beliefs are credible. In fact, although violent behaviour can occur in schizophrenia, it is much rarer than is thought. There is a small but significant increase in violence in patients with schizophrenia (in any one year 8% of such patients will commit an act of violence compared with 2% of the general population). There is, however, a much stronger association between violence and substance misuse than with schizophrenia. The proportion of all violent acts committed by those with schizophrenia is 3–4%. This leaves 96–97% of all violent acts committed by people who do not have this disorder. The risk of an individual patient with schizophrenia committing homicide is less than 1 in 3000. Moreover, the rates of suicide are much higher than homicide rates in psychiatric patients as a whole.²¹ Thus, although the risk of violence is much higher in patients with schizophrenia than in the general population, the risk is lower than is suggested in the media.²¹ It also seems likely that other factors apart from the illness itself may play a part, such as the influence of alcohol and illicit substances at the time of the offence, and social factors.

Such negative stereotypes are problematic for several reasons, beyond their empirical inadequacy. They encourage unwarranted attitudes of suspicion and distrust towards people with schizophrenia, which, in turn, can contribute to

their social isolation; this is in itself epistemically impairing. Many of our epistemic practices are intrinsically social, such as testifying (giving information to others) and interpreting (making sense of one's experiences), and it is no coincidence that Fricker focuses her analysis of epistemic injustice on those two practices.¹ Social isolation and epistemic impairment can be mutually reinforcing.

In the case of schizophrenia, this problem takes on a specific form: it is integral to our social and epistemic agency that other people perceive us as a person – an agent – capable of engaging, in a sustained and reasonable way, in testifying, interpreting and other epistemic practices. A self is a locus of epistemic and social agency. Yet stereotypes about schizophrenia abide, typically the widespread but mistaken notion that schizophrenia is chiefly characterised by a personality split, as in the good Dr Jekyll and the evil Mr Hyde. The term 'schizophrenia' was coined by the psychiatrist Eugen Bleuler to capture a split between components of the mind – knowledge, emotion and will. This idea of a split has been abandoned in modern diagnostic criteria.²² However, the stereotype of 'split personality' is, of course, a perfect example of a fragmented epistemic self with whom one cannot effectively engage either socially or epistemically.

The rare cases of homicide by patients with schizophrenia are given intense coverage in the press. Examples include Christopher Clunis, who killed a stranger who happened to be standing on the same platform at Finsbury Park tube station in London in 1992; and Matthew Williams, who had a diagnosis of paranoid schizophrenia and killed a young woman in an act of cannibalism in 2014. This creates the impression that violence on the part of patients with schizophrenia is much more common than in fact it is, a phenomenon described by psychologist Daniel Kahneman as 'what you see is all there is', namely jumping to conclusions from limited evidence: another feature of prejudice that might lead to epistemic injustice.²³ Such jumping to conclusions on limited evidence can lead to prejudice ('people with schizophrenia are violent') and hence to epistemic injustice, if a patient says she does not have violent thoughts and is not believed.

As demonstrated in this section, the specific deficits found in dementia and schizophrenia can increase the susceptibility of such patients to epistemic injustice, in addition to the global factors which apply to all mental disorders.

Possible ways of overcoming epistemic injustice

One effective way to integrate the subjective perspective of patients into medicine and psychiatry may be changes in medical and psychiatric training with a view to emphasising the psychological aspects of patient care. 'Schwartz rounds', which allow health professionals to focus on the existential, ethical and personal aspects of a medical case, are growing in popularity in the UK. We suggest that this approach should not only be taught to medical students but should become part of clinical practice.²⁴ Regular interpersonal dynamic meetings with members of a multidisciplinary team, which create a forum for discussing problematic emotional contacts with patients, can enhance understanding of these aspects of patient care and reinforce their importance.¹³

Medical students should be taught to believe what psychiatric patients tell them, unless there is good reason not to do so. Students are frequently told to put patients first, but the experience of many patients is that they are often treated as cases rather than people, and that what is important to doctors is different to what is important to patients. By listening carefully to what patients tell them, doctors can make a conscious effort to imagine how things seem from the patient's perspective. In this way the relationship can become a genuinely collaborative one, rather than one in which the doctor decides what is in the patient's best interests.²⁵

Fricker¹ notes that hearers, in this case the physicians, need to practise giving more credibility to members of groups they fear they may be giving too low levels of credibility to: in this context, to psychiatric patients. Hearers may become aware of a cognitive dissonance: they may notice that on occasions they fail to live up to their belief that members of these groups are to be taken seriously, and then make a conscious effort to give them a higher level of credibility. The hope is that, with time, this corrective policy will become second nature.

Conclusions

We have suggested that there is even greater risk of epistemic injustice in psychiatry than in general medicine. There is a need for psychiatrists to be trained to listen carefully to what patients are telling them and to engage with them in collaborative decision-making, to allow patients to have a greater epistemic role and to overcome the risk of epistemic injustice. Changes are also required in the social and political arena. Media editors should reduce the stigmatisation of psychiatric patients in media reports, especially if epistemic failure (such as reliance on negative stereotypes) can be a cause of moral failure (such as treating persons with mental disorders in an unfairly hostile or suspicious manner). Similarly, politicians should ensure that there is a fairer distribution of healthcare resources, not merely to mitigate the economic cost of mental ill health.

Prejudices against people with mental disorders are entrenched in our society in what Fricker calls the ‘collective social imagination’.¹ They go unchecked because they operate below the radar of the conscious scrutiny of our own beliefs. Those who are in a position to influence public opinion have a special responsibility to oppose these prejudices. We hope that this editorial will increase awareness of the risks of epistemic injustice in psychiatry and thus contribute to this goal.

We are grateful to two anonymous referees for their helpful comments. Havi Carel is grateful to the Wellcome Trust for awarding her a Senior Investigator Award to support her research (grant number 103340).

1.6.24 Psychiatry and the geriatric syndromes – creating constructive interfaces

Simon Thacker Mike Skelton Rowan Harwood

Correspondence

Simon Thacker

(simon.thacker@derbyshcft.nhs.uk)¹

date

2017-4

Abstract

Integrating mental and physical healthcare is difficult to achieve because of professional and organisational barriers. Psychiatrists recognise the problems resulting from fragmentation of services and want continuity of care for patients, but commissioning and service structures perpetuate these problems. One way forward may be to follow the syndromic model employed by geriatricians as a means of avoiding over-emphasis on diagnosis above the pragmatics of implementing multi-component, co-ordinated care. Commissioners need to be made aware of the overlap and complementarity of skills possessed by old age psychiatry and geriatric medicine to create joint services for people vulnerable to dementia and delirium. A re-forged alliance between the two specialties will be necessary to turn integrated care for frail, elderly people from rhetoric into reality.
